Editors-in-Chief

Yogesh B. Gianchandani is a Professor in the EECS Department and holds a courtesy appointment in the Department of Mechanical Engineering at the University of Michigan, Ann Arbor. He received a Ph.D. in electrical engineering from the same university in 1994. Prior to this, he worked as an IC designer, primarily at Xerox Corporation. His research interests include all aspects of design, fabrication, and packaging of micromachined sensors and actuators and their interface circuits. He has contributed to more than 200 papers or patents in this field, and serves on the editorial boards of several journals. He also served as a General Co-Chair for the IEEE/ASME International Conference on Micro Electro Mechanical Systems (IEEE MEMS) in 2002. At the University of Michigan, Prof. Gianchandani has served as the director of the College of Engineering Interdisciplinary Professional Degree Program in Integrated Microsystems. As of 2007, he is on a temporary assignment at the US National Science Foundation, serving in the Directorate for Engineering as a program manager for nano- and microsystems.

Professor Osamu Tabata Born in 1956. He received a MS degree and a Ph.D. degree from the Nagoya Institute of Technology, Nagoya, Japan, in 1981 and in 1993, respectively. Since 1981 for 15 years, he has been with the Toyota Central Research and Development Laboratories, Japan. In 1996, he joined the Department of Mechanical Engineering, Ritsumeikan University, Shiga, Japan. He was a guest Professor of Institute of Microsystem Technology, University of Freiburg and ETH Zurich from September to December 2000 and from January to March 2001, respectively. In 2003, he joined the Department of Mechanical Engineering, Kyoto University, Japan. He is currently Professor in the Department of Micro Engineering, Kyoto University. He is currently interested in the establishment of a technology to realize a unique and novel nanosystem by assembling the various functional components such as a microchip, and a particle, a microcapsule, and a cell, with sizes ranging from the nanometer to micrometer scale on a MEMS/NEMS substrate. He termed this concept as SENS (synthetic engineering for nanosystems), and is pursuing experimental and theoretical research on the establishment of SENS. He is an associate editor of Journal of Micro Electro Mechanical Systems as well as a member of the editorial board of Advanced Micro- and Nanosystems, and Sensors and Actuators. Also he is a program committee member of many International Conferences.

Professor Hans Zappe was born in Paris, France, in 1961 and raised in New York. He received his B.Sc. and M.Sc. in Electrical Engineering from the Massachusetts Institute of Technology in 1983 and his Ph.D. in the same field from the University of California at Berkeley in 1989. He has worked at IBM (Burlington, VT, USA) on silicon VLSI, at the Fraunhofer Institute for Applied Solid State Physics (Freiburg, Germany) on GaAs electronics and high-speed lasers, and at the Centre Suisse d'Electronique et de Microtechnique (Zurich, Switzerland) on integrated optical microsystems and surface-emitting lasers. Since 2000, he has been Professor in the Department of Microsystems Engineering at the University of Freiburg, Germany. His current research interests focus on the development of novel tunable micro- optical components, including polymer, membrane, and liquid-based optics, variable photonic crystals, and optical microsystems for medical diagnostics and clinical applications.

Preface

Microsystems have emerged from the laboratory and have become essential components in a wide range of medical and industrial products, and research instrumentation. They include not only microelectromechanical systems (MEMS), but all forms of microsensors, microactuators, and interface microelectronics, deployed as enabling components within a larger system or distributed network. Combining high functionality with small dimensions and reduced power consumption, microsystems benefit from mass-fabrication technologies to allow their manufacture in high volumes and, often, at low cost. The inclusion of electronics, when possible, reduces the cost of deployment and use, providing autocalibration and self-testing. The small dimensional scale sometimes allows physical effects to be leveraged in unconventional ways, providing surprisingly high functionality and performance. As a result, microsystems are virtually invisible to most people, yet have become indispensable in many aspects of their lives.

The microsystems field has expanded to embrace a host of technologies. The well-established discipline of microelectronics has now been joined by micromechanics, microfluidics, and microoptics to allow the fabrication of complex, multifunctional integrated microsystems. As a result, the highly interdisciplinary nature of the subject often makes it difficult for researchers to obtain an overview of the technologies and capabilities available in this established yet dynamically growing engineering field. Thanks to a superb collection of authors, reviewers, and Editorial Advisory Board members, we are confident that *Comprehensive Microsystems* represents an authoritative primary reference source that addresses this need.

As its title suggests, the book before you covers virtually all aspects of the microsystems field. In 54 chapters, the work discusses a breadth of topics, which underscores the interdisciplinary nature of research and development in microsystems and MEMS, a spectrum that has few parallels in other technical disciplines. As a readable reference work, *Comprehensive Microsystems* provides engineers, students, and educators with a unified source of information that will prove to be useful for new as well as established microsystems researchers.

The book is thematically divided into sections that cover a variety of topics; the chapters are self-contained, yet cross-referenced, allowing readers to easily obtain relevant related information. The book opens with a section on Materials, including chapters on silicon as well as metals and polymers, and continues with Fabrication and Packaging, in which the topics range from micromachining to self-assembly and packaging. Moving to an overview of some of the basic components used in microsystems, the section Electronics and System Design covers areas including electronic interface circuits and simulation, and Actuation Mechanisms has chapters on electrostatic, magnetic, and thermal actuation.

The exceptionally wide variety of application areas in which microsystems play a role is reflected in the range of sections that follow. Physical Sensing includes contributions on pressure and flow sensors, gyroscopes, and accelerometers, whereas microfluidics, micropumps, and chemical sensors are only a few of the topics found in the section Chemical and Biological Systems. Finally, the rich spectrum of activities discussed in Optical Systems includes micromirrors, the artificial retina, and biophotonics.

Realizing that the MEMS and microsystems fields have led to mature products in a number of industrial applications as well as provided inspiration for research in unexplored areas, the work concludes with a section Industrial Applications, in which chapters discuss radio-frequency MEMS, medical applications, and ink-jets, and finally Emerging Topics, a look toward the future in which MEMS atomic clocks, microcombustion

systems, and molecular machine-based nanoelectromechanical systems (NEMS) will see extensive development.

Comprehensive Microsystems provides an extensive cross section through engineering science, from fundamental physics and chemistry to complex, cross-disciplinary systems. The editors-in-chief have been privileged to work with some of the world's leading researchers as authors, reviewers, and editors of the chapters that follow. We hope that you, the reader, will find studying the work as rewarding as we have in assembling it.

Foreword

Microsystems promise to play a pervasive role in enhancing the quality of life during the next several decades. Emerging today in a plethora of products, they represent a powerful weapon for tackling some of society's most pressing problems, including many in health care, environmental quality, homeland security, energy generation, manufacturing competitiveness, and food production. In a very real sense, microsystems represent the culmination of work in three areas, each of which has sparked a revolution of its own: microelectronics, wireless communications, and sensing technology. Bringing these three areas together, microsystems will gather data from the physical world, interpret those data, and then communicate the results via distributed information networks. Increasingly based on nanotechnology, they will control the cars we drive (and monitor the roads and bridges we drive on), enable new generations of high-density information storage and display devices, revolutionize the diagnosis and treatment of debilitating disorders, and provide interfaces to the cellular, molecular, and atomic levels. Just as microelectronics transformed data processing and communications during the past half-century, microsystems are now reaching out to tackle the problems of the nonelectronic world.

Although microelectronics began with the invention of the transistor shortly after World War II, it really took off with the development of the planar process for integrated circuits in the early 1960s. It was quickly apparent that microelectronics was going to permit great progress in the processing of electronic signals, but the world we live in is not electronic. It is mechanical, optical, chemical, and thermal. Thus, researchers began exploring whether the same lithographic processes used to form integrated circuits could also be used to make devices for converting nonelectronic parameters into electronic form (integrated sensors). By the mid-1960s, researchers were realizing visible imaging devices using integrated circuit techniques, and by the late 1960s they were developing cellular probes, pressure sensors, and other devices using the same technology, augmented by selective silicon etching (later christened "micromachining"). The 1970s saw the development of anisotropic micromachining technology and wafer bonding, both necessary for creating the three-dimensional microstructures needed for transducing real-world parameters into electronic signals. They also saw the first efforts to put integrated sensors into high-volume production as the automotive industry sought to meet new exhaust emissions and fuel efficiency requirements. By the late 1970s, the vision of highly integrated digital-output self-testing auto-calibrating "smart" sensors was in place, but neither the supporting technologies nor the marketplace was quite ready for them.

The 1980s saw other important technologies added to the arsenal of sensor processes, including surface micromachining, LIGA, and deep reactive ion etching. The first serious efforts at commercialization began, and conferences dedicated to integrated sensors were launched. By the end of the decade, integrated sensors were becoming known as microelectromechanical systems (MEMS) and were generating great excitement by realizing actuators as well as sensors using the technology. Uncooled infrared sensors, flowmeters, micromotors, and self-testing accelerometers were being reported. The 1990s saw MEMS become a major worldwide effort and proliferate into a number of subfields, including optical-MEMS, inertial-MEMS, RF-MEMS, bio-MEMS, and microfluidics. Integrated gyros, microvalves, scanning surface probes, ink-jet print heads, DNA chips, and optical projection systems provided the focus for new efforts, fueled in part by new materials and processes. The present decade has seen continued proliferation into new materials, rapid growth in chemical and biological devices, and the joining of sensing (and actuation) technology with microelectronics and wireless interfaces.

These developments have taken sensors well beyond simple transducers to application-driven microsystems that solve complete problems.

Comprehensive Microsystems is a remarkably comprehensive and state-of-the-art look at the microsystems field, assembled by editors who are world leaders in microsystems and by subject authors that are expert in its many constituent areas. It begins by reviewing the diverse set of materials used in microsystems, a set that is steadily expanding to take advantage of properties ranging far beyond those found in silicon alone. The critical issues associated with fabrication and packaging are examined next. High throughput and high yield in forming complex three-dimensional microstructures are important, but unlike microelectronics, where complementary metal oxide semiconductors (CMOS) have become dominant, the diversity of microsystem structures has, so far, resisted process standardization. Both fabrication flows and unit processes still involve considerable innovation. Microsystem packaging is also more difficult than in microelectronics because, by definition, many sensors must directly contact the environment they are trying to measure, and for many devices, packaging at the wafer level is essential both for fabrication yield and for operating performance. The complex issues associated with design in the interdisciplinary multiparameter world of microsystems are discussed next, followed by chapters that examine the state of the art in optical, chemical, biological, and physical microsystems. Available techniques for microactuation are discussed, both for use in their own right (e.g., in ink-jet printers, digital light processors) and for sensor self-test. Important emerging topics are then explored, and the book concludes with comments on interface circuitry for MEMS and a look at three high-volume application areas: automotive, medical, and environmental.

Comprehensive Microsystems is an outstanding resource and window on an exciting new frontier that will be key in solving many of the most important problems facing us in the 21st century, improving the quality of life for our children, our children's children, and ourselves.

Nomenclature

a_0	Interatomic distance (m)
c	Elasticity tensor (Pa)
c_{ij}	(i, j) component of elasticity tensor (Pa^{-1})
d_s	Atomic distance along the slipping direction on slip plane (m)
d_m	Interval of the atom row (m)
E	Young's modulus (Pa)
K	Gauge factor
G	Shear modulus (Pa)
l, m, n	Direction cosine of a given direction with respect to each orthogonal base vector
R	Resistance (Ω)
S	Strain tensor
s	Elastic compliance tensor (Pa^{-1})
s_{ij}	(i, j) component of elastic compliance tensor (Pa^{-1}), in engineering notation

$\mathbf{T}$	Stress tensor (Pa)
T	Temperature (K)
T_{ij}	Component of stress tensor (Pa) in physical tensor notation
T_{λ}	Component of stress tensor (Pa) in engineering notation
α	Coefficient of thermal expansion (K^{-1})
ε	Tensile strain
γ	Surface energy (J)
ν	Poisson's ratio
Π	Piezoresistive coefficient tensor (Pa^{-1})
π_l	Piezoresistive coefficient along longitudinal axis (Pa^{-1})
π_{ijkl}	Component of piezoresistive constant tensor Π (Pa^{-1}) in physical tensor notation
$\pi_{\omega\lambda}$	Component of piezoresistive constant tensor Π (Pa^{-1}), in engineering notation
$\pi_{<lmn>}$	Longitudinal piezoresistive constant along <*lmn*> direction (Pa^{-1})
ρ	Resistivity (Ω m)
ρ_{ij}	Component of resistivity tensor (Ω m) in physical tensor notation
ρ_{ω}	Component of resistivity tensor (Ω m) in engineering notation
σ_{m}	Fracture strength (Pa)
τ_{m}	Shear strength (Pa)

1.01.1 Introduction

Silicon and related materials, such as crystalline and amorphous silicon (a-Si), silicon alloys, and compounds, are the most important materials in microsystems. The main reason is their use in semiconductor device structures and the strong dependence of fabrication technologies of microsystems on semiconductor microfabrication, such as thin-film deposition, photolithography, and etching (Plummer *et al.* 2000). In addition, silicon also acts not only as an electrical material but also as a thermal and a mechanical material (Petersen 1982). Especially, as silicon has high relative elastic constant and yield strength, many mechanical structures in microsystems are made of silicon.

Single-crystal silicon (SCS) is used in both bulk and surface micromachined structures. In the bulk micromachining process, an SCS wafer is processed using crystallographic anisotropic etching or deep reactive ion etching (DRIE) of silicon to form relatively thick (~500 μm thick) and large (0.5–10 mm^2) structures, such as pressure sensors, inertial sensors, microfluidic devices, and optical mirrors. In the surface micromachining process, relatively thin (1–10 μm thick) and small (50–1000 μm^2) microstructures are fabricated on silicon substrates using silicon-on-insulator (SOI) wafers by sacrificial etching of silicon dioxide or by using bulk silicon wafers with special etching techniques, which combines a high aspect anisotropic plasma etching method and a lateral or isotropic etching method. Inertial sensors

and optical mirrors are applications using surface micromachined SCS structures.

Polycrystalline silicon (polysilicon) used in a gate electrode and as an interconnection in a complementary metal oxide semiconductor (CMOS) device is now one of the main structural materials in surface micromachined devices. Because polysilicon is highly compatible with the CMOS fabrication process, the polysilicon device is used as an integrated inertial sensor, such as an accelerometer and a gyroscope. In addition, polysilicon is used as a sacrificial layer for the fabrication of dielectric structures, such as infrared sensors, pressure sensors, and gas sensors, in which thermal and electrical insulations to the substrate or passivation of the underlying structures is required. a-Si used in thin-film transistors for flat panel displays and solar cells is also used as a sacrificial layer in surface micromachined devices but is rarely used as a structural material because of its low resistance against chemical and mechanical attacks.

In microsystems, silicon is not only a structural material but also a functional material. Thermal-type infrared sensors detect heat due to the absorption of infrared radiation using thermopiles and bolometers, in which silicon is used as a thermoelectric material and a thermistor, respectively. As an optical material, the photoconductive effect and the photovoltaic effect of silicon are applied to sensing devices such as solar cells and photodiodes. In mechanical structures, the piezoresistive effect of silicon is widely employed for strain detection in pressure and force sensors and accelerometers.

Silicon germanium alloy has recently been used in wireless communication devices because of its low power consumption, high speed, and low noise due to its low electrical conductivity. In microsystems, because of the fabrication capability at low temperature, polycrystalline silicon germanium structures are being used these days. Recent CMOS devices can withstand temperatures of up to 520°C using a barrier metal between the aluminum interconnection and the polysilicon gate electrode. Low-stress and small-stress-gradient films can be obtained below 520°C. In addition, polycrystalline germanium (poly-Ge) film is used as a sacrificial layer, because poly-Ge is etched by a hydrogen peroxide solution, which is one reason why germanium is not widely used for semiconductor devices, although germanium has the better electrical properties as a semiconductor material when compared to silicon.

Dielectric compounds of silicon, nitride, and oxide are also widely used in microsystems. Silicon nitride films have been used as a passivation layer in semiconductor devices because of their high stability and inertness, which is also important and useful in microsystems. The deformable membranes of pressure sensors, supporting membranes, or beams of thin-film-type gas sensors are fabricated using silicon nitride films. Nitride films have excellent properties as an optical material and are also used in dielectric mirrors.

Oxide film is used as an excellent electrical insulating material, such as a gate insulating layer and an interlayer insulation of the CMOS device. Oxide is used as a sacrificial layer in the surface micromachining process where silicon structures are employed. Because the thermal conductivity is low, i.e., lesser than silicon nitride, it is used as a membrane support material in a thermal-type infrared sensor.

Thus, silicon and related materials are indispensable for microsystems. In this chapter, the process technologies and properties of these materials, especially SCS, are discussed with priority being given to mechanical properties, which is the most important property in designing, fabricating, and evaluating microsystems.

1.01.2 Single-Crystal Silicon

1.01.2.1 Structure

Silicon occupies 25.8% of the Earth's crust mass, which is the highest mass ratio next to oxygen, and exists mostly as silicate glass materials. Silicon is the material most widely used as a semiconductor. It is a covalent crystal that has a diamond cubic lattice structure, as shown in **Figure 1(a)**. The lattice constant of silicon is 5.43 Å and the distance between the neighboring covalently bonded silicon atoms is 2.35 Å. The unit cell of the cubic diamond lattice structure can be considered as two interleaved face-centered cubic lattices, with their origins in (0, 0, 0) and (1/4, 1/4, 1/4) directions. In the unit cell, eight silicon atoms are arranged at the corners, six at each face center and four at the midpoint between the center and the four corners that are not adjacent to each other. The unit cell contains eight atoms. The filling ratio of the unit cell is only 34%, which is much lower than the 74% of the close-packed structure, which contributes to easy dopant diffusions in the CMOS fabrications. The atom density in the unit cell is $4.995 \times 10^{22}\,\mathrm{cm}^{-3}$, and surface atom density on the (100) surface is $6.78 \times 10^{14}\,\mathrm{cm}^{-2}$.

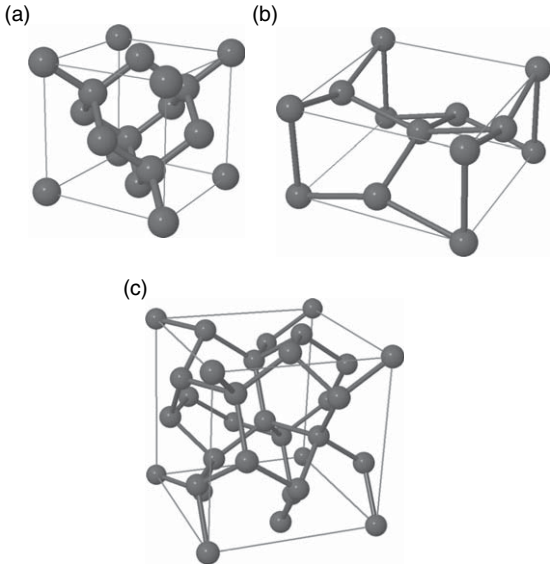

Figure 1 Structures of single-crystal silicon (SCS): (a) diamond cubic (SiI), (b) body-centered tetragonal (β-tin, SiII), and (c) body-centered cubic (BC8, SiIII) structures.

There have been many researches on the high-pressure phases of silicon (Hu *et al.* 1986), because silicon has very high strength against compressive stress. A phase transition from diamond cubic (SiI) to body-centered tetragonal (β-tin), which is a metallic phase (SiII), occurs at about 11 GPa. The β-tin silicon shows a drop of several orders of magnitude in the resistivity. Above 14 GPa, the β-tin phase shows a phase transition to a primitive hexagonal phase. This hexagonal phase changes to the close-packed structure (hexagonal close-packed structure, hcp) at about 40 GPa. The β-tin silicon transfers to body-centered cubic structure (BC8), as shown in **Figure 1(c)**, by quenching at the ambient temperature. The phase transitions from the diamond cubic to β-tin structure and from the β-tin to the BC8 structure are also observed in the microscale by a microindentation. The penetration curve using a spherical indenter shows noncontinuous points during both loading and unloading, which are identical to each of the above-mentioned phase transitions (Williams *et al.* 1999).

1.01.2.2 Crystal Growth

SCS is grown from molten polysilicon, which is reduced from silicon dioxide and purified. There are two major methods for growing single crystals: the Czochralski (CZ) and the floating zone (FZ) method. In the CZ method, which is the most commonly used growth method in the industry, polysilicon granules are put into a quartz crucible and heated in vacuum up to about 1420°C, just above the melting point of silicon. Then, a seed crystal of silicon is dipped into the molten silicon; it is then pulled up quickly at first and then slowly to solidify silicon on the seed crystal by rotating both the seed crystal and the crucible. The dopant impurities can be put into the crucible with polysilicon to control the conductive type and the concentration of the grown silicon ingot. Boron is a p-type dopant and phosphor, antimony, and arsenic are n-type dopants. This method allows a wide range control of electrical conductivity, but it is difficult to obtain a high-resistivity wafer because the impurities (mainly oxygen) accumulate during the crystal growth.

The main source of oxygen impurities in CZ silicon wafers is the crucible. Oxygen in the quartz crucible dissolves into molten silicon and diffuses into the grown silicon ingot. By applying magnetic field to the crucible, the deviation in the dopant concentration as well as the oxygen concentration is reduced and the temperature uniformity is improved because the convective flow in the molten silicon is suppressed. This method is known as the magnetic field applied Czochralski (MCZ) method.

The FZ method is used especially for making high-resistivity wafers, since the maximum resistivity of the CZ wafer is 100–1000 Ω cm because of the impurities (e.g., oxygen). In the FZ method, a polysilicon ingot is placed on top of a seed crystal. The bottom end of the ingot is molten in vacuum or in an argon gas environment using an inductive heating coil. The seed crystal is dipped into the molten polysilicon and the coil is slowly moved upward by rotating both the seed crystal and the polysilicon ingot. The molten silicon solidifies on the seed crystal. This method does not use a crucible and the impurities are segregated into the molten area. Therefore, high-purity and uniformly doped crystal can be grown. High-resistivity silicon wafer up to 20 kΩ cm is possible using this growth method.

The single-crystal ingot is sliced and then lapped and etched to remove the damaged layer during slicing. Finally, the sliced silicon wafer is polished. The crystallographic orientation of the ingot and thus the wafer is determined by the seed crystal. In CMOS device and microsystems, a (100) oriented wafer whose primary orientation flat shows <110> direction is often used. A (111) oriented wafer is used in bipolar transistor devices and microsystem devices. In bipolar transistors, a slightly (~3°)

misoriented (111) wafer is employed to make atomic steps, which act as nucleation sites for epitaxy. In microsystems, a (111) wafer is used for the in-plane isotropy of the elastic constant, which is discussed later. An (110) oriented wafer is used for the high aspect ratio trench fabrication using crystallographic anisotropic wet etching using alkaline solutions.

Another single crystal growth method is epitaxial growth. Vapor-phase epitaxy on SCS substrate using chemical vapor deposition (CVD) is the typical deposition method. Silicon atoms from the pyrolysis of silane (SiH_4) or chlorosilanes deposit on a silicon substrate and single crystal is epitaxially grown on the substrate. *In situ* doping can be easily obtained by mixing phosphine (PH_4) or diborane (B_2H_6) with the source gas during the epitaxial growth. This method is used when an SCS layer of different conductivity type, doping material, or concentration on a silicon wafer is required. For example, the highly boron-doped silicon layer is used for a p^+ etch stop layer in anisotropic etching using an alkaline solution (Seidel *et al.* 1990) or an n-type layer on a p-type substrate is used for the electrochemical etch stop for fabricating bulk-micromachined pressure sensors and accelerometers.

In the surface micromachining process, the term epitaxial polysilicon (epi-poly) is often used for a thick polysilicon layer deposited by means of the same tools as used for epitaxial SCS. This is not an accurate expression but it distinguishes this deposition method from the low-pressure chemical vapor deposition (LPCVD) method, which is the method normally used for polycrystalline silicon thin films.

1.01.2.3 Silicon on Insulator

SOI wafer, where the top SCS layer (device layer) on an oxide film (buried oxide) (Celler and Cristoloveanu 2003) is fabricated on a silicon wafer (handle wafer), is widely used in microsystems as well as in semiconductor devices. In microsystems, the most attractive feature is that the SCS can be used as structural materials in surface micromachined devices. Relatively thick SOI wafers, whose device layer thickness is more than a few microns, are widely used in accelerometers, vibrating gyroscopes, and micromirrors.

The SOI wafer is classified by its fabrication methods, such as silicon direct bonding SOI (SDB-SOI) (Lasky 1986), separation by implanted oxygen (SIMOX) (Izumi *et al.* 1978), cleavage of bonded wafer at hydrogen-implanted layer (UNIBOND®) (Bruel 1995), and epitaxial layer transfer (ELTRAN®) (Yonehara and Sakaguchi 2001). For an SOI with a thick device layer, which is more than a few micrometers thick, an SDB-SOI wafer is most commonly used.

In the SDB-SOI wafer, two silicon wafers, one or both of which are oxidized, are bonded at temperatures higher than 800°C. One silicon layer of the bonded wafer for the device layer is thinned by grinding, etching, and polishing into the designated thickness. The minimum thickness of the device layer is 1 μm, because the best uniformity of the thinning process is ±0.5 μm. The properties, such as the crystallographic orientation, conductive type, dopant material, and the concentration of two SCS layers, can be arbitrarily selected. The crystallinity of the device layer is better than that of other SOI wafers because the device layer is made of a bulk wafer without any irradiation.

The other SOI wafers, on the other hand, are not so often used for microsystems applications because it is difficult to fabricate thick device layers. For the fabrication of the SIMOX silicon wafer, the buried SiO_2 layers were formed by oxygen ion implantation into a silicon wafer. The thickness of the device and buried oxide layers can be determined from the implantation energy and dose. For example, the 150 keV and $1.2 \times 10^{18}\,cm^{-2}$ oxygen implantation and annealing at 1150°C of silicon wafer resulted in the 280-nm-thick silicon layer on the 210-nm-thick oxide layer (Izumi *et al.* 1980). The thickness of the device layer of SIMOX wafers is limited by the ion penetration depth of oxygen.

The fabrication of the UNIBOND SOI wafers is similar to that for SDB-SOI but is different in the device layer thinning process, which is known as the smart cut process. The raw silicon wafer for the device layer is first oxidized and then hydrogen is implanted. The wafer is bonded at the ambient temperature to a wafer for substrate. The bonded wafer is annealed at 400–600°C to split into two wafers at the hydrogen-implanted layer (Bruel 1995). The thickness of the device layer of UNIBOND SOI wafers is limited to 1.5 μm due to the ion penetration depth of hydrogen (Celler and Cristoloveanu 2003).

The ELTRAN SOI wafer is also characterized by the wafer thinning process. A raw silicon wafer of the device layer is first electrochemically etched to form a porous silicon layer as the splitting layer (Yonehara *et al.* 1994). The wafer is bonded to the substrate wafer at the ambient temperature. After heat treatment, the bonded wafer is split using a water-jet method. The device layer thickness of the ELTRAN SOI wafer

depends on the tools used for the epitaxial deposition. Therefore, a thick device layer (~100 μm) is possible, but is not commercially available due to its fabrication cost.

1.01.2.4 Processing

SCS is processed using various techniques in the wafer manufacturing, microfabrication process, micromachining, and assembly process. Even the mechanical processing of silicon is important for microfabrication. For example, lapping using alumina abrasive and chemical mechanical polishing using silica slurry are very important in the wafer fabrication. The chip dicing process using a diamond blade and the laser dicing are used in the packaging process. Wet chemical etching and dry etching processes are the fundamental techniques in microfabrication.

Isotropic wet etching of SCS is done using a mixture of hydrofluoric acid (HF), nitric acid, and acetic acid (Schwarz and Robbins 1976). Because etching is a two-step process, which involves oxidization of silicon by nitric acid and the etching of the oxide by HF, the etching profile can be controlled by the mixing ratio of these acids. In the high HF concentration region, the etched surface is rough, and sharply peaked corners and edges appear because of the autocatalytic mechanism in the oxidization process. When HNO_3 concentration increases, the etched surfaces become smooth and have a rounded shape. In this region, the etching reaction is dominated by oxide removal. In addition, the etch rate of silicon in a solution with the mixing ratio $HF:HNO_3:CH_3COOH = 1:3:8$ decreases steeply as dopant concentration of silicon increases, which can be used for the stiction-free sacrificial layer etching process of SOI structures (Fujitsuka and Sakata 2002).

Silicon is etched with alkaline solution, such as potassium hydroxide (KOH), ammonia (NH_3), and tetramethylammonium hydroxide (TMAH) ($(CH_3)_4NOH$) solution. The etch rate strongly depends on the crystal orientation, and the crystallographic anisotropic etching of silicon is a key technology in the bulk micromachining process. Details are described in Chapter **1.08**.

Electrochemical etching of silicon is another important wet etching method for microsystems. When a positive voltage relative to a reference electrode is applied to silicon in HF aqueous solution with or without ethanol, silicon is etched by anodic dissolution (Smith and Collins 1992). The etch rate is about $1\,\mu m\,min^{-1}$. The etching properties are significantly changed by the etching conditions, such as the current density, etchant concentrations, dopant type of silicon, its concentration, and illumination during etching. At a low current density, highly porous structures with up to 80% porosity are formed, whereas the smooth etching surface is formed at a high current density, which is called electropolishing, and it is used in wafer fabrication (Zhang *et al.* 1989). Since silicon dissolves in HF solution if holes are present, p-type silicon can be etched irrespective of its dopant concentration. In electrochemical etching, lightly-doped n-type silicon needs illumination, because holes may be generated in an n-type silicon electrode by illuminations (photoelectrochemical etching) (Lehmann 1993). The pore size can be controlled from 1 to 20 μm by the dopant concentration. The micrometer-sized pore formation can be applied to periodic structures like photonic crystals by making etch pits on the surfaces before etching (Grüning *et al.* 1995). However, a highly doped n-type silicon can be etched electrochemically (without illumination) because a positively charged depletion layer is formed by the positive bias on the n-type silicon anode. The dependence on n-type dopant concentration can be used for etch stop techniques (Smith and Collins 1992). For example, a thin diaphragm of piezoresistive pressure sensor was fabricated using n^+-silicon wafer with an epitaxially grown n-silicon layer. The 10-μm-thick n-Si layer is used for the pressure diaphragms (Esashi *et al.* 1982).

In dry etching tools, silicon is etched by various kinds of gases, such as fluoride (SF_6, CF_4), chlorine (Cl_2), chloride (CCl_4), and bromide (HBr), using a plasma reactor. The fluorine-based plasma etches silicon isotropically, whereas the chlorine- and bromine-based etchings show anisotropy. The chlorine and bromine etchings need the assistance of ion bombardment rather than fluorine etching. The CMOS industries mainly use the chlorine or bromide etchings because the selectivity to silicon dioxide films is very high. Polysilicon gate electrode can be patterned on thin gate oxide layers. Instead, fluoride etchings (SF_6, CF_4) prior to this etching are required to remove the native oxide layer.

In microsystems, high aspect ratio trench etching by pulsing sulfur fluoride (SF_6) and perfluorocyclobutane (C_4F_8) gases, known as the Bosch process, is widely employed. SF_6 plasma etches silicon isotropically and C_4F_8 deposits a fluorocarbon polymer on the surfaces. The polymer protects the sidewall of the trench during fluoride plasma isotropic etching. Details are described in Chapter **1.07**.

Silicon is etched chemically by a xenon difluoride (XeF_2) gas with an isotropic feature, which can be employed for silicon sacrificial etching in the surface micromachining for dielectric structures. XeF_2 is a white granular crystal and has the equilibrium vapor pressure of about 600 Pa. The etching can be preformed simply by putting silicon and XeF_2 in a chamber. The etching has high selectivity to silicon dioxide, polymer, and metals, which is very useful in the micromachining process. However, this high selectivity to oxide film causes problems in the fabrication because native oxide layer removal prior to this etching is required.

1.01.2.5 Properties of Silicon

Silicon is a group IV semiconductor, whose energy gap is 1.12 eV. The resistivity can be controlled in a wide range by the impurities. The resistivity of the pure silicon is 198 kΩ cm at the ambient temperature. By adding impurities such as phosphorus, boron, and arsenic to 10^{21} cm^{-3}, the resistivity of silicon can be reduced to <1 mΩ cm, as shown in **Figure 2**. Though, the detailed properties as a semiconductor are omitted here, the piezoresistive properties of silicon are described later because of its application to sensor devices.

Silicon is opaque in visible light, but transparent in infrared light with a wavelength greater than 1.1 μm. The refractive index of silicon is 3.874 at a wavelength of 632.8 nm. The properties of crystalline silicon are comprehensively summarized in Hull (1999).

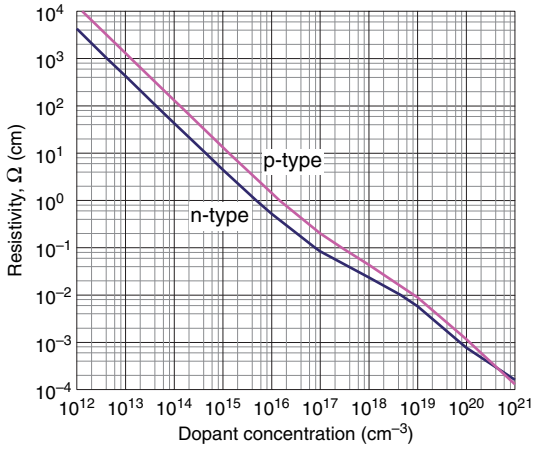

Figure 2 Resistivity of single-crystal silicon (SCS) as a function of dopant concentration.

1.01.2.6 Piezoresistive Properties

A semiconductor strain gauge using SCS has a close connection with the development of the silicon microsystems. The research on the piezoelectric effect, that is, the resistivity change by the applied strain, started in the 1950s and a large gauge factor was found in the semiconductor strain gauges when compared to metal strain gauges (Smith 1954).

The resistance change ΔR in a wire strain gauge is caused by the dimension change of the conductive wire and the piezoresistive effect

$$\frac{\Delta R}{R} = (1 + 2v + \pi_l E)\varepsilon \equiv K\varepsilon \qquad [1]$$

The gauge factor K of silicon is about 100, whereas that of a metal is about 2, which indicates that the piezoresistive effect of silicon is dominant but that of a metal is negligible.

The piezoresistive effect of semiconductor materials is caused by the change in the energy state of the conduction band by the external strain. Then the piezoresistive coefficient depends on the dopant materials and their concentrations (Kanda 1982). Since the energy band structure is anisotropic in accordance with the crystallographic structure, the piezoresistive effect is anisotropic. The first-order piezoresistive effect is described as the change in the component of the resistivity tensor ρ_{ij}

$$\Delta\rho_{ij}/\rho = \sum_{k,l} \pi_{ijkl} T_{kl} \qquad [2]$$

where π_{ijkl} is the component of the piezoresistive coefficient tensor and T_{kl} is the component of the stress tensor. In engineering notation, where the subscripts 11, 22, 33, 23, 13, and 12 are replaced by 1, 2, 3, 4, 5, and 6, respectively, eqn [2] is rewritten as

$$\Delta\rho_{\omega}/\rho = \sum_{\lambda=1}^{6} \pi_{\omega\lambda} T_{\lambda} \qquad [3]$$

The piezoresistive coefficient tensor $\boldsymbol{\Pi}$ of a cubic crystal is given by the following equation:

$$\boldsymbol{\Pi} = \begin{pmatrix} \pi_{11} & \pi_{12} & \pi_{12} & 0 & 0 & 0 \\ \pi_{12} & \pi_{11} & \pi_{12} & 0 & 0 & 0 \\ \pi_{12} & \pi_{12} & \pi_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & \pi_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & \pi_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & \pi_{44} \end{pmatrix} \qquad [4]$$

Like elastic constants, there are three independent piezoresistive coefficients, π_{11}, π_{12}, π_{44}. The longitudinal piezoresistive coefficient of arbitral directions (l, m, n) is given by the following equation:

$$\pi_l = \pi_{11} + 2(\pi_{44} + \pi_{12} - \pi_{11})\left(l^2m^2 + m^2n^2 + l^2n^2\right) \quad [5]$$

Thus, the longitudinal piezoresistive coefficient of typical directions is

$$\pi_{<100>} = \pi_{11} \quad [6]$$

$$\pi_{<110>} = \frac{1}{2}(\pi_{11} + \pi_{12} + \pi_{44}) \quad [7]$$

$$\pi_{<111>} = \frac{1}{3}(\pi_{11} + 2\pi_{12} + 2\pi_{44}) \quad [8]$$

The typical piezoresistive coefficients of both p- and n-type silicon are given in **Table 1**. According to eqn [5], the maximum piezoresistive coefficient appears in <111> directions when π_{11} and $\pi_{44} + \pi_{12} - \pi_{11}$ are of the same sign, as is the case in p-type silicon and n-type germanium. If they are opposite in sign, π_l in <111> direction becomes maximum when $\frac{1}{3}|\pi_{44} + \pi_{12} - \pi_{11}|$ is larger than $|\pi_{11}|$. When $\frac{1}{3}|\pi_{44} + \pi_{12} - \pi_{11}|$ is smaller than $|\pi_{11}|$, π_l in <100> direction shows a maximum piezoresistive coefficient.

The mechanism of piezoresistive effect is described by the many valley model. In n-type silicon, the valley of the conduction band, i.e., the minimum energy point, is changed by the external strain. The energy level along the loading axis decreases and that perpendicular to the loading axis increases, which causes the transfer of the electron from the higher energy valleys to the lower ones. As a result, the resistivity along the tensile direction decreases and that along the shear direction increases. On the other hand, the conduction band change in p-type silicon appears in the breakage of the degeneracy at the top (highest energy point) of the valence band, which appears at the large resistivity change against the shear strain.

1.01.2.7 Elastic Properties

The relationship between the stress and the strain of a linear elastic material is described by the Hooke's law

$$\mathbf{T} = \mathbf{cS} \quad [9]$$

The stress **T** and strain **S** are the 2nd rank tensors that have six independent variables. **c** is the elasticity tensor, which is a 4th rank tensor, and is described by a 6×6 matrix. Due to the matrix symmetry, the 21 elastic coefficients are independent. In addition, considering the crystal symmetry of a cubic crystal, only three stiffness coefficients are independent. The elasticity tensor **c** is expressed by engineering notation as:

$$\mathbf{c} = \begin{pmatrix} c_{11} & c_{12} & c_{12} & 0 & 0 & 0 \\ c_{12} & c_{11} & c_{12} & 0 & 0 & 0 \\ c_{12} & c_{12} & c_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{44} \end{pmatrix} \quad [10]$$

The stress–strain relationship is also described using the elastic compliance tensor **s**

$$\mathbf{S} = \mathbf{sT} \quad [11]$$

The elastic compliance tensor is described by a 6×6 matrix, which has also only three independent compliance coefficients s_{11}, s_{12}, and s_{44} that can be derived from the stiffness coefficients

$$s_{11} = \frac{c_{11} + c_{12}}{(c_{11} - c_{12})(c_{11} + 2c_{12})} \quad [12]$$

$$s_{12} = \frac{-c_{12}}{(c_{11} - c_{12})(c_{11} + 2c_{12})} \quad [13]$$

$$s_{44} = \frac{1}{c_{44}} \quad [14]$$

These stiffness and compliance coefficients for silicon are accurately measured and given in

Table 1 Piezoresistive coefficients of silicon and germanium

		π_{11}	π_{12}	π_{44}	Maximum π_l
	Resistivity (Ω cm)	($\times 10^{-12}$ Pa^{-1})			
n-Type Si	11.7	−1022	+534	−46	−1020 [100]
p-Type Si	7.8	+66	−11	+1381	+930 [111]
n-Type Ge	9.9	−47	−50	−1379	−970 [111]
p-Type Ge	1.1	−37	+32	+967	+650 [111]

Table 2 Stiffness and compliance coefficients of silicon and germanium

	s_{11}	s_{12}	s_{44}	c_{11}	c_{12}	c_{44}
	($\times 10^{-12}$ Pa^{-1})			(GPa)		
Si	7.68	−2.14	12.6	165.7	63.9	79.6
Ge	9.64	−2.60	14.9	129.2	47.9	67.0

Table 2 (Wortman and Evans 1965). Since these coefficients are related to the principal axis, the elastic constants for a particular orientation should be obtained using the tensor transformation. The elastic constants with respect to an arbitral orientation are

$$\frac{1}{E} = s'_{11} = s_{11} - 2\left(s_{11} - s_{12} - \frac{1}{2}s_{44}\right)\left(l^2m^2 + m^2n^2 + l^2n^2\right) \quad [15]$$

$$v = \frac{s'_{12}}{s'_{11}} = -\frac{s_{12} + \left(s_{11} - s_{12} - \frac{1}{2}s_{44}\right)\left(l^2l'^2 + m^2m'^2 + n^2n'^2\right)}{s_{11} - 2\left(s_{11} - s_{12} - \frac{1}{2}s_{44}\right)\left(l^2m^2 + m^2n^2 + l^2n^2\right)} \quad [16]$$

$$\frac{1}{G} = s'_{44} = s_{44} + 4\left(s_{11} - s_{12} - \frac{1}{2}s_{44}\right)\left(l^2l'^2 + m^2m'^2 + n^2n'^2\right) \quad [17]$$

where (l, m, n), (l', m', n') are the direction cosines of the loading direction and a direction perpendicular to the loading direction. Figures 3–5 show the Young's modulus E, the Poisson's ratio v, and the shear modulus G, respectively, of (100) and (110) silicon and germanium. In the (100) plane, the maximum value of 168.9 GPa appears along [011] and its equivalent directions and the minimum value of 130.2 GPa appears along [001] and its equivalent directions. The Young's modulus E, the Poisson's ratio v, and the shear modulus G of (111) silicon, 168.9 GPa, 0.262, and 66.9 GPa, respectively, do not depend on the in-plane direction, which is useful when a circular or cylindrical structure is used. In addition, the composite elastic moduli $E/(1-v)$ of (100) and (111) planes are 180.5 and 229.0 GPa, irrespective of the in-plane direction, which is very useful since it makes the deformation shape of a thin membrane structure symmetric. The calculated elastic constants of the major orientations are given in Table 3 (Brantley 1973).

The temperature coefficients of the stiffness coefficients are around −100 ppm per degree Celsius in all three independent coefficients (Hall 1967). The doping dependence of the elastic constants is expected because the elastic properties of semiconductors depend on the carrier concentration. Heavily doped (up to 5×10^{19} cm^{-3}) n-type and p-type silicon show 1–3% decrease in the stiffness coefficients and modification of the temperature dependencies (Hall 1967).

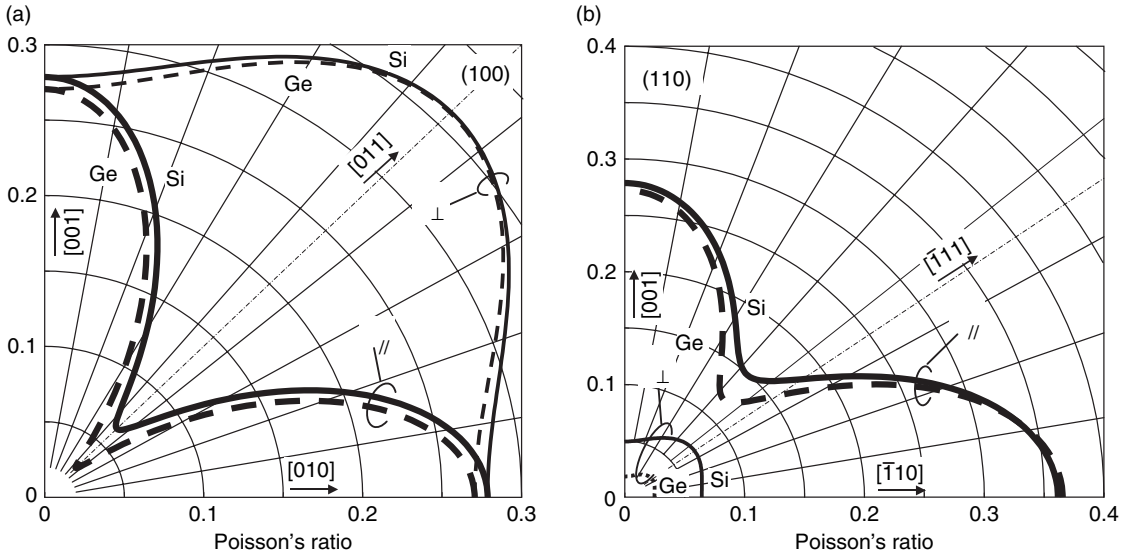

Figure 4 Poisson's ratio of silicon and germanium as a function of direction in (a) (100) plane and (b) (110) plane. $v_{\parallel}$ and $v_{\perp}$ denote the in-plane and perpendicular-to-plane Poisson's ratio, respectively.

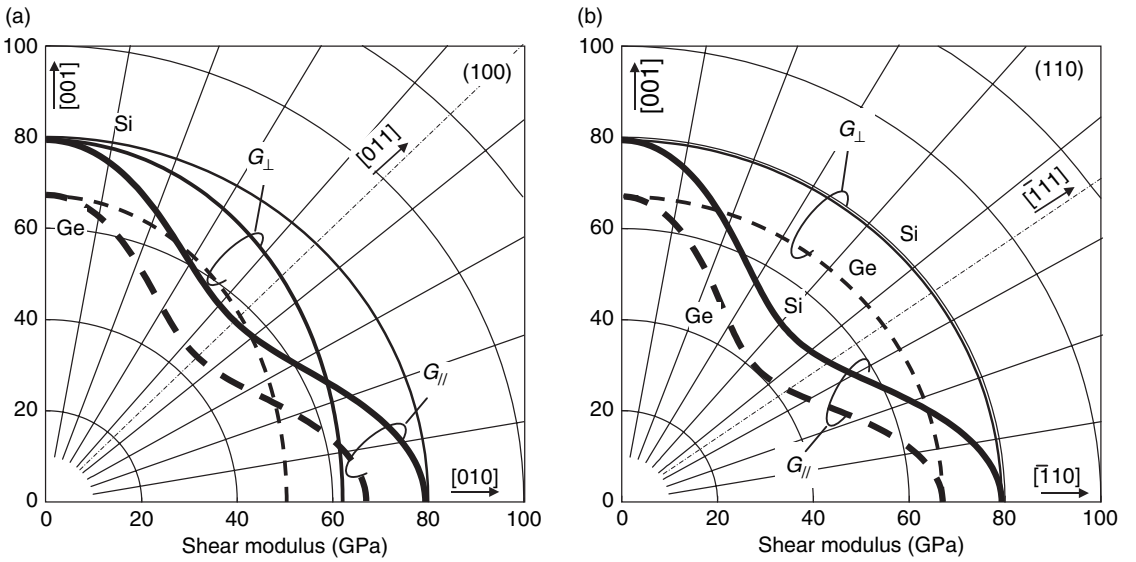

Figure 5 Shear modulus of silicon and germanium as a function of direction in (a) (100) plane and (b) (110) plane. $G_{\parallel}$ and $G_{\perp}$ denote in-plane and perpendicular-to-plane shear modulus, respectively.

Table 3 Bulk silicon elastic modulus for several crystallographic orientations

	Young's modulus		*Poisson's ratio*		
Wafer orientation	*Direction*	*GPa*	*Direction*		
(100)	<011>	168.9	<011>	<0−11>	0.064
(100)	<001>	130.2	<010>	<001>	0.279
(110)	<111>	187.5	<1−11>	<1−1−2>	0.182
(110)	<100>	130.2	<001>	<1−10>	0.279
(111)	(Any)	168.9	(Any)		0.262

In microsystems, there is no reason to negate the use of bulk elastic properties because the structures in microsystems are thick and wide enough to be considered as bulk structures. In addition, many works on the measurement of elastic properties of micrometer specimens using uniaxial tensile test have been carried out, which support the use of bulk properties. For thick (19 μm) SCS (100) films, the measured values of Young's modulus and Poisson's ratio of <110> direction are 169.0 GPa and 0.069, respectively (Isono *et al.* 2006). Though thin (~2 μm thick) SCS films show larger variation in measured values, which may be caused mainly by the variation in the thickness of the specimen, the averaged values among different measurement methods agree with the theoretical values (Tsuchiya *et al.* 2005). The Young's modulus of different crystallographic orientations and directions fabricated from SOI wafers is measured, which indicates close agreement with the bulk properties (Sato *et al.* 1998). The Young's modulus of heavily doped (about $10^{20}\,\mathrm{cm}^{-3}$) silicon microstructures sometimes showed values less by 10% or more than bulk values, which is not consistent with the above discussion. The defects introduced by the dopant may cause the reduction of the elastic coefficients.

In thin-film microstructures, the internal (residual) stress is one of the important properties of the materials. The internal stress consists of the thermal stress and the intrinsic stress. The former is generated by the mismatch of the coefficient of thermal expansion (CTE) between the film and the substrate. The latter mainly originates from the reaction of the film formation process. The internal stress of SCS is almost negligible. However, many researches showed that the doping of SCS causes internal stresses and there are several different results and different explanations for the source of the internal stress. The boron-doped membrane supported by a silicon substrate showed a small tensile stress of about 50 MPa for a membrane 2–3 μm thick. This stress is explained not only by the difference in the CTE ($1.1 \times 10^{-8}\,\mathrm{K}^{-1}$) but also by the difference in the temperature coefficient of the {100} normalized biaxial elastic modulus of the membrane ($-3.7 \times 10^{-5}\,\mathrm{K}^{-1}$) (Berry and Pritchet 1991).

A phosphorus-implanted silicon film showed tensile stress, which is attributed to the lattice dilation of phosphorus. The measured dilation constant, i.e., the ratio of the lattice strain to the dopant concentration, was $-4.5 \times 10^{-24}\,\mathrm{cm}^3$ (Lee *et al.* 1999). However, phosphorus and arsenic doping cause compressive stress in polysilicon, which is attributed to the mass and the size of the substituting ions (Orpana and Korhonen 1991).

In addition, the internal stress in the device layer of bonded SOI wafer exists near the interface to the buried oxide layer (Tan *et al.* 2003), which is caused by the oxidization process of the SCS wafer and wafer bonding process (Iida *et al.* 2000). This internal stress causes small upward deflection of the cantilever beams (Park *et al.* 2005).

1.01.2.8 Strength

The theoretical tensile strength of a perfect crystal is described in Orowan's (1948) theory, in which it is assumed that the work applied on a unit area during the fracture test is equal to the energy needed to create the unit area of two fracture surfaces

$$\sigma_{\mathrm{m}} = \sqrt{\gamma E / a_0} \qquad [18]$$

where γ is the surface energy, E is the Young's modulus, and a_0 is the interatomic distance. As for the (111) plane of SCS, the theoretical tensile strength is 32 GPa. The theoretical shear strength was evaluated by Frenkel (1926).

$$\tau_{\mathrm{m}} = (d_{\mathrm{s}}/d_{\mathrm{m}})(G/2\pi) \qquad [19]$$

where d_{s} is the atomic distance along the slipping direction, d_{m} is the distance between the row of atoms, and G is the shear modulus. As for the (111) plane of silicon, the theoretical shear strength becomes 13.7 GPa. The ratio of the shear strength to the theoretical tensile strength shows the tendency toward the fracture behavior whether it fractures by cleavage or slip. Silicon whose ratio is about 2.3 shows a cleavage fracture, because the maximum shear stress in the specimen is not less than a quarter of the tensile stress during the uniaxial tensile test.

The actual tensile strength is much smaller than the theoretical strength and has large variations, because the fabricated structure has many imperfections such as defects and surface roughness. The reported strength of SCS ranged from 0.5 to 10 GPa, which shows that there is a fracture initiating flaws whose length is >0.5 μm (Tsuchiya *et al.* 2005). In silicon microstructures, the surface geometry is considered to be the dominant parameter of the fracture strength. For example, the strength of the micromachined structure fabricated from SOI wafer using DRIE processes was dominated by the roughness of the etched surfaces (Izumi *et al.* 2005). Such

roughness can be removed or reduced by surface oxidization and by stripping away the oxide layers. The bending strength of the bulk micromachined cantilever beams improved from 6.1 to 6.6 GPa after this process (Ericson and Schweiz 1990). In addition, the loading direction should be considered. For example, the bending strength of the cantilever beams depends strongly on the loading direction. By vertical loading, the maximum stress appears at the top or at the bottom surface, which is often a polished surface (Wilson *et al.* 1996), whereas in the case of the lateral loading it appears on the sidewall surfaces, which is an etched surface (Wilson and Beck 1996).

Nowadays, the fatigue properties of SCS are being investigated widely, though it had been considered that silicon microstructure does not fracture by fatigues in the early stage of microsystems researches. In bulk micromachined devices, it was reported that the SCS cantilever beams did not fracture by fatigue after 10^7 cycles loading if it was not fractured at the first loading (Mutoh *et al.* 1990). Chen and Leipold (1985) reported that the bending strength of SCS wafer does not depend on the loading rate. These phenomena are accounted for by the fact that the defects in silicon crystal do not move at the ambient temperature.

On the other hand, the fracture by repeated stress was observed in the precracked bulk micromachined cantilever beam resonators (Connally and Brown 1992) and the loading rate effect on the bending strength of SCS cantilever beams was reported (Goto *et al.* 1996). The effect of humidity was demonstrated in both the cantilever beam (Connally and Brown 1992) and the doubly supported beam resonators (Tsuchiya *et al.* 1998a). Considering that the fracture initiates at the surface defects, the fatigue fracture is caused by the growth or widening of defects during the long-term cyclic stress application (Muhlstein *et al.* 2001a). It is well agreed that the water vapor affects or initiates the defect growth, which is discussed in detail in Section 1.01.3.

1.01.2.9 Thermal Properties

Silicon also has superior properties as a heat conducting material. At the ambient temperature, the specific heat is $713\,\mathrm{J\,kg^{-1}\,K^{-1}}$, the thermal conductivity is $156\,\mathrm{W\,m^{-1}\,K^{-1}}$, and the thermal diffusivity is $8600\,\mathrm{m^2\,s^{-1}}$. The dopant effect on the thermal conductivity was investigated for phosphor- and boron-doped silicon, both of which have a thermal conductivity of 50–70 $\mathrm{W\,m^{-1}\,K^{-1}}$ in a dopant concentration of $10^{20}\,\mathrm{cm^{-3}}$ (Slack 1964).

The CTE at the ambient temperature (300 K) is $2.616 \times 10^{-6}\,\mathrm{K^{-1}}$. It was measured in the wide temperature range and fitted to the following equation:

$$\alpha = 3.725 \times 10^{-6}\{1 - \exp[-5.88 \times 10^{-3}(T - 124)]\} + 5.548 \times 10^{-10}\,T \quad [20]$$

This equation is valid for the temperature range from 120 to 1500 K. This equation is important for the thermal stress of thin films deposited on a silicon substrate (Okada and Tokumaru 1984). The CTE is slightly changed by doping. Berry and Pritchet (1991) showed that heavy boron doping increases the CTE by $1.1 \times 10^{-8}\,\mathrm{K^{-1}}$.

1.01.3 Polycrystalline and Amorphous Silicon

1.01.3.1 Deposition

Polycrystalline silicon (polysilicon) and a-Si are mainly deposited by the pyrolysis of SiH_4 or disilane (Si_2H_6) gas in a CVD reactor. Polysilicon films deposited by the standard LPCVD process using SiH_4 gas at 630°C usually have (110) oriented columnar grain structures. Amorphous film can be deposited at 580°C or at a lower temperature. Since the deposition rate of the amorphous film by LPCVD using SiH_4 is too low, Si_2H_6 gas is often used for a-Si deposition. The amorphous film can be crystallized by annealing at 600°C or at a higher temperature. The grain size is controlled by annealing temperature; the lower the annealing temperature the larger the grain size because the nucleation rate is lower than the grain growth rate at the low annealing temperature. Crystallization at 600°C for 24 h results in polysilicon films with few micrometer grains.

Doping can be done by the same method as used for SCS, such as in ion implantation and vapor-phase diffusion. In addition, *in situ* doping during LPCVD by adding the dopant source, such as PH_4 and B_2H_6, can be used. In the surface micromachined polysilicon structures, the solid-phase diffusion from the phosphosilicate glass (PSG) films has often been employed for stress gradient control. In this case, the polysilicon film is often sandwiched by PSG layers to dope phosphor uniformly.

For thicker polysilicon films, the deposition of silicon dioxide layers using epitaxial growth tools is used. The plasma-enhanced chemical vapor

depositions (PECVDs) and sputter depositions are employed because of their lower deposition temperature mainly for sacrificial layer formation in the microsystems. For example, a PECVD a-Si film was deposited on a silicon wafer with an SiO_2 layer. Another oxide layer and vanadium oxide (VO_2) as sensing material were deposited on it and patterned to membrane structures. The sacrificial a-Si film was removed using XeF_2 gas (Chung *et al.* 2005).

1.01.3.2 Etching

Etching of polysilicon and a-Si can be done by the etching method used for SCS. Polysilicon is most widely used as structural materials for integrated sensor devices, such as pressure sensors, accelerometers, and gyroscopes. Silicate glass materials, such as nondoped silicate glass (NSG), PSG, and borophosphosilicate glass (BPSG) deposited by CVD, are used as the sacrificial layers that are removed using HF solution to release the polysilicon structures. Polysilicon films can be used as the sacrificial layers in pressure sensors and in infrared image sensors in which dielectric microstructures are employed. Polysilicon sacrificial layer is used not only for the thin cavity of capacitive pressure sensors, but for pyramidal grooves of piezoresistive pressure sensors and IR sensors. To make the pyramidal grooves in a single-crystal wafer, the sacrificial polysilicon layer is directly deposited on the wafer and the polysilicon layer is used in the undercutting layer. In sacrificial layer etching, alkaline solutions such as KOH and TMAH are widely used. But in integrated sensor devices the passivation of aluminum for electrodes is crucial. The ethylenediamine pyrocatechol (EDP) solution and silicon-dissolved TMAH solution have high selectivity against aluminum. In addition, due to the prevention of stiction, XeF_2 is examined for the sacrificial etching of a silicon layer.

1.01.3.3 Elastic Properties

The mechanical properties of polysilicon can be equated with that of SCS considering its crystal orientation and the grain boundary effect. As for the orientation, the standard polysilicon film deposited by LPCVD at 630°C has (110) orientation and the polysilicon film crystallized from the LPCVD a-Si has (111) orientation. The grain boundary has nonideality of the crystal structure, which is the source of mechanical property variations. In addition, since the impurities such as dopant and oxygen tend to segregate at the grain boundary, the effect of the grain boundary layer should be considered.

The calculated Young's moduli of randomly oriented, (110) surface-oriented, and (111) surface-oriented polysilicon are 160.3, 165.3, and 168.9 GPa, respectively. The Young's modulus was experimentally measured using tensile tests (Sharpe 2003) and bulge tests (Maier-Schneider *et al.* 1995). Most of the measured Young's modulus of polysilicon films agreed with these theoretical values. Maier-Schneider (1996) showed that the Young's modulus of LPCVD polysilicon films ranged between the theoretical values of <111> and <100> oriented polysilicon. However, sometimes the reported values of heavily doped polysilicon were lower than these calculated values because of the grain boundary effect. For example, the foundry-processed polysilicon films (multi-user MEMS processes (MuMPs), which has 2–4 mΩ cm in resistivity, shows a lower value (Sharpe *et al.* 1999). The heavily doped polysilicon films often have the oxide segregation at the grain boundary. This layer decreases the apparent Young's modulus, since silicon dioxide has a much smaller Young's modulus (70 GPa or less).

The internal stress of polysilicon is generated and its control is crucial for the surface mircromachined structure. The average internal stress and its relationship with the internal stress have been investigated since the beginning of the semiconductor fabrication process development (Adamczewska and Budzyński 1984). The standard polysilicon film and the amorphous film deposited using LPCVD have a compressive stress of about 300 MPa, because of the disorder of the crystal grain during deposition and oxygen impurities (Kamins 1990).

After the surface micromachining process has been proposed, the stress control becomes more important in order to obtain a low tensile stress and a low stress gradient film. For the low tensile stress films, high temperature anneal is the very effective method because thermal stress is not generated (Guckel *et al.* 1989, Huber *et al.* 1989). However, the CMOS backend integration limits the use of such high-temperature anneal that causes the change in the electrical properties of the transistors. For lower thermal budget in the postsurface micromachining process, a number of low-stress polysilicon processes were developed.

An as-deposited tensile stress film can be obtained at the lower deposition temperature (580–600°C) using LPCVD (Krulevitch *et al.* 1991). Though the temperature range of the tensile stress films is slightly changed by the deposition conditions, films deposited at either lower or higher temperature ranges have

compressive stress (Yang *et al.* 2000). At the temperature range, the amorphous film with compressive stress was deposited initially and was crystallized while the rest of the film was deposited. The tensile stress evolution due to crystallization was observed during postannealing of the amorphous films (Miura *et al.* 1992). The change in the stress was 1 GPa and the crystallization temperature depends on the dopant concentrations (Miura and Okamoto 1994).

Doping effects on the internal stress of polysilicon were widely investigated and were basically the same as that of SCS. The boron doping causes tensile stress and phosphorus and arsenic doping cause compressive stress (Orpana and Korhonen 1991). However, the phosphorus ion implantation at high concentration ($10^{19}\,cm^{-3}$) results in the tensile stress films. Since an as-implanted film becomes amorphous by ion bombardment, the tensile stress is induced by subsequent crystallization (Maier-Schneider 1996). Moreover, polysilicon films heavily ion implanted with both boron and phosphorus became more compressive because of the dopant segregations at the grain boundary (Orpana and Korhonen 1991). Thus, it is difficult to forecast the stress actually generated, because the stress is also changed by the crystal growth and by the densification during the doping and annealing processes.

The stress distribution along the thickness direction, which is often called the stress gradient, causes the out-of-plane deflection. For example, a cantilever beam 100 μm long and 2 μm thick shows 1-μm deflection at the free end if it has stress gradients of 30 MPa μm^{-1}. Since the stress gradient and the deflection have a linear relationship, stress gradient control often becomes a problem in the process development.

If there is no limitation in the thermal budget, which means the micromachined structure does not integrate to circuit, solid-phase doping from PSG layer is a convenient method. It is applied in the MuMPs process. Analog devices Inc. reported low-stress film in the postmicromachining process using the doping by high current ion implantation and crystallization by rapid thermal annealing (Core *et al.* 1993). Polysilicon film became amorphous by ion implantation and the rapid thermal annealing results in uniformly fine-grained polysilicon films. Lee *et al.* (1999) demonstrated the multilayered polysilicon film that is fabricated by the interleaved deposition of the low-stress film and compressive film. The low stress is obtained by averaging two different stress layers. The low-stress distribution was realized by the stress relaxation of the interface between the two different stress layers.

1.01.3.4 Strength

The strength of polysilicon films can also be equated with that of SCS. A number of experiments about polysilicon strength showed that the crack was propagated in the grains but not on the grain boundaries and the little effect of the doping. However, heavy doping may affect the surface roughness through dry etching and sacrificial etching. Heavy doping causes oxide precipitation in the grains, which acts as the mask during anisotropic dry etching, and causes residues. In sacrificial etching, HF selectively etches the grain boundaries where the dopant or oxygen precipitates. It was reported that polysilicon films fractured at the small pit on the specimen edge that should be related to the grain boundaries of the films (Tsuchiya *et al.* 1998b).

Fatigue, the decrease in strength by the cyclic stress application, was also observed using bending and tensile testing either at nonresonance or resonance (Brown *et al.* 1997). The fatigue properties were strongly affected by the humidity of test environments. A mechanism of polysilicon fatigue is proposed as reaction layer fatigue. In this theory, tiny cracks are generated and grow in the thickening native oxide layer. First, the tiny cracks are generated in the native oxide layer. Through these cracks water diffuses more easily and the oxide layer thickens. Then the crack growth and subsequent oxide thickening is repeated until they fracture the specimen (Muhlstein *et al.* 2001b, Pierron and Muhlstein 2005). The native oxide layer is so thin that no fatigue fracture is observed in bulk-scale specimens. Fatigue fracture can be controlled by surface passivation using self-assembled monolayers (Muhlstein *et al.* 2002).

1.01.3.5 Thermal Properties

The thermal conductivity of polysilicon films was measured using microstructures. The thermal conductivity of the heavily doped LPCVD polysilicon films was measured using doubly supported beams. The measured values range from 29 to 34 $W m^{-1} K^{-1}$ (Tai *et al.* 1988). An n-type heavily doped polysilicon film in a CMOS IC process has thermal conductivity of 25 $W m^{-1} K^{-1}$, which is half of that of doped SCS (von Arx *et al.* 2000, Völklein and Baltes 1992). The grain boundaries may cause phonon scattering, which reduces the thermal conductivity of polysilicon.

1.01.4 Silicon Germanium

Germanium has a cubic diamond structure like silicon but has a slightly larger lattice constant of 5.66 Å. Their alloy also has a cubic structure and the lattice constant is in between those of the two materials. Silicon germanium has higher carrier mobility for application in high-frequency devices (King *et al.* 1990) and thin-film transistors (King and Saraswat 1994). In addition, the strained silicon film is fabricated because of the mismatch of the lattice constant, which is also used for radio frequency (RF) applications (Yeo *et al.* 2000). For its application in microsystems, silicon germanium was used in a CMOS integrated device due to the low thermal budget, which is compatible with the aluminum-deposited structures (Sedkey *et al.* 2002).

1.01.4.1 Deposition

LPCVD process is widely used for the deposition of silicon germanium films. Germane (GeH_4) for Ge and SiH_4 or Si_2H_6 for Si are used as the source gas. The crystallization temperature of LPCVD polysilicon using SiH_4 is 600°C, and the films deposited below this temperature becomes amorphous and the deposition rate is too low (less than 3 nm min^{-1}) for the industries. When GeH_4 is added to the source gas, the crystallization temperature decreases and the deposition rate increases by the catalysis of Ge. A pure poly-Ge film can be obtained even at 340°C; thus, the process temperature can be significantly decreased. However, pure germanium and silicon germanium film with high germanium content has the problem of low chemical stability. They are etched by SC-1 (NH_3 and hydrogen peroxide solution) and hydrogen peroxide. The etch rates of SC-1 and hydrogen peroxide strongly depend on the germanium content. Therefore, the composition of germanium is optimized to 60–70% of the germanium content. The deposition temperature of the optimized film is about 520°C, which is compatible with aluminum-metallized CMOS devices (Sedkey *et al.* 2001).

Doping can be done by either *in situ* doping or *ex situ* doping by the ion implantation. *In situ* doping can be done by mixing PH_4 and B_2H_6 during LPCVD. p-Type poly-SiGe by B_2H_6 can be obtained more easily than n-type film by PH_4 because of the dopant activation ratio and the carrier mobility (Bang *et al.* 1995).

1.01.4.2 Fabrication

As mentioned above, pure germanium and silicon germanium with high germanium content dissolves in SC-1 and in hydrogen peroxide. The etch rate of pure germanium in SC-1 at 75°C is 30 µm min^{-1} and that of $Si_{0.4}Ge_{0.6}$ is 50 nm min^{-1}. The etch rate of $Si_{0.4}Ge_{0.6}$ in hydrogen peroxide at 90°C is very low (~0.01 nm min^{-1}), whereas the rate of pure germanium is still high (~5 µm min^{-1}). The plasma etching of silicon germanium film has been investigated. Basically, the same gas system as that used for silicon, such as fluorine, chlorine, and bromine gas, can be used.

The surface micromachined structures on the aluminum-metallized CMOS wafer was demonstrated with two different sacrificial layer and etching combinations. One is PSG as the sacrificial layer and HF as the etchant as is the case with polysilicon surface micromachining. The other is the polygermanium film as the sacrificial layer and hydrogen peroxide as the etchant of sacrificial layer.

1.01.4.3 Mechanical Properties

The stiffness and compliance coefficients of germanium are described using the same formulae as for silicon. They have three independent coefficients that can be accurately measured, and are given in **Table 2** (Wortman and Evans 1965). **Figure 3** shows the elastic properties of (100) and (110) germanium and silicon with respect to the in-plane directions. The Young's modulus and Poisson's ratio in the (111) plane are 137.5 GPa and 0.251, respectively.

There are little works on the measurement of mechanical properties of poly-SiGe films. The reported Young's modulus of poly-SiGe film is 132 GPa (Franke *et al.* 2003), which is less than the expected Young's modulus, which may be caused by the high dopant concentration and by the impurities because of the low deposition temperature.

The internal stress control is the critical issue in the surface micromachined devices. The low-stress poly-SiGe film can be obtained at a low temperature (Franke *et al.* 2003, Rusu *et al.* 2003, Sedkey *et al.* 2002). The stress gradient of the as-deposited poly-SiGe is positive, which means that cantilever beams have upward deflections. The gradient can be reduced by annealing at 500–550°C. The origin of the upward deflection is reported as the amorphous layer near the substrate interface has compressive stress (Sedkey *et al.* 2002).

The fracture strain was evaluated using on-chip testing structures, which deforms the cantilever

beams laterally. The fracture strain of poly-SiGe is 1.3%, which is comparable to that of the surface micromachined polysilicon structures (Franke *et al.* 2003). Sharpe (2003) reported that the tensile strength using the uniaxial tensile test is 1.0 GPa.

1.01.4.4 Thermal Properties

The thermal conductivity (Glassbrenner and Slack 1964), specific heat, and CTE of pure germanium crystal at the ambient temperature (300 K) are $60\,W\,m^{-1}\,K^{-1}$, $310\,J\,kg^{-1}\,K^{-1}$, and $5.8\times10^{-6}\,K^{-1}$, respectively. The thermal conductivity of SiGe alloy was measured as a function of the silicon content, which shows a significant decrease in the conductivity (Steele and Rosi 1958). For the $Si_{0.56}Ge_{0.44}$ alloy, the thermal conductivity is $10\,W\,m^{-1}\,K^{-1}$, which is one-sixth that of Ge and one-sixteenth that of Si, which is caused by the decrease in the phonon mean free pass due to the scattering by the solution strain associated with the alloying component. Such a small conductivity is useful in thermoelectric materials. Many applications in microsystems as well as in high-temperature thermoelectric generators, such as thermopiles (Van Gerwen *et al.* 1996), miniaturized thermoelectric generators (Strasser *et al.* 2002), and lateral Peltier elements (Wijngaards and Wolffenbuttel 2005), have been proposed. The measured Seebeck coefficients of n-type and p-type poly-SiGe ranged from −75 to $179\,\mu V\,K^{-1}$ and from 59 to $131\,\mu V\,K^{-1}$, respectively.

1.01.5 Silicon Nitride

Silicon nitride structure consists of SiN_4 tetrahedron and NSi_3 triangles, which form the amorphous structure, i.e., random networks with no symmetry and periodicity. Stoichiometric silicon nitride has the silicon to nitrogen atomic ratio of 0.75, which can be changed by various deposition conditions.

1.01.5.1 Deposition

Silicon nitride film is deposited by both the LPCVD and the PECVD tools using SiH_4 or dichlorosilane (SiH_2Cl_2) as the silicon source and NH_3 as the nitrogen source. The comparison of PECVD and LPCVD silicon nitride are summarized in Stoffel *et al.* (2003). Organic silane gas (tri(dimethylamino)silane) can be used in the PECVD system. These silicon nitride films are amorphous and the ratio of silicon to nitride can be controlled by the gas composition or the deposition condition (RF power).

1.01.5.2 Etching

Silicon nitride film can be etched using the hot phosphoric acid solution at 160°C. Since this solution attacks photoresist, the CVD oxide films are used for the hard mask layers, which makes wet nitride etching difficult. HF slowly etches ($\sim10\,nm\,min^{-1}$) silicon nitride, but the selectivity to silicon dioxide by the concentrated HF and buffered HF solutions is high enough (>100) to use the passivation layer in the silicon dioxide sacrificial etching.

In dry etching, plasma etching using CF_4, CHF_3, and SF_6 is widely employed for nitride etching. Fluorine atoms are adsorbed onto the surface as tetrafluorosilane (SiF_4) and nitrogen (N_2). Due to the high stability with respect to chemicals and the high mechanical strength, silicon nitride films are used as the mask layer for crystallographic anisotropic etching of silicon and as the structural and passivating materials of pressure sensors.

1.01.5.3 Mechanical Properties

The standard silicon nitride film Si_3N_4 deposited by LPCVD at 800°C has a Young's modulus of 300 GPa and a high tensile stress of about 1 GPa. The measured Young's modulus for CVD nitride films ranges from 83 to 380 GPa (Edwards *et al.* 2004), whose variation is caused by the deposition conditions mainly for the CVD tools but for the silicon and nitrogen ratio, which is discussed later. PECVD nitride films show larger variation; a lower modulus has been reported, which is caused by the hydrogen and carbon impurities from the source gas and the high porosity because of low deposition temperatures (Minkiewicz *et al.* 1994).

The high tensile stress does not allow the deposition of nitride films thicker than 300 nm and causes reliability problems in thin-film structures such as pressure sensors and in the passivation films in semiconductor devices. The thermal stress of silicon nitride film is compressive, since the CTE is larger than that of silicon. The intrinsic stress generated during the deposition process is compressive (Irene 1976).

It is well known that low-stress nitride films by LPCVD can be obtained by increasing the silicon compositions (Sekimoto *et al.* 1982), which is widely employed in microsystem applications. Many works show that there is a linear relationship between the internal stress and the refractive index. When the

silicon content is increased by increasing the ratio of the silicon source gas, the refractive index increases from 2.0 of stoichiometric films and the internal tensile stress of about 1.0 GPa decreases. The film whose refractive index is 2.2 is stress-free and the larger refractive index films show the compressive stress. The change in the refractive index originates from the silicon refractive index, which is higher than that of the stoichiometric silicon nitride film.

Nitride films deposited by the PECVD process show a similar relationship between the silicon–nitrogen ratio, the refractive index, and the internal stress (Taylor 1991). In addition, PECVD films have more variables such as residues from the source gas, RF powers, and a lower deposition temperature. The measured internal stress of the nitride films shows larger variations.

Strength is high and excellent fatigue properties are measured. The strength measured by tensile tests (Koskinen and Johnson 1989, Sharpe 2003, Yoshioka *et al.* 2000), bulge tests (Yang and Paul 2002), and on-chip structures (Fan *et al.* 1990) ranged from 4 to 8 GPa. A smaller degradation in strength by humidity was observed (Tsuchiya and Sakata 2001). The fatigue test using resonant structures has been reported, which demonstrates a small decrease in strength during 109 loading cycles (Chuang *et al.* 2005).

1.01.5.4 Thermal Properties

The thermal properties of LPCVD low-stress nitride films were measured using the two-layer composite microbridge resistors. The thermal conductivity is $3.2\,W\,m^{-1}\,K^{-1}$, the thermal diffusivity is $1.3 \times 10^{-6}\,m^2\,s^{-1}$, and the heat capacity is $0.7\,J\,kg^{-1}K^{-1}$ (Mastangero *et al.* 1990). The thermal conductivity of PECVD nitride films for CMOS passivation is $2.23\,W\,m^{-1}\,K^{-1}$ (von Arx *et al.* 2000) at the ambient temperature.

The reported CTE values of LPCVD silicon nitride films ranged from $2.5–3.85 \times 10^{-6}\,K^{-1}$ (Tokuyama *et al.* 1967). The values of $2.8 \times 10^{-6}\,K^{-1}$ (Riethmuller and Benecke 1988) and $3.0 \times 10^{-6}\,K^{-1}$ (Temple-Boyer *et al.* 1998) are often used for calculation. The CTE of PECVD nitride films shows a larger variation. Martyniuk *et al.* (2004) reported that the CTE values increase from 2.6×10^{-6} to $5.2 \times 10^{-6}\,K^{-1}$ with decreasing deposition temperature from 300°C to 50°C. Minkiewicz *et al.* (1994) showed the CTE dependence on compositions. The value increases from 1.8×10^{-6} to $2.6 \times 10^{-6}\,K^{-1}$ by increasing Si content from the stoichiometric composition.

1.01.6 Silicon Dioxide

Silicon dioxide has a glassy amorphous structure, which shows no symmetry and periodicity in the structure. The structures of glasses are described as the random network model. In silicon dioxide, the structures have 3D networks that are composed of a silica tetrahedra. The silica tetrahedra share corners, not edges or faces, and each oxygen ion on the corner is linked to not more than two cations at the center of the tetrahedra.

Silicon dioxide films are widely used in semiconductor processes, such as for device insulation and gate oxide films. Impurities in silicon dioxide occupy two different positions in the network structures. Impurities such as phosphor and boron substitutes silicon in the network known as network formers, in which boron forms triangles and phosphor forms tetrahedra but with only three of the four corners linked to other polyhedras. In the semiconductor process, phosphorous-doped and boron- and phosphor-doped silicon dioxide films are used as dielectric layers, which are called PSG and BPSG, respectively. Other impurities such as sodium, potassium, and lead occupy random positions distributed throughout the structure known as network modifiers. A sodium-containing glass is important in microsystems applications, which is used as the substrate in anodic bonding. Pyrex (sodium borosilicate glass) glass has a CTE similar to that of SCS.

Oxide film is used as a sacrificial layer in SCS/polycrystalline silicon structure, as a mask in the crystallographic anisotropic etching of silicon, and as a support membrane of gas sensors and infrared sensors because of its low thermal conductivity.

1.01.6.1 Deposition

The deposition methods of silicon dioxide film are classified into thermal oxidization and chemical and physical vapor depositions. The oxide film is grown by the thermal oxidization of silicon at 900°C or above, which is known as thermal oxide film. The thermal oxidization process involves oxygen diffusion to oxidized film and the oxidization process at the oxide/silicon interface. The thickness of the thick oxide films is proportional to square root of the oxidization time. The practical oxide thickness is limited to 2 or 3 μm.

The oxide film can be deposited by CVD using SiH_4 and nitrous oxide (N_2O) at 900°C or using tetraethylorthosilicate (TEOS, $Si(C_2H_5O)_4$) at 720°C. *In situ* doping can be done by mixing PH_4, B_2H_6,

trimethylphosphite (TMP, $(CH_3O)_3P$), and trimethylborate (TMB, $(CH_3O)_3B$). Because of the need for a low thermal budget after aluminum deposition, PECVD at a temperature below 400°C is employed widely. These doped oxide films reflow at low temperature, which is useful in planarization process for multilayer polysilicon deposition. Sputter deposition is a technique for making oxide films. It is useful because of low deposition temperature and easy composition control, especially for the bonding layer in the anodic bonding process. However, since control of the film quality is difficult and it often suffers from low breakdown strength, the use of sputtered films is limited.

1.01.6.2 Etching

Silicon dioxide film is etched by HF solution. The reaction of the etching is as given below:

$$SiO_2 + 6HF \rightarrow H_2SiF_6 + 2H_2O \qquad [I]$$

The etch rate for thermal oxide by concentrated HF solution (49%) is about 1 μm min^{-1} at the ambient temperature. However, the concentrated HF solution degrades easily with use, whereas buffered HF solution has a small decrease in the etch rate. The etch rate by 1:6 buffered hydrofluoric acid (BHF) solutions is about 0.1 μm min^{-1} at the ambient temperature. The etch rate increases with the temperature and the higher activation energy than for the concentrated HF solutions. Phosphorous-doped oxide film is etched more quickly. The etch rate of PSG film is a few micrometers per minute, about 10 times that of the thermal oxide, which is useful as a sacrificial layer for polysilicon structures (Poenar *et al.* 1994). BPSG films that can be reflown at lower temperatures have a lower etch rate when compared to PSG films with higher boron contents (French and Wolffenbuttel 1993). HF solutions do not attack silicon but polysilicon grain boundaries are attacked slowly, and the roughness of polysilicon surfaces increases by HF etching. Ammonium fluoride etches SCS very slowly; the etch pit formation based on alkali solution anisotropic etching also increases the surface roughness. Both of them are used in the stiction reduction processes. Thin (<0.2 μm) doped polysilicon films permeate the HF solution and the underlying sacrificial oxide layers can be etched. The grain boundaries are etched during the subsequent cleaning process and the polysilicon layer becomes a porous structure that has permeability.

Gas-phase etching of oxide film using anhydrous HF with water or methanol has been proposed. The etch rate is about 0.1 μm min^{-1}. Gas-phase etching is convenient for SCS structures using SOI wafer. However, it is difficult to employ for polysilicon structures where PSG sacrificial layer is used because of the residues originating from the dopant and the low selectivity to the silicon nitride film. More simply, HF vapor etching can be done by placing chips just above the concentrated HF solution, in which vaporized HF and water etches the oxide layers. This reaction is agitated by lamp heating.

Plasma etching using CF_4 and/or CHF_3 gas is employed for oxide films. CF_x radicals etch oxide films to form CO and CO_2 from oxygen and SF_4 from silicon. The source gases are also the source of the fluorocarbon polymer that forms side wall passivation, which results in an anisotropic profile.

1.01.6.3 Mechanical Properties

The Young's modulus of bulk silica glass and Pyrex grass is 72 and 68 GPa, respectively. The thermal oxide film shows similar values around 70 GPa (Petersen 1978). However, the Young's modulus of LPCVD and PECVD oxide films has wide variations, which ranges from 30 to 70 GPa. The carbon and hydrogen impurities and pore in the films are the origin of this variation.

The internal stress of thermal and CVD oxide, which is about −300 MPa, is compressive, which is mainly caused by the thermal stress generated by mismatch of the thermal expansion. The internal stress of oxide film by PECVD shows a wide range of variations, which ranges from compressive to tensile stress. Remaining organic materials and water and pore seem to be the source of variation. After annealing at 900°C or above these films have a compressive stress similar to thermal oxide films. The internal stress of the porous or doped oxide films changes with time because of the absorption of water (Chen *et al.* 2003).

The strength of oxide films is measured by both bending and tensile test. The measured strength ranges from 0.5 to 2 GPa. The strength in the air is a half of that in a vacuum, which shows that the strength decreased significantly with the presence of water vapor in the test environment. The static fatigue can be enhanced by the water in the air (Tsuchiya *et al.* 2000).

1.01.6.4 Thermal Properties

The thermal conductivity and the temperature dependency of CMOS oxide films were measured using microstructures. The thermal conductivity of various oxide films, such as thermal, LPCVD, and PECVD

(TEOS) oxide, and BPSG and PSG is almost the same, i.e., about 1.0 $W\,m^{-1}\,K^{-1}$ (von Arx *et al.* 2000).

The CTE of thermally grown oxide is $5 \times 10^{-7}\,K^{-1}$ (Blech and Cohen 1982), which is similar to that of bulk fused silica glass.

1.01.7 Summary

Comprehensive descriptions of silicon and related materials, silicon germanium, silicon oxide, and nitride, as the fundamental material in microsystems are provided. SCS has excellent electrical, mechanical, and thermal properties, which is used not only for the substrate of semiconductor and microsystem devices but also for the sensing structures in inertial sensors. Polycrystalline silicon and silicon germanium films have properties similar to those of SCS and the integration of controlling circuit to microsystem devices adds special features. The properties of silicon and silicon germanium are summarized in **Table 4**. Silicon nitride and silicon dioxide as

dielectric materials in semiconductor devices have wide applications in microsystems. The properties are summarized in **Table 5**.

The importance of silicon and related materials does not change although many materials are being introduced in microsystems. The description of the properties of these materials should be investigated further, especially for the mechanical properties. The mechanical reliability of silicon and related materials, which has not been well understood, needs to be investigated.

Biography

Toshiyuki Tsuchiya received his MS degree from the University of Tokyo and his Ph.D. degree from Nagoya University in 1993 and 2004, respectively. He worked with Toyota Central Research and Development Laboratories from 1993 to 2004. In 2004, he became an associate professor of the Department of Mechanical Engineering, Kyoto University, and since 2005 he has been an associate professor of the Department of Micro Engineering, Kyoto University. He is currently engaged in the research of silicon surface micromachining, its sensor application, and thin-film mechanical property evaluation. He is a member of IEEE, Material Research Society, the Japan Society of Mechanical Engineers, and the Institute of Electrical Engineers of Japan.

1.02.1 Compound Semiconductors for Microsystems

Compound semiconductor microsystems have become an emerging technology because of their unique intrinsic properties, which offer a number of materials-based advantages for optoelectronic and sensing applications. The intrinsic properties of these materials such as direct or indirect band gap, variation of band gap (from zero via narrow to wide), piezoelectricity, piezoresistivity, variable thermal conductivity, higher saturation velocity of electrons, operation at high temperature and high frequencies make them superior to the well-developed silicon technology. The zincblende structure of most common compound semiconductors allows piezoelectricity, which leads to interesting sensing applications. The compound semiconductor materials allow monolithic integration of optoelectronic devices such as lasers, light-emitting diode (LEDs), and photodiodes with micromechanical structures. This enables

light generation, transmission, modulation, and detection on a single chip. Furthermore, epitaxially grown single-crystalline compound semiconductor layers give rise to well-controlled mechanical characteristics. The epitaxial advantage also facilitates the growth of monolithic multilayers with ternary and quaternary alloys, enabling precise lattice matching. This introduces a wide variety of heterostructure-based physical effects for microsystems. The monolithic multilayers can be selectively etched to release the mechanical structures, as the compound semiconductors are very rich in chemistry.

Micromachining on compound semiconductors has been successfully applied to fabricate cantilevers, membranes, waveguide switches, radio frequency (RF) inductors, microbolometers, micromotors, wavelength-tunable microcavity devices such as optical filters, optical amplifiers, vertical cavity surface-emitting lasers (VCSELs), LEDs, and photodiodes.

Diverse nature of compound semiconductors provides numerous possibilities to design various material compositions. However, compounds from group III–V (gallium arsenide (GaAs)-, indium phosphide (InP)-, and nitride-based materials) and compounds from group IV (SiGe and SiC materials) have been used for microsystems due to their material properties, which is required for the present technological advances. The structural and mechanical properties of these materials are listed in **Table 1**. Dielectric material-based micromechanical structures with group II–VI compound semiconductors have also been investigated for (hybrid) microsystems by Keating *et al.* (2006).

GaAs-based materials are most extensively studied for optoelectromechanical devices in compound semiconductors as is silicon in semiconductors. The GaAs-based materials are promising for the fabrication of integrated sensors because of their direct band gap, high piezoelectricity, piezoresistivity, and thermoelectricity properties, which are used as a light source and detectors, dynamic and static pressure and temperature sensors, respectively (Hjort *et al.* 1994b). These materials also take advantage of GaAs/aluminum gallium arsenide (AlGaAs) material systems, which can be monolithically grown with lattice matching, and either one of them can be selectively etched to create microstructures. The possibility of semi-insulating GaAs material facilitates easy separation of the individual devices of a circuit, which enables high-speed performance of field-effect transistors (FETs) and MEMS for the development of monolithic microwave-integrated circuit (IC) on a single chip. Thermal conductivity of GaAs is three times lower than that of silicon and thus has a better prospect of meeting the requirement for maximum thermal resistance. In GaAs, the physical mechanisms that change the resistance due to an applied stress are different from that of silicon. AlGaAs is a very interesting semiconductor with piezoelectric properties for force and resonant sensors, with high Seebeck coefficients for infrared thermopile sensors, and with a wide energy gap, when compared to silicon and GaAs, for high-temperature sensors (Dehé *et al.* 1995). Thus, excellent bolometric infrared sensors have been realized using suspended AlGaAs membranes. Recently, strain-driven, self-assembled 3D micro/nanostructures have also been fabricated on GaAs-based materials (Prinz *et al.* 2001). Because of all these features, GaAs-based materials meet the special requirements of integrated microoptoelectromechanical systems (MOEMS) for various applications.

Micromachining on InP closely resembles the techniques used for GaAs. Many of the properties of InP are similar to GaAs in terms of crystal structure and mechanical properties (Greek *et al.* 1999, Pruessner *et al.* 2003). However, the band gap of InP-based materials make them the promising candidate for light source of optical fiber communication systems because of low loss and low dispersion at 1.3 μm and 1.5 μm wavelengths. Micromachined InP/air gap distributed Bragg reflector (DBR)-based tunable vertical cavity devices such as filters, VCSELs, and photodiodes are attracting much interest because of their unique features of a wide continuous wavelength tuning and 2D array integration, thus making it possible to realize dense wavelength division multiplexing (DWDM) systems on InP.

Recently, some efforts have been directed toward employing wider band gap compound semiconductor materials such as gallium nitride (GaN) (Davies *et al.* 2004, Strittmatter *et al.* 2001, Yang *et al.* 2006) and SiC (Mehregany and Zorman 2004) for microsystems owing to their excellent electrical and mechanical properties with regard to chemical inertness and their high-temperature stability, which make them a suitable choice for MEMS applications in harsh environments.

Polysilicon is widely used for surface-micromachined MEMS structures with silicon IC compatibility, which needs high-temperature processing (>800°C). An alternative low-temperature processing material is poly-SiGe. Micromachined bolometers and thermopiles with superior thermoelectric properties have been fabricated using poly-SiGe by Dong *et al.* (2003). Freestanding SiGe micro/nanostructures such as tubes, helical coils, and bridges have also been fabricated on SiGe (Prinz *et al.* 2001).

Table 1 Structural and mechanical properties of the compound semiconductors

	GaAs	*InP*	*GaN*	*$Si_{1-x}Ge_x$*	*3C-SiC*
Crystal structure	Zincblende	Zincblende	Zincblende/wurtzite	Diamond (random alloy)	Zincblende
Lattice constant (Å)	5.6533	5.8687	4.52/a-3.189 c-5.18	$(5.431 + 0.20x + 0.027x^2)$	4.3596

Microsystems have been successfully implemented on compound semiconductors; however, there is a skepticism with regard to the mechanical strength of some of the III–V compound semiconductors such as GaAs- and InP-based materials for microstructures. However, measured fracture properties of GaAs are shown to be sufficiently enough, with an average fracture strength of 2.7 GPa, which is at least three times as high as that of most construction steels (Hjort *et al.* 1994a).

1.02.2 Micromachining Aspects

The basis of micromachining is similar for compound semiconductors and silicon; however, there are some key factors that influence the micromachining on compound semiconductors such as epilayer growth and etching process.

1.02.2.1 Epilayers

Advanced crystal growth techniques enable the growth of most of the compound semiconductors in well-controlled single-crystalline layers. The crystal growth techniques such as molecular beam epitaxy (MBE) and metal–organic chemical vapor deposition (MOCVD) allow epilayers to be grown on a substrate, monolayer by monolayer, with great precision. These epilayers of compound semiconductor heterostructures provide more flexibility and precision in micromachining, which results in very sharp interfaces. Due to different composition, these layers can easily be etched by wet or dry etching techniques with an excellent compositional selectivity. A precise control in thickness and composition of compound semiconductor-based micromechanical structures such as cantilevers, membranes, or bridges can be achieved directly via the thickness of the grown materials over an etch stop layer. Also, stress of epitaxial films is much more accurately controllable, by control of the lattice mismatch, than that of polycrystalline materials-based microstructures.

1.02.2.2 Etching Process

Etching plays a major role in micromachining. In general, wet and dry etching have been employed for the micromachining of compound semiconductors. The zincblende structure of the most common compound semiconductors has different etching when compared to a diamond-like silicon semiconductor. As a result, the underetching rates and profiles are controlled by the crystallographic directions and thus the sacrificial layer etching is determined by the choice of patterning orientation. Hjort *et al.* (1994a, b, 1996) have extensively investigated the basis of micromachining on III–V compound semiconductors. Various sacrificial etch systems for compound semiconductors have been documented in literature (Hjort 1996) and are listed in **Table 2**, including sacrificial AlGaAs, InGaAs, and InGaN (indium gallium nitride) layers for GaAs, InP, and GaN structures, respectively. Ion implantation-induced material modifications have also been used to form a etch stop layer in GaAs materials for micromachining (Miao and Hartnagel 2004); however, this method gives less freedom to fabricate complicated microsystems and is not cost effective.

Figure 1 shows three basic surface micromachining process steps that are as follows:

1. The device multilayer (layers B and C) structure grown by epitaxy or other deposition methods on a substrate material A (**Figure 1(a)**).
2. The device structure is photolithographically masked and then the uncovered areas are subsequently etched (vertical) to define the mesa structures. Depending on the process, slightly sloped sidewalls, vertical sidewalls, or slightly undercut sidewalls can be obtained (**Figure 1(b)**).
3. Etching sacrificial layers by selective underetching (horizontal etching) to enable freestanding mechanical structures (**Figure 1(c)**).

Selective etching is an important step in micromachining. Vertical and horizontal etching are done by wet or dry etching, which is dependent on the etch chemistry of the elemental composition of the layer for horizontal underetching; a highly selective wet chemical etching is used to underetch the sacrificial layer. To underetch a thin layer over its entire area, the selectivity must be extremely high. The critical reaction product in semiconductor etching is dissolved in hydrogen gas, which is unable to diffuse out through such a narrow gap. This gas has to be diffused out by proper rotation of etching solvents without giving pressure to the releasing microstructures.

The etching of semiconductors proceeds by the successive dissolution of layers of the materials. An additional factor arises for compound semiconductors, since they are polar semiconductors and have different surface activity, e.g., in GaAs, the (111) Ga and (111) As faces have different etching rates. Because the As face has two dangling bonds per

Table 2 Sacrificial layer wet etching of compound semiconductors by addition of new materials

atom whereas Ga face has no dangling bonds, the etches are much slower when compared to that for the As face.

Micromachining on III–V nitrides such as GaN, InGaN, and AlN suffers from low chemical reactivity. Therefore, III–V nitrides have been confined to dry etching processes such as reactive ion etching and plasma etching. Nevertheless, considerable progress has been made on the fabrication of micromechanical structures by photoelectrochemical (PEC) etching, which is rapidly developing as an efficient technique for micromachining on III–V nitride material systems (Strittmatter *et al.* 2001). The mechanism of PEC etching involves the creation of electron–hole pairs, the subsequent oxidative dissociation of the semiconductor into its component elements (a reaction that consumes the photogenerated holes), and the reduction of the oxidizing agent in the solution by reaction with the photogenerated electrons. The dissolution rates of a semiconductor can be altered in acid or base solutions by illumination with light ($E > E_{gap}$). Generally, n-type material is readily etched under these conditions, while p-type material is not due to the requirements for confining photogenerated holes at the semiconductor-electrolyte interface. The PEC etching mechanisms rely heavily on the absorption of incident light, and it can be defect selective, dopant selective, and band gap selective. Using InGaN as a sacrificial layer, GaN micromechanical structures have been fabricated by band gap-selective PEC etching with an illumination power of 3.5 mW cm^{-2}. Using dopant-selective PEC etching with an opaque mask, a n-GaN layer was selectively etched below p-GaN layer by illumination with light ($E > E_{gap}$) while immersed in an aqueous KOH solution with a lateral etching rate of 30 μm min^{-1} (Strittmatter *et al.* 2001).

Silicon carbide (SiC) is a very hard material and it is not etched by any acids at room temperature in its single-crystalline condition. However, KOH at molten temperature (>600°C) and some high-intensity plasma are used to etch SiC. A micromolding technique has been used to fabricate mechanical

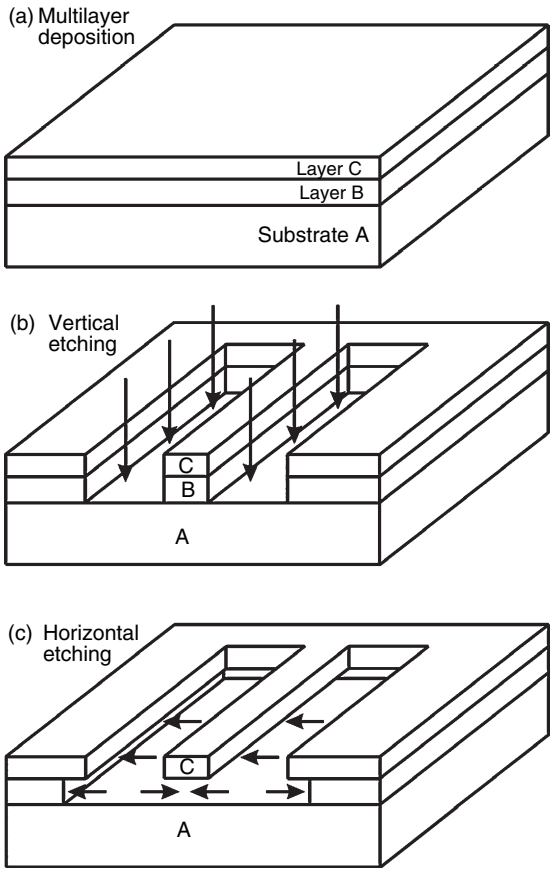

Figure 1 Three basic surface micromachining process steps: (a) multilayers structure deposition of layers B and C on substrate A; (b) vertical etching; and (c) horizontal etching (sacrificial layer etching).

structures on SiC (Yasseen *et al.* 2000). The PEC etching technique (Shor *et al.* 1992) has also been employed for SiC, which allows for selective removal of n-SiC from an underlying p-SiC layer.

In order to provide an overview on micromachining to the reader, postetching process is briefly explained here. After etching the sacrificial layer, freeze drying or critical point drying (CPD) process is used to avoid the sticking, due to the capillary pull, of the released freestanding microstructures. In freeze drying, the rinse solution is replaced through a gradual series of dilutions with *t*-butyl alcohol, which freezes at 25.6°C and then sublimated. In the CPD, the rinse solution is gradually replaced by liquid CO_2 at elevated pressures inside a high-pressure chamber and then the sample is taken to the critical point of CO_2, where the interface between the liquid and gas does not exist. This technique is highly successful with nearly 100% yield.

1.02.3 Compound Semiconductor Microsystems

1.02.3.1 Micromachined Sensors

1.02.3.1.1 Cantilevers, suspensions (beams), and membranes

Cantilevers are most commonly used in micromechanical structures in the field of MEMS as an actuator, resonator, and transducer and also as an element to evaluate the basic mechanical properties of a material. **Figure 2** shows an InP cantilever structure as an example of a compound semiconductor cantilever. This cantilever is fabricated on a (100) InP substrate of thickness 1.7 μm, typical optical waveguide thickness, using $In_{0.53}Ga_{0.47}As$ layer as a sacrificial layer (Pruessner *et al.* 2003).

Due to a higher thermal resistivity and operation at high temperatures, GaAs-based materials are able to perform electrothermal conversion with higher conversion efficiency than silicon. GaAs-based micromachined thermal converter sensors such as RF and microwave power sensors (Dehé 1996, Dehé *et al.* 1995, Lalinský *et al.* 1995, 1999, 2005), infrared thermal sensors (infrared bolometers) (Dehé *et al.* 1995, Leclercq *et al.* 1998), pressure sensors (Dehé *et al.* 1995), and thermally actuated microactuators (Lalinský *et al.* 2000a, b) have already been fabricated. Recently, piezoelectric sensing at cryogenic temperatures has been explored in FETs fabricated from GaAs/AlGaAs heterostructures (Beck *et al.* 1996), GaAs/AlGaAs cantilevers with integrated FETs (Beck *et al.* 1998), AlGaAs suspensions coupled to

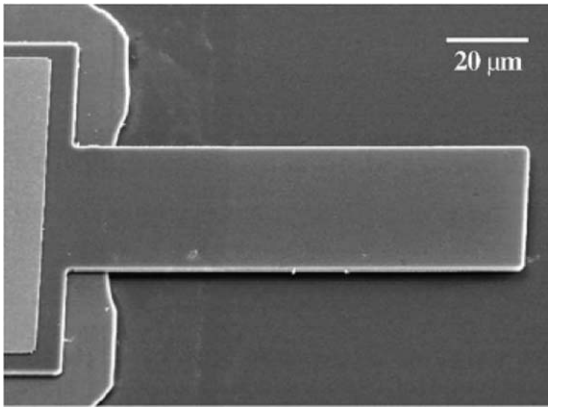

Figure 2 Micromachined InP cantilever. (Source: Reprinted from *Sens. Actuators A*, **105**, Pruessner M *et al.*, Mechanical Property measurement of InP-based MEMS for optical communications, 190–200, Copyright (2003), with permission from Elsevier.)

single-electron transistors (Knobel *et al.* 2002), and nanomechanical displacement sensing using quantum point contacts (Cleland *et al.* 2002).

For MOEMS application, GaAs/AlGaAs-based piezoelectric multimorph actuators have been proposed and designed by Ongkodjojo *et al.* (2005). This multimorph structure is designed to enhance the piezoelectric effect. More recently, Li *et al.* (2006) have demonstrated microscale piezoelectric bimorph cantilever actuators on AlGaAs (**Figure 3**). They used different Si-doping concentrations in AlGaAs to realize bottom and top electrodes as well as the piezoelectric layer in a single-lattice-matched heterostructure, virtually eliminating residual stress-induced curvature and offering the potential to reduce damping compared to traditional devices with polycrystalline piezoelectric layers and amorphous metal electrodes.

Yamaguchi *et al.* (2004) have been reporting on the magnetopiezoresistance of micromechanical cantilevers fabricated from 2D InAs/AlGaSb heterostructures, which show large enhancement of piezoresistance by quantum effects. **Figure 4** shows a suspended cantilever with a width of 4 μm and a length of 10 μm. InAs-based cantilevers systems have an additional advantage of structure-size reduction to a nanometer scale. This is a gain because the native electron accumulation in the near-surface region of InAs allows fabrication of conductive cantilevers of nanometer scale.

Micromachining on GaAs has also been applied to enhance microwave and millimeter-wave passive devices and circuits beside the microsensors and microactuators (Han *et al.* 2006, Leclercq *et al.* 1998, Pantazis *et al.* 2005). GaAs-based micromachined membranes have been used for millimeter-wave passive circuit elements such as inductors, capacitors, transmission lines, and filters antennae. These elements need high resistive membranes to reduce high-frequency losses and parasitic capacitance. This has been implemented on semi-insulating GaAs substrates by bulk micromachining techniques. A fully monolithically integrated millimeter-wave receiver module, having the antenna as well as the detecting Schottky diodes on the same GaAs membrane, has been reported by Neculoiu *et al.* (2006).

Recently, attention has been focused to explore microsystems on III–V nitride-based materials. The III-V nitrides are emerging materials for shorter wavelengths, high temperature, and high frequency applications. The piezoelectric constants of nitrides are approximately an order of magnitude higher than that of more conventional III-V compound semiconductors such as GaAs and InP (Bykhovski *et al.* 1996, Gaska *et al.* 1997, Strittmatter *et al.* 2001). Micromachined GaN sensors such as GaN Schottky diodes and GaN MIS diodes for piezoelectric strain sensing and high electron mobility transistor (HEMT) capacitance pressure sensor have already

been fabricated (Strittmatter *et al.* 2003a, b). However, there is a hurdle to develop III–V nitride-based microsystems due to the lack of suitable underetching processes because the nitrides are chemically stable and insoluble in most common etchants at room temperature as discussed in Section 1.02.2.2. Moreover, GaN epilayers have been grown on sapphire or SiC substrates due to the lack of bulk GaN substrate. The sapphire and SiC substrates are expensive. However, recently, GaN-based materials have also been grown on silicon, which is motivated by the potential of using silicon as a less expensive substrate material. Chen and coworkers (Yang *et al.* 2005, 2006) and Davies *et al.* (2004) have fabricated GaN membrane structures on silicon substrates. Chen and coworkers have used GaN on patterned silicon (GPS) technique and fabricated suspended cantilevers array released by isotropic wet etching and a microdisc released by anisotropic wet etching. The suspended GaN microstructure, cantilevers array, is shown in **Figure 5**. They have also integrated HEMTs on the cantilevers, which can sense the change in the stress induced by deflections applied to the cantilevers. Another interesting piezoelectric III–V nitride material is AlN which is light, stiff, and piezoelectrically active that can be epitaxially grown on silicon (Cleland *et al.* 2001, Olivares *et al.* 2005). AlN is also used to integrate semiconducting electronic and surface acoustic devices (Cleland *et al.* 2001). Iborra *et al.* (2004) have demonstrated the microsystem feasibility on AlN by fabricating suspended bridge structures consisting of an AlN/polysilicon piezoelectric bimorph structures, **Figure 6**. The integration of III–V nitride microstructures on silicon takes advantage of III–V nitride-based piezoelectricity and of piezoresistivity properties of transducer elements such as cantilevers or membranes in silicon MEMS devices.

(Source: Yang Z, Wang R, Wang D, Zhang B, Chen K J, Lau K M 2005 GaN on patterned silicon (GPS) technique for GaN-based integrated microsensors. *IEEE, IEDM Technical Digest*, pp. 298–301; reproduced with permission from IEEE.)

1.02.3.1.2 Micromotors

Though SiC has been established as a microelectronic material for use in high-temperature and high-power applications, attention has also been focused on developing microsystems due to the outstanding chemical and mechanical properties along with its piezoresistance. SiC exists in many different polytypes; of these, the cubic 3C–SiC and the hexagonal 6H–SiC and 4H–SiC have been studied for device applications. The 3C–SiC is the only polytype that can be grown in single-crystalline form on silicon. This enables the fabrication of microsystem on 3C–SiC by taking advantage of silicon micromachining process. Mehregany and coworkers have extensively studied SiC materials for microsystems (Mehregany and Zorman 1999). Various microsystems such as resonators, piezoresistive pressure sensors, accelerometers, and micromotors have already been fabricated on SiC (Atwell *et al.* 2003, Eickhoff *et al.* 1999, Jiang *et al.* 2006, Mehregany and Zorman 1999, Roy *et al.* 2002, Wiser *et al.* 2005).

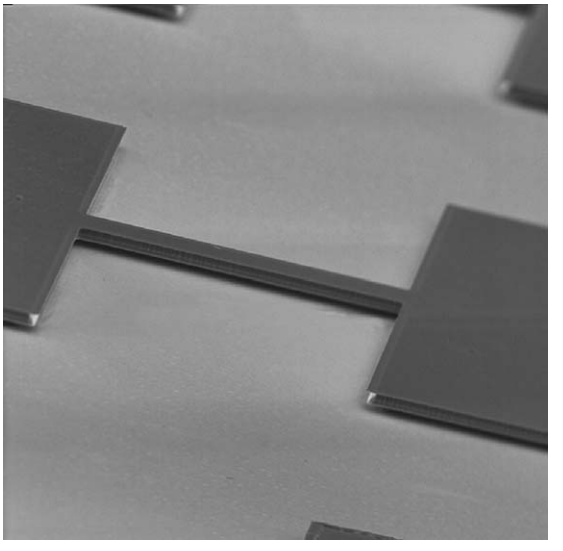

Figure 6 Microbridge structure consisting of a bimorph of AlN/polysilicon, the length and the width of the bridge are 100 and 20 μm, respectively. (Source: Reprinted from *Sens. Actuators A*, **115**, Iborra E *et al.*, Piezoelectric properties and residual stress of sputtered AlN thin films for MEMS applications, Copyright (2004), with permission from Elsevier.)

Although SiC properties are attractive for microsystems, unfortunately micromachining has been challenging because of the chemical inertness and high hardness. Due to physical process limitations, PEC and silicon bulk micromachining techniques have not been used to fabricate complex 3D bulk-micromachined structures on SiC. An alternative approach has been developed by Rajan *et al.* (1999) to create 3D bulk-micromachined structures on SiC. This approach uses silicon molds fabricated by deep reactive ion etching combined with poly-SiC deposition and silicon etching to produce fuel atomizers. Yasseen *et al.* (2000) have developed a micromolding technique that uses polysilicon molds in conjunction with poly-SiC film deposition and mechanical polishing to pattern poly-SiC films. This process has been successfully applied to fabricate micromotors as shown in **Figure 7**.

1.02.3.1.3 Microbolometers

Microbolometers are devices with a temperature-dependent resistor and an IR absorber for measuring incident electromagnetic radiation. To reach high bolometer performance, temperature coefficient of resistance (TRC) has to be high enough. Though a wide variety of materials (Richards 1994) have been used for microbolometers, IC-compatible materials have an advantage of integrating the electronic devices. GaAs and SiGe materials have TRC >4% per Kelvin, which is higher than that for silicon. Infrared microbolometers have been fabricated on AlGaAs/GaAs material systems by Dehé *et al.* (1995). Their simulated results indicate that the maximum responsivity and detectivity of $Al_xGa_{1-x}As$ is for the aluminum concentration of $x = 0.3$–0.45. One of the advantages of these bolometers is that they do not need cooling as in the case of quantum well (QW) diode detectors; however, cooling increases the performance by an order of magnitude. SiGe has high TRC and is IC compatible with silicon technology. Recently, Dong *et al.* (2003) have demonstrated an uncooled microbolometer infrared detector based on polycrystalline SiGe. The SEM image of the poly-SiGe microbolometers with two and fourfold suspended microbridge is shown in **Figure 8**. The devices were fabricated using silicon anisotropic etching, bulk micromachining, and ICP etching. The bolometers have maximum detectivity of $8.3 \times 10^8\,\mathrm{cm\,Hz^{1/2}\ W^{-1}}$ at 15 Hz with a thermal response time of 16.6 ms.

1.02.3.2 Wavelength-tunable Devices

Wide and continuous wavelength-tunable devices such as filters, lasers, and photodiodes with high spectral purity and fast tuning have a high demand for many applications such as DWDM-based optical communications, sensorics, analytics, spectroscopy, process control, metrology as well as medical diagnostics. Of these, DWDM has revolutionized telecom and datacom by increasing the signal capacity of embedded fiber, i.e., the incoming optical signals are assigned to specific wavelengths within a designated frequency band and then multiplexed onto one fiber. This process allows multiple data channels to be transmitted over one fiber while maintaining system performance and enhancing transport systems. The DWDM provides potentially unlimited transmission capacity. During the last decade, such devices have been implemented in micromachined MOEMS. Micromachining takes advantage of the vertical cavity-based tunable filters, lasers, and photodiodes to achieve wide and continuous tuning by a single tuning parameter, the actuation voltage, that varies the resonator length.

1.02.3.2.1 Micromachined tunable filters

Tunable Fabry–Pérot (FP) filters are key devices for wavelength-tunable applications. The tuning principle of electrostatically tunable micromachined vertical cavity FP optical filter is shown in Figure 9. The filter structure consists of an air cavity (length L) defined between p-doped top DBR and n-doped bottom DBR, which create a p–i–n junction. When the p–i–n junction is reversed biased, an electrostatic force acts between these two DBRs, and cavity length L decreases by increasing the reverse bias as shown in Figure 9, and the reverse bias increases from left to right. Depending on L, the filter is transparent for only one wavelength while blocking the others. Thus, the cavity length can be continuously tuned to select a specific resonance wavelength. In an ideal case, the effective cavity length is just a multiple of $\lambda/2$ of the individual wavelength.

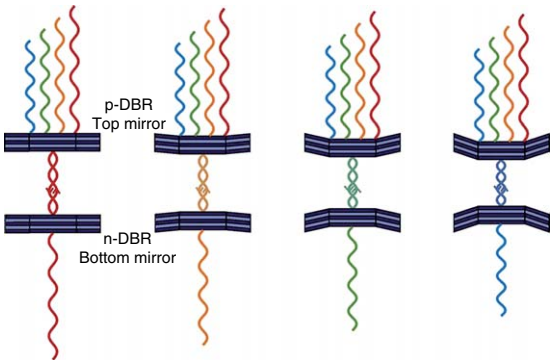

Figure 9 Tuning principle of electrostatically tunable vertical cavity Fabry–Pérot optical filters: from left to right reverse bias between the top and the bottom DBRs increases by decreasing the cavity length L.

Micromachined compound semiconductor tunable filters have been implemented on GaAs-based materials for a short wavelength of <1 μm (Amano *et al.* 2003, Lin 2004, Tayebati *et al.* 1998a, Vail *et al.* 1995) and on InP-based materials for a long wavelength of >1 μm (Dantec *et al.* 1999, Hillmer *et al.* 2002, Irmer *et al.* 2003, Strassner *et al.* 2005, Streubel *et al.* 1996). Several materials such as Si_3N_4/SiO_2, Si/SiO_2, SiO_2/TiO_2, $Al_xGa_{1-x}As/GaAs$, InP/air gap, and $AlO_x/GaAs$ have been investigated to fabricate top movable DBR tunable filters with cantilevers and four suspension membrane geometries. However, among these materials, the $AlO_x/GaAs$ and InP/air gap are promising for GaAs-based and InP-based materials, respectively, because they have high refractive index contrast, which provides a spectrally broad reflectivity spectrum. These DBR structures can also be grown monolithically, enabling a monolithic fabrication process rather than postgrown dielectric DBR structures.

InP-based tunable filters play a major role in telecom DWDM systems. An InP/air gap-based DBR structure has a very high refractive index contrast of $\Delta n = 2.167$ at 1.55 μm, enabling the achievement of a very high reflectivity with only a very few numbers of DBR periods. Figure 10 shows SEM image of a micromachined InP/air gap-tunable filter; Figure 10(a) shows a filter membrane in the middle with four suspensions connecting to supporting posts and Figure 10(b) shows a magnified view of the top and bottom DBRs (InP membranes/air gaps) separated by an air cavity. The filter structure consists of a 2.5-period p-doped top DBR, an intrinsic λ air cavity ($\lambda = 1.55$ μm), and a 3.5-period n-doped bottom DBR. Each DBR period consists of $3\lambda/4$-thick InP membrane and a $\lambda/4$-thick air gap. The air gaps and air cavity have been formed in the filter structure by selectively etching the GaInAs sacrificial layers using $FeCl_3$ etchant.

The tuning range and the required voltage for tuning depend on many parameters such as suspension lengths, number of suspensions, suspension widths, membrane diameter, membrane and suspension thickness as well as cavity length. Filters having

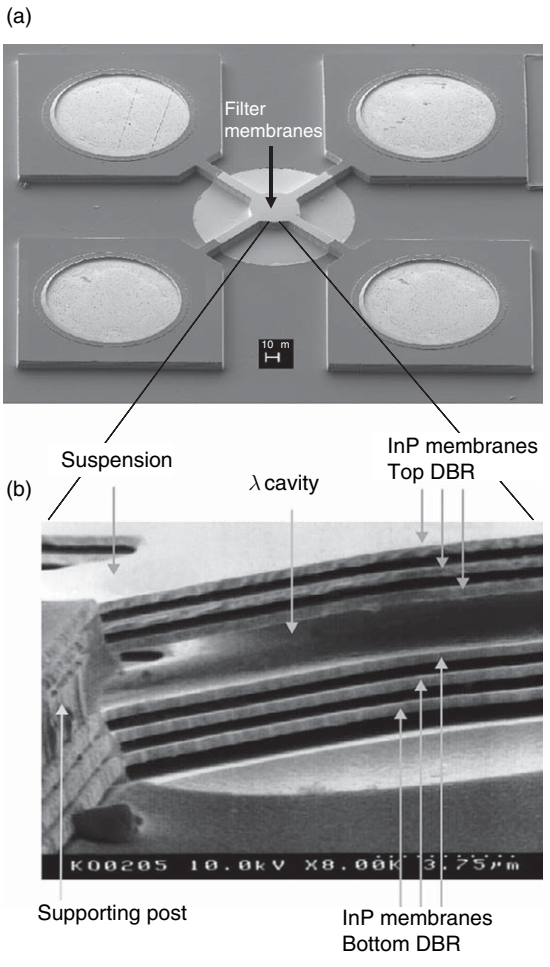

Figure 10 Micromachined multiple InP membranes/air gaps filter, (a) filter membrane in the middle with four suspensions connected to the supporting post and (b) resonator details.

four suspensions of 40 μm length, 40 μm membrane diameter, three $3\lambda/4$ InP membranes, separated by $\lambda/4$ air gaps, a $\lambda/2$ cavity and an air gap 637.5 nm to the InP substrate show a tuning range of 142 nm with a low tuning voltage of 3.2 V (Hillmer *et al.* 2002). The transmission dip of the device is located at $\lambda = 1.599\mu m$ for nonactuated membranes ($V = 0$) and at $\lambda = 1.457\mu$m. Thus, a continuous tuning of >9% of the absolute wavelength is obtained. This tuning range already exceeds the spectral width of the unchirped QW semiconductor laser gain profiles, typically in the range of 110 nm. Due to miniaturization, the efficiency of the electrostatic force increases considerably (Hillmer *et al.* 2002). Another filter with four suspensions of 30 μm length, 20 μm membrane diameter, three $3\lambda/4$ InP membranes, separated by $\lambda/4$ air gaps, a λ cavity and a spacing of 465 nm to the InP substrate, and even a larger tuning range has been obtained. The filter is weakly strained and thus at $V = 0$ has curved membranes. Using an electrostatic tuning voltage of 28 V they obtained 221 nm tuning (**Figure 11**), and the inset shows the corresponding reflectance spectra (Hasse *et al.* 2006). These filters have a fast tuning, low actuation voltages, and extremely wide tuning ranges; they are batch process-compatible and thus have a low-cost production. Therefore, these filters have a potential application in DWDM systems.

One of the issues in the InP/air gap DBR is to realize a strain-free InP membrane due to the arsenic carryover arsenic memory effect during the growth of the InP/GaInAs epilayers structure. Special care has to be taken to ensure optimum lattice matching in the epitaxial growth process since compressive strain and vertical strain gradients are very critical, leading to undesired bends in the underetched membranes. The arsenic incorporation in the InP layer creates a compressive strain in the InP membranes and causes slight bending in the membranes. As a consequence of the membrane bending a remarkable influence exists in the filter properties such as spectral tuning range, filter line transmission, line width, and lateral mode structure. Arsenic carryover effects on InP

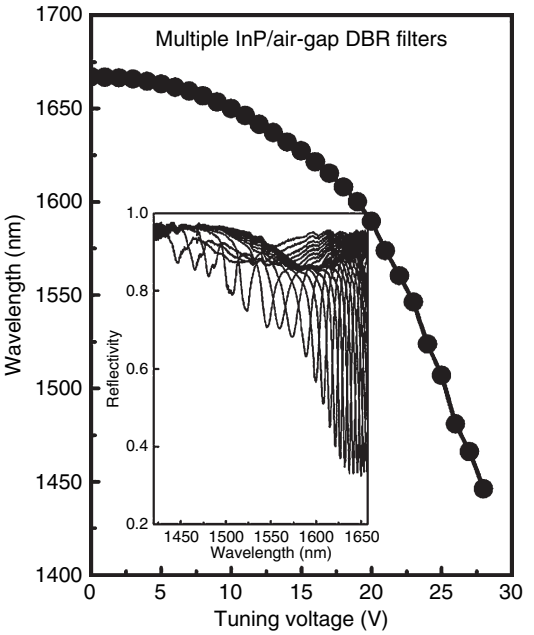

Figure 11 Measured tuning characteristics and the corresponding reflectance spectra (*inset*) of the InP/air gap filter under electrostatic actuation.

membranes have been investigated in detail by Strassner *et al.* (2000). They proposed growth interruption and compensation mechanism to compensate the arsenic carryover-induced compressive strain in the InP membranes. Recently, Kussorow *et al.*, (2006) have carried out a systematic investigation on the compensation layer thickness as a function of compressive strain in the InP membrane.

An alternative configuration for GaAs-based micromachined tunable cantilever filter structure with thermal tuning was proposed and implemented by Amano *et al.* (2003) for short wavelength applications. This filter structure is controlled by a thermal strain force and has a tuning range of 18.1 nm for the tuning voltage of 4.9 V (0.79 nm K^{-1}). The dynamic response of this kind of filters is lower than that of electrostatically actuated filters.

Table 3 compares the micromachined electrostatically tunable filters of compound semiconductors with multiple-period DBRs and shows the development progress over a decade. One of the important properties of a tunable filter is the full width at half maximum (FWHM), which influences the finesse of the wavelength tunability. Especially for DWDM applications a small FWHM of 0.8 nm is necessary. A more stable filter membrane geometry and flat membrane (without bending) will give higher finesse. A detailed comparison of dielectric-based DBR structure tunable filters from the DWDM application point of view has been discussed by Hillmer *et al.* (2006).

1.02.3.2.2 High-performance tunable VCSELs

The most exciting application of micromachining in direct band gap compound semiconductors is the monolithically fabricated wavelength-tunable light sources. The tunable lasers enable dynamic networks with wavelength reconfiguration, networking flexibility, and cost reduction. Micromachining takes advantage of the vertical cavity geometry of VCSEL and allows mechanically tunable laser diodes with a single tuning parameter (actuation voltage). The top movable DBRs have been fabricated by micromachining the active region of the VCSELs, which can be electrostatically actuated to tune the wavelength by changing the cavity length. This device gives a circular beam profile and enables 2D integration and batch processing.

Several research groups have been reporting various approaches to implement mechanically tunable lasers. Of these, cantilever VCSEL (c-VCSEL) by Chang-Hasnain (2000) and membrane VCSEL (m-VCSEL) by Harris (2000) are investigated in detail on GaAs-based materials, which are based on a monolithic approach. **Figure 12(a)** and **12(b)** shows the schematic diagram of a top emitting tunable c-VCSEL with a cantilever, consisting of a movable top DBR and a fixed bottom DBR, a cavity layer with an active region, and a SEM image of the fabricated device, respectively (Chang-Hasnain 2001). The top mirror consists of three parts: a p-DBR, an air gap, and a top n-DBR that is freely suspended above the laser cavity and supported by the cantilever structure. **Figure 13** shows the continuous tuning spectra of the c-VCSEL with a single tuning control across 20 channels in C-band at a spacing of 100 GHz with side-mode suppression ratio >45 dB. The advantages of c-VCSEL are that the complete epilayer structure can be grown in one single step and electrically pumped monolithic wavelength-tunable device. The disadvantage is polarization dependence. Tuning is achieved with a reverse-biased junction, which is embedded in the top DBR.

Harris and coworkers have proposed a membrane-based movable top DBR and implemented tunable VCSELs (Harris 2000, Larson and Harris 1996, Larson *et al.* 1995). A schematic diagram of the tunable m-VCSEL and lasing wavelength tuned near 960 nm are shown in **Figures 14** and **15**, respectively. The basic tuning mechanism of c-VCSEL and m-VCSEL is the same, i.e., the cavity length is decreased as a

function of tuning voltage. However, the micromachined top mirror (membrane) geometry and materials are different from c-VCSEL. The top mirror consists of four suspensions extending from four posts at a diagonal position to support the central mirror. Two different material systems have been used for the top DBR mirrors, one is a semitransparent Au reflector/electrode on top of a SiN_xH_y phase-matching layer and GaAs cap, and the other is Al_2O_3/GaAs-based. The Al_2O_3/GaAs system has low loss, high refractive index contrast, and high mechanical strength when compared to other materials.

Tayebati *et al.* (1998b) have reported a new class of tunable VCSELs for short wavelength application in which the spatial mode of the laser oscillation is

controlled by the curvature of the actuable top DBR. The device tuned from 863 to 833 nm under a 13-V voltage swing.

Recently, micromachined tunable vertical cavity semiconductor optical amplifiers (VCSOA) have also been reported (Cole *et al.* 2005). The difference between VCSOA and VCSEL is the reduced mirror reflectivity used in the resonant cavity structure of VCSOA. The VCSOA is an alternative to erbium-doped fiber amplifiers and conventional in-plane SOAs for use in fiber-optic communication systems, and it is also of low cost.

1.02.3.2.3 Micromachined tunable hybrid dielectric DBR structures

The InP-based tunable long-wavelength VCSELs are highly desirable for telecommunication applications; however, few devices based on monolithic approach operating at 1.55 μm have been reported (Chang-Hasnain 2000, Sun *et al.* 2004, Vakhshoori *et al.* 1999). Some of the major design issues that have to be overcome are the low index contrast and poor thermal conductivity of lattice-matched DBRs on InP materials. Therefore, hybrid integrated two-chip concept-based dielectric top DBR tunable VCSELs have been proposed and demonstrated for long-wavelength applications (Kögel *et al.* 2006, Maute *et al.* 2004, Riemenschneider *et al.* 2003, 2004, Tarraf *et al.* 2004, Tayebati *et al.* 1998b). The two-chip concept devices are based on an active region and an air gap cavity embedded between two DBRs of different materials. This has the advantage that both parts can be optimized separately and then be integrated.

Tarraf *et al.* (2004) have carried out a detailed investigation on the stress in the dielectric (Si_3N_4/SiO_2) top DBR mirrors for the two-chip hybrid integrated VCSELs. They have implemented micromachined continuously tunable 1.55-μm VCSELs by precisely curved dielectric top DBRs using the two-chip concept. The curved top DBR structure is designed for a precise lateral mode control. The dielectric DBR period comprises a Si_3N_4 and a SiO_2 layer, each with an optical thickness of $\lambda/4$ at 1550 nm. The air gap length L and the membrane curvature were adjusted by precisely tailoring the intrinsic stress of the dielectric layers across the DBR by varying the duty cycle plasma excitation frequency intervals during the deposition in the plasma-enhanced chemical vapor deposition (PECVD) system. **Figure 16** shows a schematic cross section of the device. The correlation between the design of the membrane and the vertical distribution of the stress across the DBR forces the membrane to

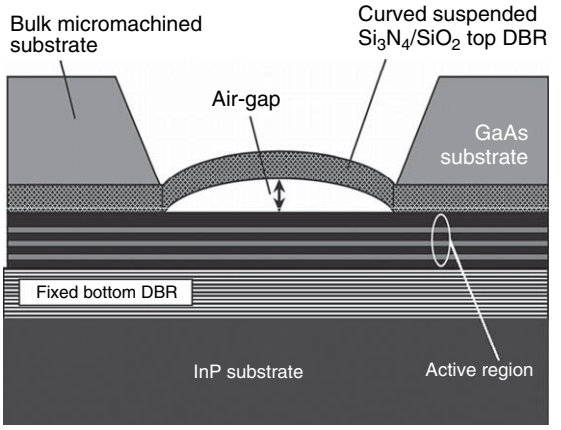

Figure 16 Cross-sectional view of the two-chip concept-based tunable VCSEL.

bend toward the GaAs substrate after substrate removal. Thus, a radius of curvature of 4.5 mm and an air gap length L of 16 μm are obtained. The circular membrane has a diameter of 300 μm and is fixed to the substrate by four suspensions (600 μm length and 70 μm width). The bottom DBR is designed for a central wavelength of 1575 nm and consists of 48 InP/InGaAsP pairs yielding 99.8 % nominal reflectivity. The semiconductor part of the resonator has an optical thickness of 4.5λ and consists of a periodic gain active region optimized for optical pumping. The total cavity (length L) consists of a $3\lambda/2$ long active region, embedded by two InP confinement layers and the air gap. The spectral tuning is achieved through micromechanical actuation of the membrane. The deflection is achieved electrothermally by injecting a small heating current through a thin metallic layer on top of the flexible suspensions. The metallic layer acts as a heating resistor, converting the dissipated power into thermal heat, which increases the length of the suspensions slightly. The VCSEL is optically pumped and shows a continuous tuning range of 26 nm. The device has a free spectral range (FSR) of 47 nm and a side-mode suppression ratio of 57 dBm. The laser peak has a line width (FWHM) of 0.1 nm, resulting in a finesse of approximately 470, which is the ratio of FSR to FWHM. The relation between wavelength tuning and heating power due to thermal actuation is exactly linear with a sensitivity of $7\,\text{nm}\,\text{mW}^{-1}$ (Tarraf *et al.* 2004).

Maute *et al.* (2004) and Riemenschneider *et al.* (2004) have reported electrically pumped two-chip concept-based long-wavelength-tunable VCSELs. The VCSELs consist of a single air gap, a GaAs/AlGaAs top mirror with 24.5 pairs, and a dielectric CaF_2/a-Si DBR bottom mirror (2.5 pairs) with an additional gold

coating, incorporating a tunnel junction for improved current injection, and reduced optical loss (**Figure 17**). The top mirror has a concave bending with a radius of curvature of 5.5 mm, resulting in an initial deflection of 6.5 μm after removing the substrate. By injecting a small heating current through the doped membrane material the flexible suspension warms up and slightly expands and thus the clamped membrane deflects and the VCSEL resonator increases. This tunable VCSEL shows a continuous tuning over 40 nm at long wavelengths. The gold mirror, in combination with a thin dielectric DBR, leads to a high reflectivity and to a low thermal resistance for transferring the heat out of the active region. This device appears to be a promising candidate of its kind for tuning at long wavelengths.

In the following, different FP filter designs are compared with respect to finesse, FSR (corresponding to the usable tuning range), and FWHM (corresponding to the linewidth of the filter dip). In a rough approximation, both FSR and FWHM are proportional to the inverse cavity length L. Since the finesse is the FSR divided by the FWHM, the finesse does not depend on L in this theoretical model. Larger cavities (e.g., two-chip concepts) theoretically show not only smaller FWHM (which is desirable) but also smaller FSR (which is not desirable). For small cavity lengths (e.g., monolithic single-chip concepts) the situation is reversed. Therefore, a counteracting situation reveals that small cavities are beneficial for larger FSR and larger tunability, and larger cavities are beneficial for smaller FWHM. In practice the theoretically predicted FSR values are also found experimentally. On the contrary, in practice it is much more difficult to obtain the theoretically predicted low FWHM values. Due to membrane bending, stress, interface and surface roughness, and individual layer thickness fluctuations, the FWHM is often much higher than theoretically predicted. This in practice causes a dependence of the finesse on cavity length. In summary, larger cavities (e.g., two-chip concepts) show in practice smaller finesse than do smaller cavities (monolithic single-chip concepts). When membrane and cantilever-based FP filters are compared, the membrane-based devices show larger finesse and much lower polarization dependence.

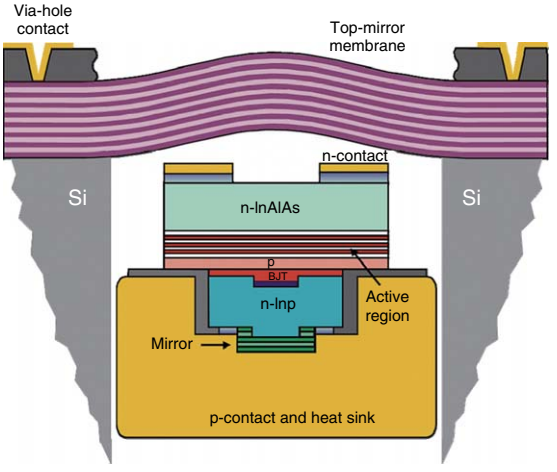

Figure 17 Schematic cross-sectional view of two-chip tunable VCSEL. (Source: Maute M, Böhm G, Amann MC, Riemenschneider F, Halbritter H, Meissner P 2004a Micromechanically and widely tunable long-wavelength VCSELs. *IEEE 19th International Semiconductor Laser Conference*, 119–20, © 2004, reproduced with permission from IEEE.)

Wavelength tuning was also achieved by refractive index modulation by changing the temperature and current injection. Temperature tuning is limited to low tuning range and slow speed. Current tuning is complex and continuous tuning is difficult. Therefore, electrostatic mechanical tuning has greater tuning range than that achieved by refractive index modulation.

1.02.3.2.4 Tunable photodiodes

Optically transmitted signals are finally converted into electronic signals by a photodiode. A highly sensitive high-speed photodiode is necessary for optical communication and sensing application. Especially for optical communication, a highly selective and wide continuously tunable photodiode is necessary for wavelength tracking in the DWDM system, which enables ultrahigh capacity transmission. Various kinds of photodiodes such as p–i–n photodiodes (PIN-PDs) and metal–semiconductor–metal photodiodes have been reported in the literature. The PIN-PD allows tunable photodiodes because of the geometry, which can be integrated with micromachined movable top mirrors. There are also reports on tunable photodiodes using quantum confined Stark-effect; however, this is limited in the tuning range.

Micromachined tunable photodiodes design basically can have two different choices, both related to the position of the absorption layer: resonant cavity-enhanced (RCE) photodiode or FP filter photodiode. In the RCE, an absorption layer is placed inside the cavity and the standing wave intensity increases sharply at resonance and so does the photodiode response. In the FP filter photodiode two separate devices can be considered: filter and photodiode where the filter is tuned to a desired wavelength to pass to the photodiode.

Resonant cavity-enhanced QW tunable photodiodes for long wavelength have been proposed and implemented by Leclercq *et al.* (2000). In these devices the absorption layer is placed between the top dielectric DBR mirror and the bottom InP/air gap DBR mirror. The preliminary results of this device show 9 nm selectivity, 18% quantum efficiency with a dark current of 10^{-6} A cm^{-2} at 2 V.

Wu *et al.* (1996) have developed a tunable micromechanical vertical cavity photodiode using a cantilever as a top DBR mirror, which has a geometry similar to their c-VCSEL geometry. The device consists of, starting from the substrate, 13-period n-doped AlAs/GaAs fixed bottom DBR, an absorbing region, which is sandwiched between the top and the bottom DBRs, formed from three 8-nm $In_{0.16}Ga_{0.84}As$ strained QWs in a λ cavity, a fixed portion of the top 2-period p+-doped $Al_{0.6}Ga_{0.4}As/Al_{0.1}Ga_{0.9}As$ DBR, and a movable top mirror with 18-periods n-doped $Al_{0.6}Ga_{0.4}As/Al_{0.1}Ga_{0.9}As$ DBRs. By applying a tuning voltage to create electrostatic attraction, the cantilever is attracted toward the substrate, thereby changing the air gap spacer thickness and consequently the resonant FP wavelength. They have achieved 30-nm continuous tuning for the resonant cavity detector with a 7-V tuning voltage.

Hybrid integrated long-wavelength-resonant vertical cavity photodiode have also been fabricated by Christenson *et al.* (1997). The device consists of a GaAs-based DBR, i.e., wafer bonded to InP-based active layers, with a micromachined tunable top dielectric DBR mirror to produce the wavelength shift. A tuning range of 75 nm has been achieved for a voltage of 50 V, which is relatively high. Another hybrid integrated two-chip concept-based long wavelength-tunable photodiode by placing the PIN-PD outside the resonant cavity has been reported by Peerlings *et al.* (1999). The device consists of a PIN detector part and a micromachined actuator part. The membrane mirror of the actuator, supported by two beams, is realized by selective wet chemical etching of the bulk InP substrate. The device geometry allows the use of dielectric DBR mirrors as it is a two-chip concept. Micromachining has also been used to fabricate resonant cavity-enhanced untuned photodiodes by fabricating InP/air gap DBRs (Huang *et al.* 2004). The main advantage of this device is a high detection efficiency at resonance.

1.02.3.2.5 Optical waveguide switches

All-optical technology uses photons to carry the signal, which escalates the limitation imposed by the present electronic technology. In all-optical technology, optical fibers transmit information over long distances and micromachined optical switches manipulate the optical signals directly rather than converting them into the electrical domain for manipulation, thereby increasing the network speed together with greater channel density. The advantages include reduced crosstalk, noise, and power dissipation at high frequencies when compared to electrical interconnects. All-optical technology also enables optical ICs on a single chip where MEMS play a key role because optics relies on the precision motion that MEMS can give. In all-optical systems, electronics control the optical signals from outside the optical signal path. This enables system implementers to optimize electronics and optics independently to achieve the all-optical integration. As in electronic ICs, more function can be added into the all-optical IC in a single chip.

Optical waveguides have been utilized to tight optical confinement for dense integration. Such integrated optics enables the monolithic integration of many optical components in a compact device. Micromachining enables movable and actuated waveguides. Optical waveguide MEMS switches play a vital role in light propagations, network reconfigurations, and optical cross connections. This device provides light propagation in the wafer plane, allowing dense integration, monolithic fabrication, small size and low cost, and increased manufacturability due to decreased assembly and packaging requirements. There have been numerous optical waveguide MEMS devices implemented in silicon; these devices are limited to passive optics due to the indirect band gap in silicon. Recently, optical waveguide MEMS switches have been implemented on GaAs and InP compound semiconductors.

GaAs-based waveguide MEMS switches have been demonstrated by Spahn and coworkers (Bakke *et al.* 2002). They have demonstrated 1×2 switches based on lateral deflection of a planar waveguide (**Figure 18**). The waveguide consist of 4-μm-thick GaAs/AlGaAs layers while the released layer is composed of 2 μm of AlGaAs. The switch characteristics show low actuation voltage (3–20 V), short switching times (32–200 μs), and low crosstalk (30 dB).

Ghodssi and coworkers have demonstrated micromachined InP waveguide switches, which have potential application in optical communications as well as in sensors by taking advantage of the direct band gap. They have developed suspended waveguides supported by lateral tethers (Kelly *et al.* 2004), optical waveguide MEMS switches with evanescent coupling mechanism (Pruessner *et al.* 2005), and electrostatically actuated end-coupled optical waveguide devices on

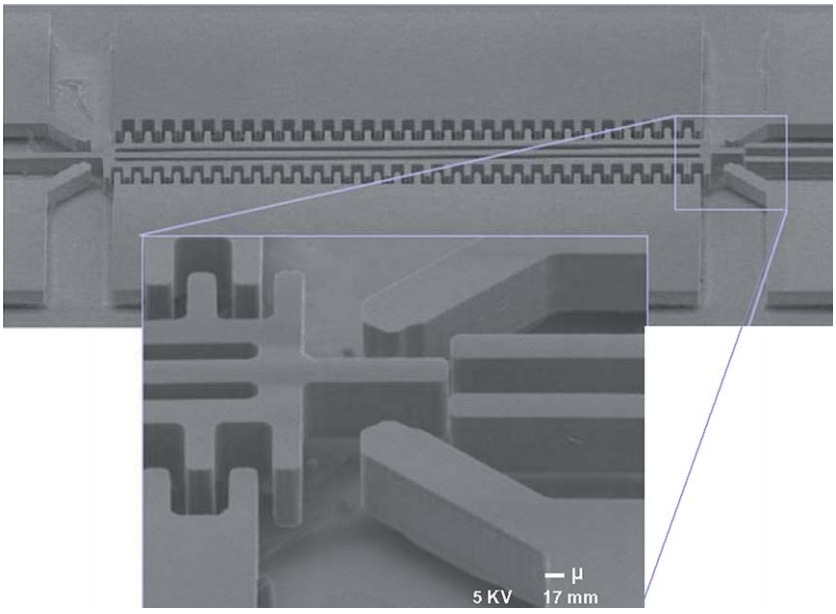

Figure 18 GaAs optical waveguide switch. (Source: Bakke T, Tigges C P, Lean J J, Sullivan C T, Spahn O B 2002 Planar microoptomechanical waveguide switches. *IEEE J. Select. Top. Quantum Electron*. **8**, 64–72, © 2002, reproduced with permission from IEEE.)

InP. The optical switch with evanescent coupling mechanism has two closely spaced waveguides, and the coupling is controlled by changing the gap and the coupling length between the two waveguides via electrostatic pull-in. This enables both optical switching and variable optical coupling at voltages below 10 V (Pruessner *et al.* 2006). This device has a channel isolation as high as 47 dB and coupling efficiencies of up to 66% with switching losses of <0.5 dB. **Figure 19** shows a 1×2 end-coupled optical waveguide switch, which has a comb-drive actuator and serpentine suspension for low-voltage switching of <7 V. They have also developed resonant sensors with integrated optical readout by modifying the optical waveguide switch (Pruessner *et al.* 2005). Using this approach, they have also demonstrated electrostatically actuated in-plane (horizontal) tunable FP filters with integrated waveguides revealing a tuning range of ~400 nm, which covers the entire CWDM spectral range (Datta *et al.* 2004). This filter geometry allows monolithic integration of InP-based devices such as edge-emitting lasers, waveguides, and photodiodes on single chips.

1.02.3.3 Hybrid Integrated Microsystems

In this chapter, compound semiconductor-based microsystems have been discussed; however, it is worthy to mention hybrid integrated microsystems, which give great opportunity for developing on-chip mechanical components that can be integrated with optical devices for both optical communication and optical sensing systems. Though monolithic integration is desired, as discussed in other sections of this

chapter, in reality, highly functional optical systems need micromachined hybrid (different individual devices of different main materials) integrated microsystems such as optical scanners (Sasaki *et al.* 2003), laser-to-fiber coupling (Ishikawa *et al.* 2003), external cavity continuous tunable lasers (Liu *et al.* 2003, 2004), and a free-space micro-optical bench (Lin *et al.* 1997). More complicated micromachined hybrid integrated systems such as Smart Dust has been conceptually proposed and partially implemented by Kahn *et al.* (2000). The Smart Dust consists of microfabricated sensors, optical receivers, passive and active optical transmitters, signal processing, control circuitry, and power on a single chip.

The hybrid integrated microsystems mostly take MEMS devices from silicon and optical devices from direct band gap compound semiconductors. The silicon and compound semiconductor each possess desired properties that the other does not; there have been many efforts to grow III–V material directly on silicon substrates in order to take advantage of each material's capabilities on a single chip. Unfortunately, due to large differences in the lattice constants, and the thermal expansion coefficients of these materials, defect densities in the heteroepilayer are high and device performance results are poor. To circumvent this issue, hybrid integration has been adopted to integrate compound semiconductor optical devices onto silicon MEMS. Hybrid integration needs a special bonding technology such as wafer bonding, epilayer transfer/grafting, or flip chip bonding. The choice of the bonding method depends on the initial substrate and the final applications. A heteromicromachining concept is also implemented by Fricke *et al.* (1999), which integrates compound semiconductors with silicon by using etching selectivity of these two materials.

A multidisciplinary team of end users and suppliers has collaborated for developing a novel broadly enabling process for the design and the fabrication of hybrid integrated light emitters and detectors with silicon on insulator (SOI)-based MOEMS (Kubby *et al.* 2001). This system has crystalline silicon optical components (mirrors and lenses), which can be rotated out of plane using hinges defined in polysilicon layers. With these mechanical devices, laser diodes and control as well as detection electronics have also been integrated using flip chip bonding.

Sasaki *et al.* (2003) have demonstrated an optical scanner on a 3D micro-optical bench by 3D photolithography using resist spray-coating techniques on silicon wafers. This system consists of an edge-emitting laser chip mounted on the bulk silicon terrace facing the scanning mirror. The laser emission is reflected to the out-of-plane direction by the skew mirror. An optical scan angle of more than 30° and a cutoff frequency of 100 Hz have been reported. This is close to the specification required for barcode readers.

A laser-to-fiber coupling is a critical task in the optical fiber network. This has been successfully achieved by a hybrid integrated micromechanical mirror with an optical laser diode (**Figure 20**) (Ishikawa *et al.* 2003). The advantages of this system are active alignment, batch assembling, and compactness.

Continuous tunable lasers have also been developed by hybrid integration using silicon-based comb-drive actuators. Uenishi (1996) have reported micromachined nickel micromirrors to compact coupled-cavity edge-emitting lasers. The micromirror has a height of 19 μm and a width of 50 μm, and the facet reflectivity was estimated to be 63%. Recently, Liu *et al.* (2003, 2004) have developed an external cavity continuous tunable lasers using micromachined blazed grating, circular/flat mirror integrated with fiber onto a single silicon chip (**Figure 21**). The device with blazed grating has a tuning range of 30.3 nm with a resolution of 0.03 nm V^{-2}, a maximum power of 0.4 dBm, and a side-mode suppression ratio of 26 dB. The circular mirror works in multilongitudinal modes. More recently, Li *et al.* (2005) have achieved hybrid integrated photonic subsystems for optical network application by integrating tunable lasers and optical switches on a single silicon chip with a dimension of 3.5 mm × 3 mm × 0.6 mm. The hybrid integrated microsystems are, generally, limited to miniaturization due to manual assembling of the optoelectromechanical compounds.

1.02.4 Self-Assembled Micro/Nanostructures

Micromachined self-assembled structure on compound semiconductor materials is an exciting and less-explored technique. First, Prinz *et al.* (1996) demonstrated that strained bilayers can be used to form micro/nanotubes and coils. The structures were formed by lattice-mismatched epitaxial layers, for example, GaAs/InGaAs, that rolled up when released from the substrate due to the lattice mismatch-induced built-in strain. The strain-induced deformation is determined by the lattice mismatch, elastic properties, and the thickness of the bilayers. By taking advantage of this technique, various micro/nanostructures have been reported on InGaAs/GaAs and SiGe/Si material systems by Prinz *et al.* (2001), Prinz (2004), and Schmidt *et al.* (2001, 2002).

1.02.4.1 Self-Assembly Mechanism

The basic principle of a self-assembled technique is as follows: when two single-crystalline epitaxial layers of materials A and B with different lattice constant a ($a_A < a_B$) are grown pseudomorphically on a substrate of material A (e.g., GaAs/InGaAs on GaAs or Si/SiGe on Si), the layer B is biaxially compressed in the plane of the substrate. The strained bilayer, consisting of the layers A and B, is released from the substrate by selective etching of an additional sacrificial layer, the freestanding bilayer bends with a curvature radius owing to relaxation of mechanical stress. The interatomic forces in the bilayer act to increase the interatomic distance in the compressed B layer and to decrease it in the tensile-stressed A layer (**Figure 22**). The elastic forces F_1 and F_2 are oppositely directed, and they give rise to a nonzero moment of forces M, which tend to bend the bilayer. Under the action of this moment, the initially planar bilayer rolls up in a scroll. The rolled-up layers stick together, thus forming a perfectly bonded tube wall (**Figure 23**). The

Sci.*, **532–535**, Prinz A V, Prinz V Y, Application of semiconductor micro- and nanotubes in biology, 911–15, Copyright (2003), with permission from Elsevier.)

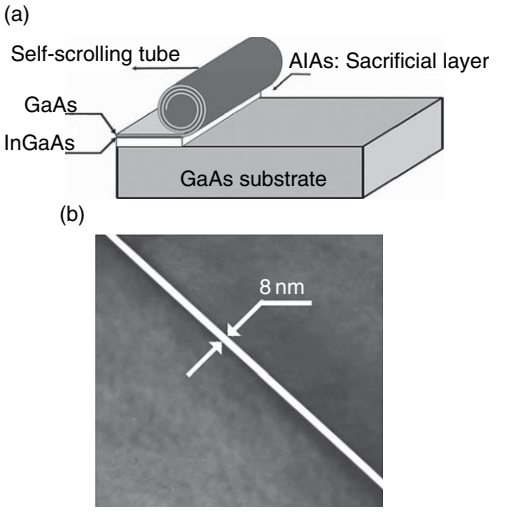

Figure 23 Self-rolling nanotube: (a) schematic diagram of a single tube of an InGaAs/GaAs bilayer rolling with length L and (b) an SEM image of the tube. (Source: Reprinted from *Physica E*, **23**, Prinz Y V, Chekhovskiy A V, Preobrazhenskii V V, Semyagin B R, Gutakovsky A K, 2002 A technique for fabricating InGaAs/GaAs nanotobes of precisely controlled lengths. *Nanotechnology* **13**, 231–3, Copyright (2003), with permission from Elsevier.)

radius of curvature of the tube structure can be determined using the following equation:

$$R = \frac{d\{[3(1+m)^2] + [1+(mn)][m^2 + \frac{1}{mn}]\}}{6\varepsilon(1+m)^2} \qquad [1]$$

where n is the ratio of Young's modulus of the bilayers, m is the thickness ratio of the bilayers, and ε is the strain due to lattice mismatch. Recently, the rolled-up single-crystalline nanotube structures have been probed using X-ray microdiffraction by Krause *et al.* (2006).

1.02.4.1.1 3D micro/nanostructures

A new class of precise micro/nanostructures such as tubes, scrolls, ring, and helices have been fabricated by self-rolling of strained compound semiconductor bilayers (Prinz 2004, Prinz *et al.* 2001). By using this technique, ultrathin epitaxial layers, down to few monolayers, can be controllably detached from the substrates by selective etching of the underlying sacrificial layers and rolled up, under the action of internal stresses, into various cylindrical micro/nanostructures. The diameter of the tubes can be scaled by changing the overall layer thickness, the built-in strain, and the thickness ratio of the top and lower layers. Schmidt and coworkers have also reported various nanoobjects on InGaAs/GaAs and SiGe/Si material systems (Deneke and Schmidt 2004, Schmidt *et al.* 2001, 2002). They have measured the tube diameter as a function of bilayer thicknesses, which agrees with theory (**Figure 24**) (Deneke and Schmidt 2004). Furthermore, the directional rolling concept was introduced in order to direct the free-standing micro/nanotubes to a particular orientation or to fabricate arrays of structures (Vorob'ev and Prinz 2002). This technique enables novel nanostructuring architecture for nanotechnology to fabricate atomically precise 3D nanostructures.

Novel physical phenomena have also been explored from the strained bilayer nanostructures. The numerical simulations of the quantum confinement in nanocorrugated freestanding InAs layers and quantum properties of InAs/GaAs nanotubes have been reported by Osadchii and Prinz (2000, 2006), respectively. Kleiner (2003) has shown that any curved electron gas-containing layers placed in a magnetic field should generate spin-polarized currents. This effect opens up new possibilities in using spin currents in integrated solid-state spintronic devices. The magnetotransport properties of 2D electron gas in rolled-up QWs have been reported by Vorob'ev *et al.* (2004). A difference between the magnetoresistances of planar and rolled QWs has been observed, i.e., the electrical resistance of the active layer increases after the detachment of the layer from the substrate due to the depletion region formed in the active layer at its rear-free surface.

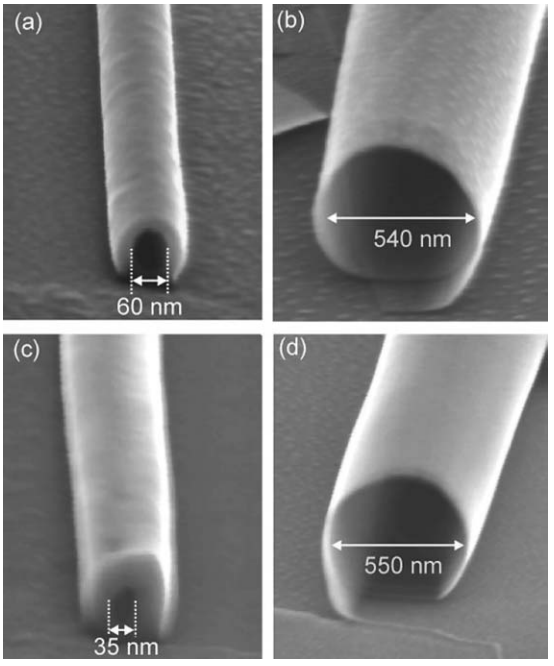

Figure 24 Four typical tube openings consisting of the following as-grown bilayers: (a) 1.4ML $In_{0.33}Ga_{0.67}As$/6.4ML GaAs, (b) 14.1ML $In_{0.33}Ga_{0.67}As$/19.1ML GaAs, (c) 1.4ML InAs/6.4 ML GaAs, (d) 1.4ML InAs/20.4 ML GaAs. 1.02.4.2 Micro-Origami Technique

In the strain-driven bilayers, a hinge concept was introduced and self-assembled 3-D microstructures have been fabricated by Vaccaro *et al.* (2001). The hinges connect released structures with the substrate. This technique is called micro-origami technique, which is in a way similar to the origami technique of paper folding. They applied this technique to fabricate freestanding 3D microstructures such as micromirrors, retroreflectors, and microstages on compound semiconductors. These 3D structures can be electrostatically actuated.

In addition to the strained bilayer, the hinge plays a role in determining the standing position of the released microstructures. The simple hinge structure is formed by a thin flexible layer, with no sliding parts that could get stuck or be degraded by friction.

Furthermore, top (scale)-down to submicron (nano)-order mechanical systems are feasible because the simple structure of the hinge does not impose limitations in the lithographic process. The main advantage of this technique is that 3D microstructures are self-assembled by the strain force built in the bilayers, whereas conventional techniques need manual assembling process. This enables monolithic integration of optoelectronic devices with micromechanical structures.

A schematic cross-sectional view of a micromirror produced by micro-origami technique is shown in **Figure 25**. This micromirror epilayer structure from the top consists of a compensation layer (InGaAs), a component layer (GaAs), an etch stop layer (AlGaAs), a strained bilayer (GaAs/InGaAs), and a sacrificial layer (AlGaAs/AlAs) above the substrate. In the micromirror structure, the component layer can be used to have passive optical elements such as DBR structures. The sacrificial layer thickness is kept constant whereas the bilayer and compensation thicknesses can be varied to position the micromirror at a desired angle. The SEM image of a retroreflector fabricated by micro-origami technique is shown in **Figure 26**; the mirrors are released from the substrate and stand vertically (Aida *et al.* 2002).

The hinged 3D microstructures have been fabricated by photolithography and the wet etching process. The first step is to fabricate hinges, the second step defines the shape of the microstructure (e.g., micromirrors) by vertical etching and then the micromirrors are released by etching (horizontal) the sacrificial layer (see **Figure 1**). Finally, the postetching process is followed as discussed in Section 1.02.2.2. When the sacrificial layers are etched away by selectively etching, the strain in the bilayer results

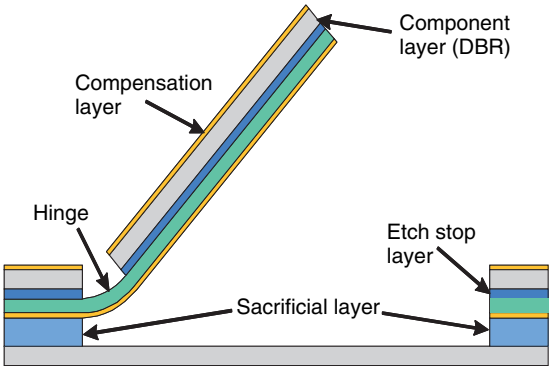

Figure 25 Schematic cross-sectional view of an self-assembled micromirror by micro-origami technique.

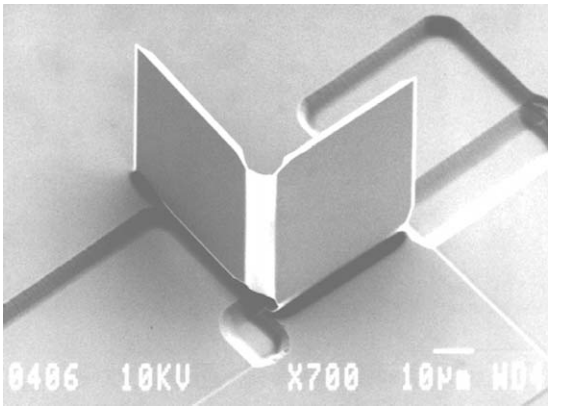

Figure 26 Self-assembled retroreflector micromirrors. (Source: Aida T, Vaccaro P O, Kubota K 2002 On the design and fabrication precision of micro-origami devices. In: IEEE/LEOS (eds.) *Optical MEMS 2002*, Lugano, Switzerland, pp. 43–4, © 2002, reproduced with permission from IEEE.)

in a deformation, which lifts the micromirror out of the substrate and is self-positioned. The micromirror standing position depends on the bilayer thickness, composition, and the width of the hinge. In order to maintain the micromirror flatness, a compensation layer is to be added above the strained bilayer. A flat or curved mirror surface, depending on the application, can be obtained by controlling the thickness of the compensation layer.

Kubota *et al.* (2003) proposed and implemented a complex self-assembled microstage in the InGaAs/GaAs materials system using two types of hinges that bend toward opposite directions, called valley fold and mountain fold. After releasing the multilayered structure from the substrate by the selective etching of a sacrificial layer, the microstage moves into its final position powered by the strain release in the InGaAs layers, where the stage is kept parallel to the substrate at a height of 50 µm owing to the combination of the two types of hinges (**Figure 27**). By taking advantage of strain-driven self-assembling mechanism, Dharmarasu *et al.* (2004) have designed micromirrors with a self-locking mechanism, which has side plates that lock the micromirror at the desired angle. The elevation angles of micromirrors and side plates are independently controlled by varying the hinge width for a given bilayer thickness. The geometry of these side plates assists in locking the micromirror precisely with the substrate at the designed value and keeps the micromirror flat. The undercut effect on the micromirror is suppressed and the stiction of the micromirrors with the substrate is eliminated by the self-locking mechanism.

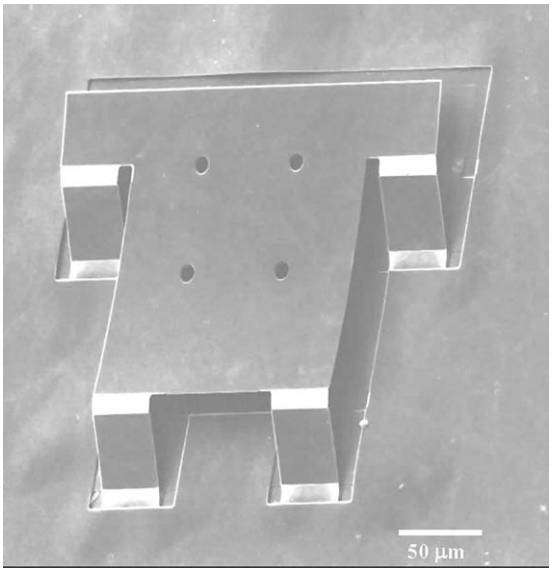

Figure 27 A microstage that elevated 50 μm above the substrate using valley-fold and mountain-fold hinges. (Source: Kubota K, Fleischmann T, Saravanan S, Vaccaro P O, Aida T 2003 Self-assembly of micro-stage using micro-origami technique. *Jpn. J. Appl. Phys*. **42**, 4079–83, © 2003, reproduced with permission from Japanese Journal of Applied Physics.)

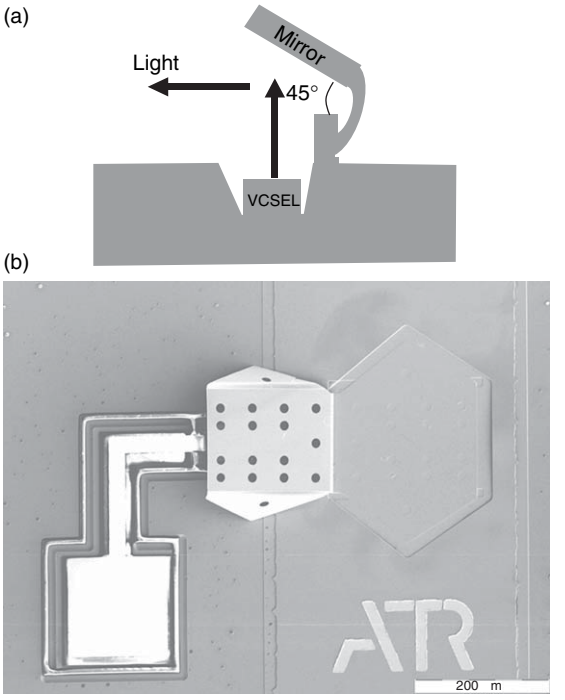

Figure 28 Monolithic integration of self-assembled micromirror with VCSEL: (a) a schematic illustration and (b) an SEM image of the integrated device.

1.02.4.3 Monolithically Integrated Microsystems

Monolithic integration of GaAs-based cantilever, laser diode, and photodiode on lateral geometry has been demonstrated by Ukita *et al.* (1993). Recently, GaAs-based self-assembled micromirrors with LEDs and VCSELs have been integrated monolithically on vertical geometry by Dharmarasu *et al.* (2005). The schematic cross section and an SEM image of the integrated device are shown in **Figure 28(a)** and **28(b)**, respectively. The device epilayer structure was grown in a single step. The micromirrors were self-assembled by the strain-driven mechanism at an angle of 135°. The micromirror is positioned to deflect the vertically emitted light parallel to the substrate and therefore enables the optical elements to be cascaded and integrated on the same substrate. This result shows the feasibility of monolithic integration of compound semiconductor-based micromachined structures (mirrors and lenses) with active optoelectronic devices (LEDs, VCSELs, and photodiodes), which enables light generation, transmission, and detection on a single chip for optical ICs.

1.02.5 Summary and Future Prospects

A comprehensive review of microsystems on compound semiconductors is presented. Material properties, micromachining aspects, various kinds of micromachined sensors, and microsystems have been discussed in detail. They include cantilevers, membranes, waveguide switches, RF inductors, microbolometers, micromotors, and wavelength-tunable microcavity devices such as filters, VCSELs, LEDs, and photodiodes. Wavelength-tunable microsystems, both monolithic and hybrid, approaches have been accomplished by various research groups. These systems have potential application in wavelength division multiplexing system for optical communication systems. Optical waveguide switches, which manipulate the optical signal directly rather than converting them into the electrical domain for manipulation, have also been demonstrated on compound semiconductors. The performance of these microsystems can be enhanced further by the introduction of photonic crystal structures (photonic band gap), which confine and control the light such as polarization and spectral control.

Furthermore, micromachined self-assembled micro/nanostructures have also been explored. This might introduce a new architecture and phenomena on compound semiconductor micro/nanosystems, enabling monolithic integration of optoelectronic devices.

When compared with silicon, many of the compound semiconductors have superior intrinsic properties such as optoelectronic properties, high piezoelectric and piezoresistive constants, and wide band gap enabling high-temperature and high-frequency applications. On the other hand, some of the compound semiconductors (group III–V) have lower mechanical strength; however, they are still fully satisfactory as reliable microsystems.

The cost has always been a concern with the compound semiconductors technology; however, the maturing technology, batch processing with high-volume manufacturing, and high yield will, hopefully, drive down the cost. There is already a need for non-classical CMOS development, especially on III–V compound semiconductors, for improving the capability of CMOS where compound semiconductor microsystems can be integrated as in silicon technology.

The III–V nitride and SiC materials with much potential, as discussed in this chapter, are attractive options in optoelectronic as well as sensing applications. However, much development is foreseen to improve the epilayers of these materials on cheap substrates as well as to improve the sacrificial etching processes. By the introduction and maturity of material deposition techniques such as MBE and MOCVD it is possible to achieve the goal.

Furthermore, fundamentally new architectures for the challenging future requirements can be achieved through optical technology where compound semiconductor microsystems can play a key role. The advancing microsystem technology on compound semiconductors has already begun to integrate optoelectromechanical devices into a single chip, which would play a key role in optical technology, and also to mimic one or more of our five human sensors.

Biographies

Dharmarasu Nethaji received his Ph.D. degree in Physics (compound semiconductors) from the Anna University, India, in 1999 and part of the Ph.D. research was carried out at Friedrich Schiller University, Germany. He was awarded DAAD, Germany, fellowship in 1998. He has been working in the field of compound semiconductors for the past 12 years. From 1999 to 2002 he worked at Toyota Technological Institute, Nagoya, Japan, on III–V compound semiconductor multijunction space solar cells. From 2002 to 2005 he worked at the Advanced Telecommunications Research Institute International, Kyoto, Japan, on III–V compound semiconductor-based optical and mechanical devices. He has integrated optical devices (LED and VCSEL) with micromirrors and also achieved high-density LED arrays (2400 dpi). Since 2006 he has been with the Institute of Nanostructure Technologies and Analytics (INA) at the University of Kassel, Germany, where he is heading the optoelectromechanical devices group. He has published more than 50 papers, holds 4 patents, and is a member of the Indian Association for Crystal Growth, India.

Hartmut Hillmer holds a diploma (1985) and a doctoral thesis (1989, summa cum laude) in Physics on optically detected electronic transport in Si and III/V QW structures, both in physics from Stuttgart University. From 1989 to 1998 he was with German Telekom Research Center, Darmstadt, and in 1991 with NTT Optoelectronics Labs, Atsugi-shi, Japan. His habilitation thesis (1996) was on chirped DFB gratings by bent waveguides, ultrafast lasers, and MBE growth of AlGaInAs strain-compensated QW laser structures (Darmstadt University). Since 1999 he has been a full professor in the electrical engineering faculty of Kassel University, Germany, and holds the chair of Technological Electronics. His current research interests are technological implementation, characterization and theoretical model calculations of optoelectronic III/V semiconductor devices: spectral tuning of semiconductor lasers and filters, microsystem technology, and nanotechnology. From 2000 to 2002 he was the dean of the electrical engineering faculty, starting a course in applied computer engineering, and is one of the founding members of the Center for Interdisciplinary Nanostructure Science and Technology (CINSaT). He coordinates the participation of Kassel University with the NanoNetwork Hessen. He was awarded the GINO Innovation award in 2005 and the European Grand Prix of Innovation in 2006. He has published more than 190 papers, holds 14 patents, and is a member of IEEE and the German Physical Society (DPG).

1.03.1 Introduction

Metals and alloys are promising materials to realize microelectromechanical systems (MEMS) with higher performances, since they have wide variety of mechanical properties (elastic modulus, strength, fracture toughness, and fatigue properties) and functional properties (electric and magnetic properties). This chapter is devoted to describing the mechanical properties of metallic thin films, which usually differ from those of counter bulk materials. Section 1.03.2 is focused on the elastic and tensile properties of thin films, while the fatigue and fracture properties are discussed in Section 1.03.3. The mechanical properties data of various materials including amorphous, metallic glasses, and intermetallics, measured by various methods, are presented and their dispersions are discussed in terms of film structure and length-scale effects. In addition, new strengthening methods for thin films are introduced and recent activity in Japan for standardization of micromechanical tests is reported.

In the last part, special attention is paid to shape-memory alloy (SMA) thin films. These intermetallic films have begun to attract considerable interest as powerful microactuators for MEMS. Their mechanical properties and shape-memory behavior are discussed in connection with their microstructures first and then some promising applications of thin-film SMA microactuators are introduced along with the description of their microfabrication techniques.

1.03.2 Mechanical Characterization

1.03.2.1 Introduction

The continued development of MEMS devices is dependent on continued innovation in materials development for application on the micrometer scale. To date, single and polycrystalline silicon have been used in MEMS devices because of their compatibility with micromachine processing. In order to develop high-performance MEMS, however, the application of materials other than silicon is required. Metals and alloys have wide variety of mechanical properties (elastic modulus, strength, fracture toughness, and fatigue properties) and functional properties (electric and magnetic properties). This indicates that the use of metallic materials is promising to realize MEMS with higher performances.

For designing MEMS, materials selection is important to enable durable MEMS, and it is necessary to know the mechanical properties of free-standing metallic thin films on the micrometer scale. There are several length-scale effects on the properties of such microsized elements. Length-scale effects include several factors and may be classified into two categories (Spearing 2000). One is intrinsic effect, and this includes cube–square scaling law and mechanism-dependent scaling effects. The mechanism-dependent scaling effects have been investigated extensively for metallic materials particularly based on the plastic strain gradient mechanism (Hutchinson 2000). The other is extrinsic effect, and this includes microstructure, surface roughness, and micro/nanosized defects, which are usually process-dependent properties, because the microstructure of thin films strongly depends upon their preparation method and defects that may be introduced during processing. Both these types of length-scale effects are considered to affect the properties of microsized elements, and this suggests that we are not able to use the data of counter bulk materials for designing MEMS.

In these materials properties, mechanical properties including elastic constants, yield stress, tensile strength, fracture strength, fatigue properties, and fracture toughness are essential for designing and developing reliable and durable MEMS. These mechanical properties are also important as database for simulation-based design methodology of MEMS.

In Section 1.03.2, mechanical properties of metals and alloys films, which have been and will be used in MEMS devices, are described. Particularly, elastic and tensile properties are emphasized in this section. The mechanical properties including fatigue and fracture of conventional metals and alloys for MEMS materials are also well reviewed in literatures (Allameh 2003, Connolley *et al.* 2005, Spearing 2000). Therefore, new metallic MEMS materials including intermetallics and amorphous and metallic glasses are mentioned in this section.

1.03.2.2 Characterization Method

1.03.2.2.1 Elastic Properties

Elastic properties of metallic thin films are one of the fundamental parameters for the design of MEMS including spring elements, which are used as mechanical sensing and actuating devices. Particularly, the elastic constants determine the

sensitivity of pressure sensor and accelerometer, and the required force during actuation of radio frequency (RF) switch and micromirrors. The measurement methods for elastic constants can be divided into two groups (Ogi *et al.* 2005). One is static or quasistatic method and the other is dynamic one. Static methods include microtensile test and nanoindentation, and dynamic methods include flexural vibration method, ultrasonic method such as electromagnetic acoustic resonance (EMAR), resonant ultrasound spectroscopy (RUS)/laser, and picosecond-laser ultrasound methods.

Microtensile testing method is a simple technique to obtain Young's modulus. Young's modulus can be determined from the slope of the linear elastic portion in the stress versus strain (or force versus elongation) relation, same as bulk materials. In microtensile method, microsized tensile specimens should be prepared from thin-film layers using suitable micromachining technique such as lithography or focused ion beam (FIB) machining. If the gripping of the specimen is not completed, bending and torsional stresses arise during loading, which may affect significantly the stress–strain relationship. In addition, dimensional errors and strain measurement error may also affect the measurement values. Care should be taken with this measurement.

In nanoindentation technique, it is not necessary to remove substrate and to prepare special-type specimen, and elastic modulus in nanometer region can be measured. This technique would therefore be the most suitable to measure elastic constants for in-depth (out-of-plane) direction. The measurement of elastic modulus for in-plane direction is, however, difficult to obtain by this technique. The accuracy of the measurement value depends on those of the indenter shape, and its calibration is essential.

In the flexural vibration method, a cantilever-type specimen is prepared from thin-film layer, and the specimen is vibrated by application of external force. Elastic constants are determined from the resonance frequency and resonance mode. In this measurement method, the gripping (fixed) condition of specimen should be paid attention because a complete fixed (rigid) boundary is assumed in the calculation and gripping condition may affect the measurement accuracy.

The principal advantage of ultrasonic measurement methods is the high accuracy and resolution. Particularly, in the RUS method, the accuracy of the resonance frequency is usually 10^{-6} to 10^{-7}, so the elastic constants can be measured with high resolution. In addition, elastic constants can be measured without removing the substrate in the RUS method, and this is suitable to measure elastic constants of thin films on substrate.

1.03.2.2.2 Tensile Properties

Uniaxial tensile properties are the most important since these properties are essential for designing actual MEMS. Many investigations, therefore, have been carried out for measuring tensile properties of metallic thin films (Connolley *et al.* 2005). The specimen size is, however, usually very small, and there are several difficulties in measuring accurate mechanical properties. Recent progress of the tensile testing method of MEMS materials is described by Sharpe, Jr., *et al.* (2003).

1.03.2.3 Mechanical Properties

1.03.2.3.1 LIGA Ni

The typical pure metal for MEMS application is nickel prepared by LIGA (an acronym for the German words *Lithographie, Galvanoformung und Abforming*) process (Hruby 2001). The LIGA process consists of X-ray or ultraviolet (UV) lithography, electroplating, and molding to produce microscale components. X-ray lithography is used to produce a polymer mold (typically poly(methyl methacrylate) (PMMA)), and then the metallic components are formed by electroplating into the mold. This process can create high aspect ratio structure using a deep molding (more than 100 μm deep). The LIGA process is considered to be one of the most suitable techniques to fabricate metallic microcomponents, as this process uses an electroplating process. Pure Ni is the most common material for this process, but this process basically can be applied for any metals and alloys that can be deposited by electroplating.

LIGA Ni is expected to be applied to micromechanical components of MEMS including accelerometer, RF switch, and connector, and the mechanical properties of LIGA Ni films have therefore been investigated intensively. Young's modulus values for LIGA Ni have been measured (Cho *et al.* 2003, Hemker and Last 2001, Lee *et al.* 2005, Mazza *et al.* 1996, Sharpe and McAleavey 1998) by tensile testing. Mazza *et al.* (1996) obtained Young's modulus of LIGA Ni, which is consistent with that of bulk value (207 GPa, *Metals Handbook*, 10th ed., vol. 2, ASTM International). Other researchers, however, reported that the Young's modulus values were between 150 and 180 GPa (Cho *et al.* 2003, Hemker

and Last 2001, Lee *et al.* 2005, Sharpe and McAleavey 1998), and these values were significantly smaller than that of bulk Ni. These Young's modulus values were measured using microtensile specimens, the loading axis of which is parallel to in-plane direction of the film. In as-deposited LIGA Ni films, the grain structures tend to be columnar and tend to have a <001> crystallographic out-of-plane texture (Last *et al.* 2000). Hemker and Last (2001) modeled in-plane Young's modulus of an out-of-plane textured thin film and calculated the in-plane Young's modulus value to be 171–177 GPa. These values are consistent with measured values, and this suggests that the decrease in Young's modulus values of LIGA Ni film is due to the preferred crystallographic orientations. In contrast, Young's modulus values for out-of-plane direction were obtained by dynamic method (Majjad *et al.* 1999) and nanoindentation (Stauss *et al.* 2003). The measured Young's modulus values were 195 and 200 GPa. This indicates that LIGA Ni thin films have anisotropic mechanical properties.

In addition to elastic modulus, tensile properties of LIGA Ni were also investigated widely. Yield stress (usually 0.2% proof stress) obtained was between 300 and 400 MPa, and tensile strength was between 550 and 800 MPa for as-deposited condition (Allameh *et al.* 2003, Buchheit *et al.* 2003, Cho *et al.* 2003, Hemker and Last 2001, Lee *et al.* 2005, Mazza *et al.* 1996, Sharpe and McAleavey 1998). These values are higher compared to those of bulk Ni (0.2% yield stress of 59 MPa and tensile strength of 317 MPa, *Metals Handbook*, 10th ed., vol. 2, ASTM International). The grain diameter of as-deposited LIGA Ni film is very fine and of the order of several micrometers (Buchheit *et al.* 2003, Hemker and Last 2001), and the high strength of LIGA Ni films is due to the grain refinement. Actually, if the as-deposited Ni film is annealed at high temperature and the grain growth occurs, the tensile strength decreases (Hemker *et al.* 2001). The tensile properties of as-deposited condition seem to be very scattered. The strength of the film generally depends on the grain structure including texture and the defects involved in the film, and these depend on processing parameters during electroplating conditions for LIGA Ni. The above-mentioned data were obtained in the films with various grain diameter and film thickness. Further investigation on the relation among mechanical properties, microstructure, and processing conditions is required.

Other metals and alloy thin films including Ni–Fe and Ni–Co have been prepared by the LIGA process; the mechanical properties were measured (Buchheit *et al.* 2003, Cheng and Chen 2004, Stauss *et al.* 2003) and similar results have been obtained. The detailed mechanical properties of LIGA films were also reviewed by (Connolley *et al.* 2005). The mechanical properties measured in selected investigations are shown in **Table 1**.

1.03.2.3.2 Conventional Metallic Thin Films

Pure metals including Al, Au, Ag, Pt, Rh, and Ru thin films have been used as electrode, contact and

$Pd_{76}Cu_7Si_{17}$ BMG	57.9	–	1140 (bending)	Hata *et al.* (2001)

interlayer materials as well as mechanical components, and these metals are usually deposited on Si. Au thin film is one of the attractive materials for MEMS including RF switches because of its high conductivity that is useful for reducing the loss. Mechanical properties of Au films are therefore required to design mechanical components in the devices.

Young's modulus of Au film is a fundamental property for the devices and has been measured by several methods including microtensile and bending testing. Espinosa and Prorok (2003) and Espinosa *et al.* (2004) measured Young's modulus values of Au thin films of thickness 0.1–0.5 μm prepared by e-beam evaporation. The Young's modulus was determined by membrane deflection experiment (MDE). The resultant Young's modulus was 53–55 GPa, which is significantly lower than that of bulk Au (80 GPa, *Metals Handbook*, 10th ed., vol. 2, ASTM International). Baek *et al.* (2005) measured Young's modulus of Au films prepared by electroplating. The Young's modulus was determined by resonance frequency of cantilever beams, which was electrostatically excited. Young's modulus values obtained were 35.2–43.9 GPa and were also smaller than that of bulk Au. In these films, a strong <111> texture in the thickness direction was observed, and this may be one reason that the Young's modulus values were smaller than that of the bulk material. In contrast, Son *et al.* (2003) obtained Young's modulus values of 110–130 GPa for cantilever specimens prepared from e-beam-evaporated Au thin films of thickness 0.56–1.26 μm. Nanoindentation tests were also performed on these films, and Young's modulus values obtained were 110.4–122.7 GPa. These Young's modulus values are higher compared with the bulk value. In these tests, Young's modulus in out-of-plane direction is considered to be measured, and the similar texture was also observed in these films. The difference of Young's modulus is therefore due to the anisotropy of Au thin films, because the Young's modulus of Au in <111> direction is 117 GPa (Courteny 1990).

Yield stress and tensile strength of Au films varied significantly depending on the grain diameter, the film thickness, and the texture (Emery and Povirk 2003a,b, Son *et al.* 2003). The reported yield stress and tensile strength were 210–340 MPa and 230–350 MPa, repectively, for as-deposited Au films, and these values are much higher compared with that of the bulk Au (130 MPa, *Metals Handbook*, 10th ed., vol. 2, ASTM International). The relation between the mechanical properties and the microstructures in Au films is rather complicated and further investigations are required. Some of the mechanical properties measured for Au thin films are given in **Table 1**.

Mechanical properties of other metallic thin films were also investigated; however, the reported values were scattered, because the fabrication methods and conditions affect the microstructures and defects involved, and this changes the mechanical properties of metallic thin films. In addition, size effects on the mechanical properties of thin films should also be considered. In metallic thin films, the deformation process is governed by the dislocation mechanism, and the motion of dislocation is often controlled by specimen size (Espinosa *et al.* 2006). However, these effects have not been completely analyzed yet. Mechanical properties of metallic thin films, foils, and wires are also summarized in the literature (Connolley *et al.* 2005).

1.03.2.3.3 Multilayer Thin Films

Multilayer metallic thin films are expected to reduce the residual stress and to improve the function. However, the mechanical properties of metallic multilayered thin films have not been intensively investigated yet. This may be due to the difficulty in measurement and analysis methods in these films.

1.03.2.3.4 Amorphous

Amorphous metals or metallic glasses have no crystal structures and no grain boundaries. This means that the mechanical properties are homogeneous and isotropic even if the material size decreases to the micrometer range. In addition, amorphous alloys usually exhibit high corrosion resistance compared to conventional metals and alloys. This property is an advantage for the application of bio-MEMS. These characteristics are favorable for microdevices, and amorphous metals or metallic glasses are considered to be one of the candidate materials for future MEMS. For practical applications of these materials, the evaluation of mechanical properties in the thin-film form is required.

Ogi *et al.* (2002) measured elastic properties of a Ni–P amorphous alloy thin film prepared by electroless plating on an Al–Mg alloy substrate and obtained a complete set of effective elastic stiffness coefficients by EMAR method. The resulting coefficients were those of a transverse isotropic material. C_{11} was 140 ± 14 GPa, whereas C_{33} was 85 ± 3.0 GPa (the film growth is along the x_3 direction), and strong anisotropy between the in-plane and normal

directions was observed; the in-plane Young's modulus is larger than the normal Young's modulus by 34%, for example. The anisotropic coefficients can be interpreted by considering a micromechanics model for local incomplete cohesion (thin ellipsoidal voids) aligned parallel to the film surface. Takashima and Higo (2004) measured Young's modulus of electroless-deposited Ni–P amorphous alloy thin film by microtensile testing and obtained Young's modulus of 115 GPa; this value is comparable to that obtained by Ogi *et al.* (2002) for the in-plane direction. Takashima *et al.* (2001) also measured fracture toughness values of Ni–P amorphous alloy thin film and obtained similar anisotropic crack growth resistance between in-plane and out-of-plane directions.

Shibata *et al.* (2005) measured the complete set of elastic moduli of an Fe–Si–B amorphous-alloy thin film using thickness resonance with EMAR and RUS/laser methods. From the thickness-resonance measurements, out-of-plane shear moduli (C_{44} and C_{55}) were found to be 73.2 and 71.0 GPa. This indicates that the amorphous-alloy thin film shows transverse isotropic elastic symmetry. RUS/laser measurements gave the remaining moduli: $C_{11} = 193.6$ GPa, $C_{33} = 234.3$ GPa, $C_{23} = 72.1$ GPa, $C_{12} = 79.8$ GPa, and $C_{44} = 72.1$ GPa. From the ratios of the elastic modulus ($C_{33}/C_{11} = 1.21$ and $C_{44}/C_{66} = 1.26$), the amorphous Fe–Si–B thin film shows elastic anisotropy between in-plane and the out-of-plane directions in the range of 20–30%.

Tensile properties of amorphous thin films have not been widely investigated yet. Takashima and Higo (2004) performed microtensile tests for an electroless-deposited Ni–P amorphous-alloy thin film. Stress–strain relation is linear until fracture and fracture strength was 2 GPa. Shear bands were observed near the fracture surface and vein pattern was observed on the fracture surface. The fracture strength and the deformation behavior were similar to those obtained for Ni–P amorphous alloys. Mechanical properties measured for amorphous thin films are given in **Table 1** together with those for metallic glass thin films described in Section 1.03.2.3.5.

1.03.2.3.5 Metallic Glasses

Metallic glass is a kind of amorphous, but metallic glasses show viscous flow in a certain temperature range called super-cooled liquid region. If the metallic glasses are formed in this temperature range, microcomponents are expected to be easily prepared using a micromold (Saotome *et al.* 2003).

Zr- and Pd-based metallic glasses are expected to be applied for MEMS, because these two systems are easy to prepare thin films by sputtering. Hata *et al.* (2001) measured Young's modulus of Pd-based ($Pd_{76}Cu_7Si_{17}$, atomic%) and Zr-based ($Zr_{75}Cu_{19}Al_6$, atomic%) metallic glass thin films, prepared by an RF magnetron sputtering, using a thermomechanical analyzer and a microbending testing. The measured Young's moduli of the Zr- and Pd-based metallic glasses are 83.4 and 57.9 GPa, respectively. The Young's modulus of Zr-based thin film is comparable to those obtained for Zr-base bulk ones, but the Young's modulus of Pd-based thin film is lower than those reported for bulk ones (Wang 2005). The tensile strength of the Zr-based film was 1.61 GPa and that of Pd-based film was 1.14 GPa, and these values are slightly smaller than those obtained for bulk metallic glasses (Wang *et al.* 2004). A conical spring-type linear actuator, which is capable of stepwise displacement vertical to the substrate, and an on-chip microvariable inductor have been developed using metallic glass thin films (Fukushige *et al.* 2003, Hata *et al.* 2003).

1.03.2.3.6 Intermetallics

MEMS devices for high-temperature use are expected to be developed for aeronautics and space applications. One class of materials currently being expected to be developed for such applications is intermetallics because of their high-temperature strength and creep resistance. Application of these materials on the micrometer-scale requires an understanding of the effect of a reduction in size on their mechanical properties. The investigations of intermetallics for MEMS materials are, however, very limited. Halford *et al.* (2005) performed fracture tests on microsized, lamellar-structured TiAl and revealed that the lamellar orientation at the crack tip affects their fracture behavior. For the microsized, lamellar-structured TiAl, fracture toughness values (K_Q) are 1.5–7 MPa $m^{1/2}$ (Takashima *et al.* 2005) and are significantly smaller than that obtained for bulk material (18 MPa $m^{1/2}$) (Halford 2003). This indicates that extrinsic toughening mechanisms (crack tip shielding effects in the crack wake region) are not activated effectively, as the crack length is only few micrometers for microcomponents in MEMS devices (Takashima *et al.* 2005). This should be considered for applying these kinds of materials to MEMS.

TiAl thin films are also applied to bimorph actuators. Qu *et al.* (2002) prepared TiAl thin films by DC

magnetron sputtering from Ti and Al targets. The Young's modulus of the film was 175 GPa and this is higher than those of conventional metallic films. They also fabricated TiAl/SiO_2/TiAl bimorph structures. Further investigations on these materials are expected for future MEMS.

1.03.2.4 Strengthening Method

In order to further improve the performance and the reliability of MEMS devices, it is desirable to strengthen materials. It is, however, rather difficult to apply conventional strengthening methods to MEMS materials, as the sizes of MEMS are of the order of micrometers and controlling the mechanical properties based upon microsized structural modifications is no longer applicable to such small-scale materials. Strengthening based on nanostructural control would be one of the most promising methods for microsized materials, thus making its development necessary for potential candidate materials for MEMS applications.

1.03.2.4.1 Amorphous Alloy Thin Film

Tarumi *et al.* (2003) found that nanocrystals are formed under irradiation by FIB at an angle of <70° to the surface of Ni–P amorphous-alloy thin film. In contrast, nanocrystals are not formed under FIB irradiation at an angle between 70° and 90° to the surface, although Ga ion implantation does occur in the amorphous layer. The formation of nanocrystals in the amorphous phase is expected to be effective for improving the mechanical properties of amorphous thin film, with ion implantation also being a technique for improving the mechanical properties of bulk materials. In addition, the beam diameter of FIB can be focused to <100 nm, and this technique can irradiate microcomponents in MEMS. This indicates that FIB is applicable for strengthening microsized components in MEMS.

Figure 1 shows a transmission electron micrograph (dark field image) of Ni–P amorphous thin film after FIB irradiation at an angle of 15° from its surface. Nanocrystals with a diameter of approximately 10 nm are clearly observed in the irradiated area, and their crystallographic orientation is aligned to one direction as shown in Figure 1. This type of nanostructural modification is expected to be a new strengthening method for MEMS components.

A selective strengthening method for microcomponents in MEMS by ion implantation through FIB irradiation has been developed. Ion implantation by

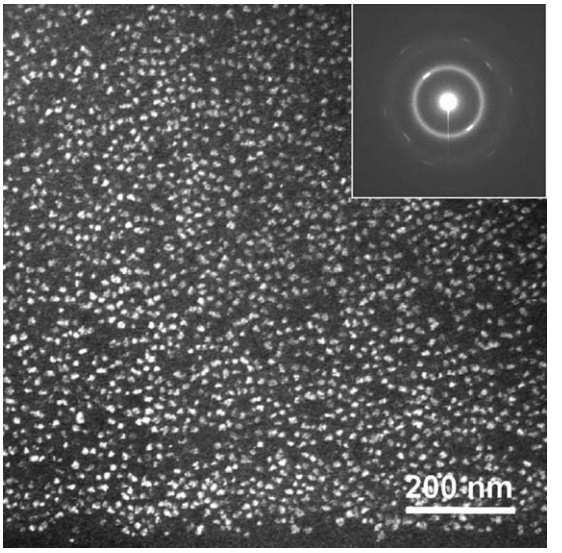

Figure 1 Selected area diffraction pattern (SADP) and dark-field electron micrograph (DFEM) taken from the focused ion beam (FIB)-irradiated plane of Ni–P amorphous alloy thin film. In the DFEM, uniform distribution of a large amount of nanocrystals is observed throughout the irradiated plane.

FIB was also performed on the surface of microcantilever specimens of Zr–Ni ($Zr_{65}Ni_{35}$) amorphous alloy (Kubota *et al.* 2005). In this irradiation, the Ga concentration increased to 8 at.% near the surface. Bending tests were carried out on specimens and compared (Figure 2). The bending strength of a

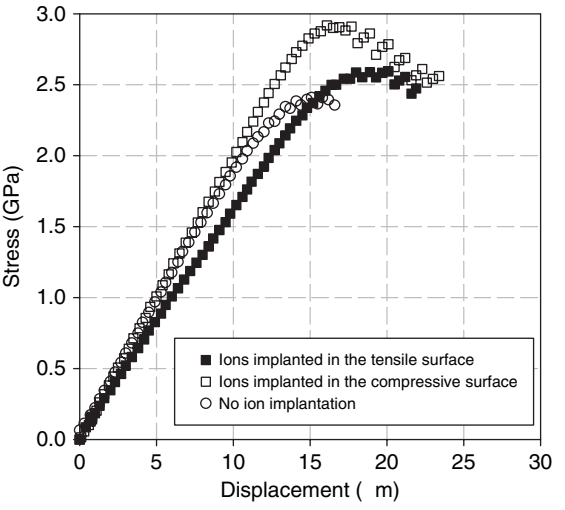

Figure 2 Load-displacement response of a microsized sample of Zr–Ni ($Zr_{65}Ni_{35}$) with Ga ions implanted in the compressive surface, with Ga ions implanted in the tensile surface, and without ion implantation.

Zr–Ni alloy has been shown to increase from 2.4 to 2.6 GPa by implantation on the cantilever's tensile surface or to 2.9 GPa by implanting the compressive surface. Ions implanted on the tensile surface and on the compressive surface are confirmed to increase the bending strength in comparison to samples with no ion implantation. These results suggest that ion implantation causes an increase in strength of the microsized material tested.

The small areas over which this implantation can be applied allow the capability to selectively strengthen regions of MEMS by implantation of ions on the surfaces of amorphous materials. Control over variables such as which surface is implanted, the dose applied, and the angle at which it is applied also allow further potential of developing this technique to locally customize properties. This can be achieved with only a minimal addition to the processing of batch-produced MEMS products.

1.03.2.4.2 Nanocomposite Thin Film

Deposited metallic thin films generally exhibit superior mechanical properties compared to those of counter bulk materials. This is considered to originate from the nanosized grain structures of the deposited thin films. These mechanical properties would be further enhanced by forming nanocomposite in the thin film layer. To date, several ceramic nanoparticle-reinforced metallic thin films have been prepared. Li and Li (2003) fabricated nanosized, Si_3N_4-reinforced NiFe nanocomposite layer of thickness up to 400 μm on a Cu substrate by electroplating technique. Permalloy (79% Ni, 21% Fe) was electroplated in the solutions with different percentages of nanosized amorphous Si_3N_4 particles (<30 nm). The microhardness of NiFe nanocomposite increased with increasing Si_3N_4 contents in as-deposited condition. Shi *et al.* (2006) prepared Ni–Co/SiC nanocomposites with various contents of SiC nanoparticles by electrodeposition. Ni–Co/SiC nanocomposite layer of thickness 20 μm were prepared on a Cu substrate by electrodeposition in a nickel–cobalt-plating bath containing SiC nanoparticles. The microhardness, wear, and corrosion resistance of the nanocomposite layer also increased with increasing content of the nano-SiC particles in as-deposited condition. Ceramic nanoparticle-reinforced nanocomposite films are expected to be applied to MEMS to improve their performances.

1.03.2.5 Standardization

Mechanical properties of structural thin films for MEMS are extremely important for designing and fabricating the devices, because the mechanical properties directly determine their performance, reliability, and durability. In developing MEMS, the fabrication of prototype device is relatively expensive and the development of simulation-based design tool is required. The database of mechanical properties on thin films that supported the simulation tool is needed to realize the simulation-based design. The mechanical properties of thin films are, however, dependent on their fabrication processes, as the microstructure of thin films is varied widely by processing. In addition, mechanical properties of these thin films have been measured by researcher's own methods, and it is rather difficult to compare the data obtained in each institute. This is due to the fact that there are no standard tensile testing methods including preparation of specimens, specimen size, and testing procedures for thin film materials.

In Japan, a round-robin test on tensile testing of thin films including metallic materials was performed and the cross-comparison of Young's modulus, tensile strength, and fracture strain was made (Tsuchiya *et al.* 2005). The materials used were single and polycrystalline Si, and Ti and Ni thin films deposited on Si wafers and microsized specimens were prepared from the thin film layer on the same wafer using a photolithography technique. The geometry of each test piece was such that it fits the testing machine at the institute, but the dimensions of the parallel parts of each test piece were standardized at 20 and 50 μm in width and 100 and 500 μm in gauge length, and these dimensions are approximately 1/1000 of the test pieces specified in ISO 6892 for tensile testing of metallic bulk samples. Methods for gripping the test piece, including electrostatic gripping (Tsuchiya *et al.* 1998), adhesives, mechanical gripping, and on-chip methods (Sato *et al.* 1998a), were examined by each institute. Mechanical properties including Young's modulus, tensile strength, and fracture strain were measured at each institute and compared. The results of round-robin tests revealed that there were no apparent differences between measuring methods, and the measured properties and deviations had almost the same values. The details of the round-robin test results are described in the literature (Tsuchiya *et al.* 2005).

Based on their results, the proposed draft of tensile testing of thin films was submitted to IEC, and the

international standard was specified as IEC 62047-2 (2006–08) *Semiconductor devices – Micro-electromechanical devices – Part 2: Tensile testing method of thin film materials*. In addition to tensile testing, standardization for axial fatigue testing of thin films was also submitted to IEC and accepted as a new proposal (IEC 62047-6 *Semiconductor devices – Micro-electromechanical devices – Part 2: Axial fatigue testing methods of thin film materials*).

Nanoindentation measurement procedure is also standardized in ISO standards (ISO 14577-1, 2, 3). These testing methods are specified for instrumented indentation, but this practice can be applied to nanoindentation. If these standardized testing methods are used to evaluate mechanical properties of thin films, the cross-comparison of the mechanical properties will be possible, and this is useful for developing MEMS. Standardization for other mechanical-related properties including elastic modulus, residual stress, fatigue, and fracture is desired.

1.03.2.6 Summary

Many research results show that metallic thin films deposited on substrate have anisotropic mechanical properties. This anisotropy originates from the grain structure of the thin films, which is often columnar, and the textures (preferred crystallographic orientations). The texture of thin films generally depends on the preparation process and its condition. Furthermore, some defects including microcracks are often formed during the processing. This anisotropic mechanical property is also found for amorphous alloy thin films that have no crystal form.

In addition to the anisotropy, there are several length-scale effects on the mechanical properties. These length-scale effects include intrinsic mechanism-dependent effects (attributed to the dislocation motion in metallic materials) and extrinsic effects such as surface roughness and dimension errors. These length-scale effects also affect the mechanical properties of metallic thin films.

These facts indicate that the mechanical properties of metallic thin films for MEMS applications should be measured using samples prepared by the same processing of the applied devices. The development of a database for mechanical properties including microstructures and processing is expected for the development of design technology in MEMS.

1.03.3 Shape-Memory Alloy Thin Films

1.03.3.1 Introduction

In the past decade, SMA thin films formed by sputtering have been attracting great interest as powerful actuators in MEMS such as microvalves, microfluid pumps, and micromanipulators (Bellouard 2002, Fu *et al.* 2004, Ishida and Martynov 2002, Krulevitch *et al.* 1996, Miyazaki and Ishida 1999) since the SMA thin films possess the largest available force and displacement as compared to the other type of actuators including electrostatic, electromagnetic, and piezoelectric ones (**Table 2**). The large surface-to-volume ratio in the thin films reduces the response speed to several tens of milliseconds, though bulk SMA alloys cannot be cycled at a rate of less than 1 Hz. Furthermore, they have compatibility with batch processing technology of silicon micromachining, so the actuators can be powered and controlled electrically by resistive heating of the films, utilizing the potential of integrated microelectronics.

Microdevices fabricated by the silicon micromachining process are demanded in a variety of fields such as medicine, biotechnology, semiconductor industry, and other industrial fields. The first microvalve using SMA thin films emerged in 1992 (Ray *et al.* 1992). Since then, intensive research works have been done to clarify the properties of SMA thin films and, simultaneously, many efforts to fabricate some other microdevices driven by SMA thin films have been made. This article reviews the properties of SMA thin films and introduces MEMS applications.

Table 2 Comparison of microactuators

Driving principle	*Range of motion*	*Force*	*Work output per volume ($J\,m^{-3}$)*	*Response speed*	*Driving voltage (V)*
Electrostatic	Large	0.04 N	1.8×10^5	3 kHz	5–100
Piezo	0.1%	40 MPa	1.2×10^5	10 kHz	20–30
Shape-memory effect (thin film)	5%	600 MPa	3.0×10^7	100 Hz	1–10

1.03.3.2 Mechanism of Shape-Memory Effect

Shape-memory effect (SME) refers to the ability of certain materials to remember an original shape even after rather severe deformation. Some special alloys such as TiNi, AuCd, and CuAlNi spontaneously return to their original, predeformed shape when heated, even if they are deformed beyond the elastic region at a low temperature (typically, up to about 5% for a Ti–Ni film). An example is shown in **Figure 3**. The film was first bent and then put into the hot water. **Figure 3(b)** shows that the film reverted to the original, straight shape when heated in the hot water. At this time, the film produces a large force. Using this recovery force, the film can move or grasp a small object.

The SME originates from the change of the crystal structure associated with the martensitic transformation. The martensitic transformation is defined as a diffusionless transformation described by a shear-like mechanism, as shown in **Figure 4(a)** and **4(b)**. In **Figure 4**, the crystal structure of the parent phase (a high-temperature phase) is represented by a square (**Figure 4(a)**) and that of the martensite phase (a low-temperature phase) by a parallelogram (**Figure 4(b)**), for simplicity. As the crystal structure of the martensite has lower symmetry than that of the parent phase, multiple formation of martensites with the same structure but in different orientations is possible, as shown in **Figure 4(b)**. Upon cooling, they form at the same amount to minimize the total elastic energy in the material and, as a result, macroscopic deformation cannot be detected in the stress-free state. The deformation associated with the change of the crystal structure, however, appears under a stress, since the deformation of the martensite proceeds in the way of the conversion from one martensite to another martensite (**Figure 4(c)**). The lattice distortion due to the change of the crystal structure generally amounts to about 20 times more than the elastic deformation and thus a large deformation is obtained. Even after unloading, the shape still remains deformed, but it reverts to the original shape as soon as the crystal structure returns to that of the parent phase by heating (**Figure 4(a)**). The important information obtained from **Figure 4** is that an external stress is necessary to utilize the transformation strain. As the martensite is very easy to deform when compared with the parent phase, an SMA film shows a reversible and repeatable shape change under a certain load (usually called a bias force). This bias force is a critical issue in designing a thin-film SMA actuator, as discussed later.

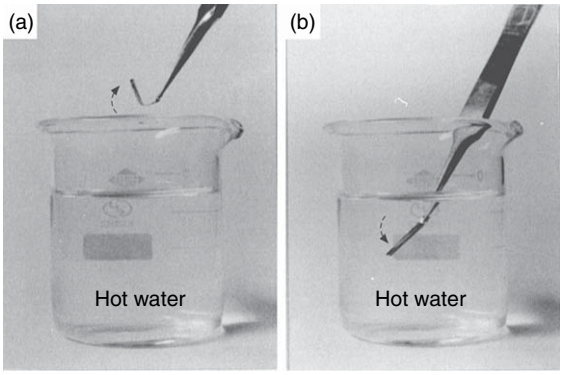

Figure 3 Shape-memory effect (SME) of sputter-deposited TiNi Film: (a) before and (b) after immersion in hot water.

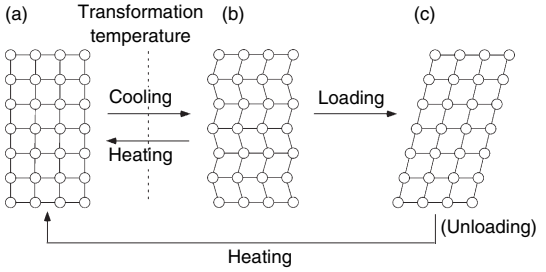

Figure 4 Schematic illustration of shape-memory effect (SME) due to change of crystal structure through transformation: (a) at high temperatures; (b) at room temperature; and (c) under a stress at room temperature.

1.03.3.3 Sputtering Process

SMA thin films of thicknesses ranging from 0.5 to 20 μm can be produced by sputtering. They are deposited on various substrates such as silicon wafers, polyimide films, and glass plates. **Figure 5** shows the schematic illustration of a sputtering apparatus. In the sputtering process, positively charged argon ions strike the target biased negatively and remove target atoms. These sputtered atoms condense on the substrate to form a thin film.

The early difficulties to overcome in fabricating thin films were porous structure, oxygen contamination, composition deviation, and so on. Sputtering parameters such as substrate temperature, sputter gas pressure, target-to-substrate distance, and target power play an important role in the structure and composition of deposited films. For example, if

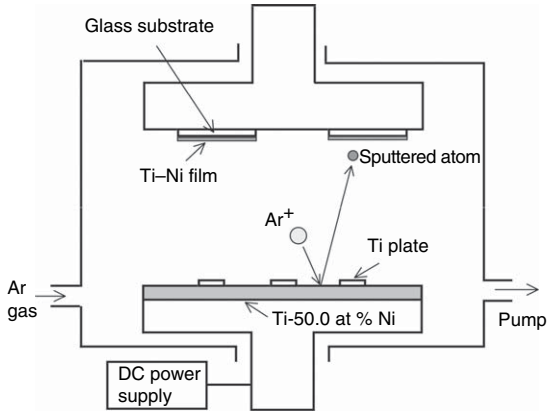

Figure 5 Schematic illustration of a sputtering apparatus.

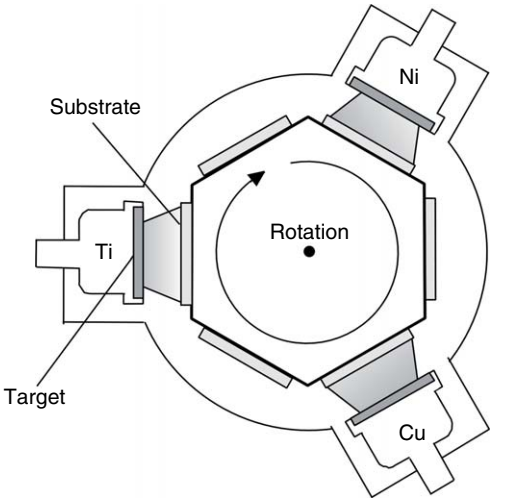

Figure 6 Schematic illustration of a carrousel-type magnetron sputtering apparatus (the view from above).

substrates are not heated, as-sputtered thin films are amorphous. These films require postsputtering heat treatment for crystallization. On the other hand, heated substrates (typically above 600 K) produce crystalline films with $<110>_{TiNi}$ fiber texture and fine-grained structure (Hou *et al.* 1995).

Sputtering gas pressure is another important parameter that influences the film structure. High gas pressure produces porous columnar structure, resulting in brittleness (Ishida *et al.* 1993). Oxygen contamination also causes brittleness and composition shift of deposited films by the formation of Ti-rich oxide. To avoid this contamination, a high-vacuum system (base pressure, 2×10^{-5} Pa) is necessary, but more important is presputtering of a Ti target with the shutter closed. Sufficient presputtering prior to sputtering can reduce the oxygen partial pressure effectively because of the getter effect of titanium.

The deviation of film composition from the target composition and its variation both in the plane and across the thickness are still troublesome problems, since a small shift of film composition causes a large change of the martensitic transformation temperature. The composition shift arises from the differences in sputtering yield, angular flux distribution, and lateral diffusion due to the collision with Ar gas and so on between sputtered species. In addition, the development of localized target wear and the variation in target composition with sputtering time make composition control difficult. After all, precise composition control is experientially achieved depending on the excellent reproducibility of sputtering. In most cases, the composition of Ti–Ni films shifts to the Ni-rich side because of higher sputtering yield of nickel. The compensation is done by placing titanium plates on top of the Ti–Ni target (**Figure 5**) or by using multiple targets. The former method involves a difficulty in reproducing film composition, though it is convenient. On the other hand, the latter method is suitable for precise control of film composition, since the supply of a constituent element from each target can be controlled independently. **Figure 6** shows a carrousel-type magnetron sputtering apparatus employed by the authors to produce Ti–Ni–Cu ternary alloy thin films (Ishida A *et al.* 2005). This apparatus has a rotating substrate holder at the center, which is surrounded by several targets. The power of each target can be controlled independently, allowing any composition.

1.03.3.4 Microstructure and Shape-Memory Behavior of Sputter-Deposited Thin Films

Amorphous films offer the opportunity to design the shape-memory behavior of the films by heat treatment. Therefore, most of the material science research works have been focused on the amorphous films.

For Ni-rich Ti–Ni thin films, conventional heat treatment, i.e., solution treatment followed by aging treatment, is available to stabilize the shape-memory behavior, in the same manner as for bulk materials. This heat treatment produces the same microstructure as that in bulk materials (i.e., distribution of fine Ti_3Ni_4 in the TiNi matrix) (Ishida *et al.* 1996).

In contrast, Ti-rich Ti–Ni thin films show peculiar fine microstructures, which have not been reported in bulk materials. **Figure 7** summarizes the microstructures of the films crystallized from the amorphous state (Kawamura *et al.* 2000). When an amorphous Ti-48.2 at.%Ni thin film is heat-treated at various temperatures, the microstructure in the TiNi matrix changes drastically in the sequence of (d) plate precipitates along {100} planes of the TiNi matrix, (c) plate precipitates and spherical Ti_2Ni precipitates, and (b) spherical Ti_2Ni precipitates, with increasing heat-treatment temperature (Ishida *et al.* 1997). The high-resolution electron microscopy revealed that the plate precipitates have coherency with the matrix, while the spherical Ti_2Ni precipitates are semicoherent with the matrix. Besides semicoherent Ti_2Ni precipitates, Ti_2Ni particles that do not show any specific orientation relationship form in films containing higher Ti content (**Figure 7(a)**).

The drastic change in microstructure with heat treatment and composition severely affect the shape-memory characteristics. **Figure 8** demonstrates the useful shape memory characteristics of the thin films containing the coherent plate precipitates (**Figure 7(d)**). In these experiments the strain of the film was measured during cooling and heating under a constant stress of 400 MPa. When cooled, the film shows elongation due to the martensitic transformation at a certain temperature. The strain associated with the martensitic transformation should completely recover due to the reverse martensitic transformation on heating. However, if plastic deformation is introduced during transformations, the residual strain remains after a thermal cycle, meaning that such a film is not suitable for an actuator. The Ti-50 at.%Ni thin film, which has no precipitates, shows a large transformation strain but a large plastic strain after a thermal cycle. On the other hand, the Ti-45.2 at.%Ni thin film shows no residual strain but a small transformation strain. The Ti-47.9 at.%Ni thin film annealed at 723 K for 1 h exhibits both a large transformation strain, which is comparable to

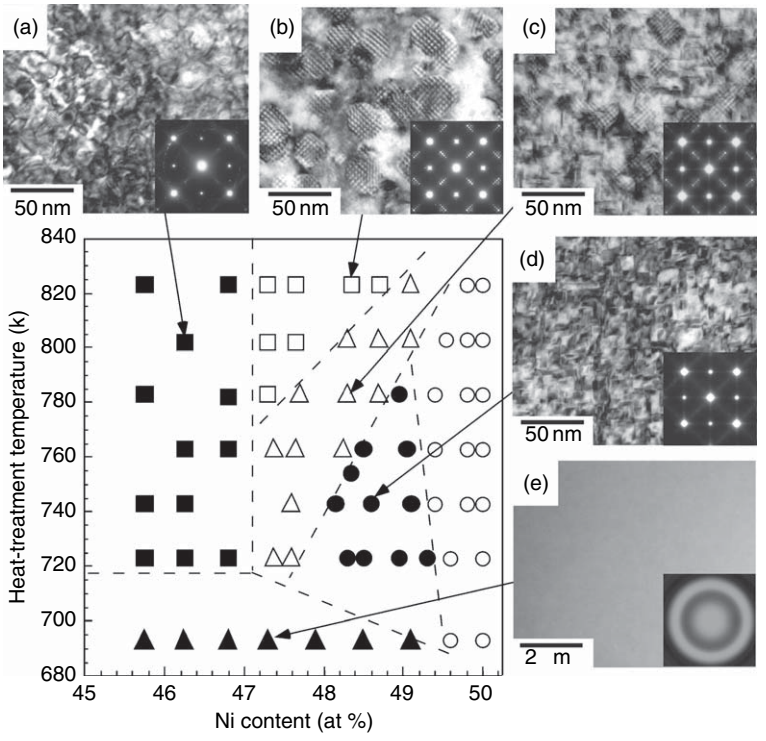

Figure 7 Various precipitates in the Ti–Ni matrix of Ti-rich Ti–Ni thin films heat-treated at various temperatures for 1 h: Solid squares (■) are Ti_2Ni particles with random orientation (a); open squares (□) are Ti_2Ni precipitates with the same orientation as that of the matrix (b); open triangles (△) are plate precipitates and oriented Ti_2Ni precipitates (c); solid circles (●) are plate precipitates (d); open circles (○) indicate no precipitates; and solid triangles (▲) are amorphous films (e). (Source: Kawamura Y, Gyobu A, Saburi T, Asai M 2000 Structure of sputter-deposited Ti-rich Ti–Ni alloy films. *Mater. Sci. Forum* **327–328**, 303–6.)

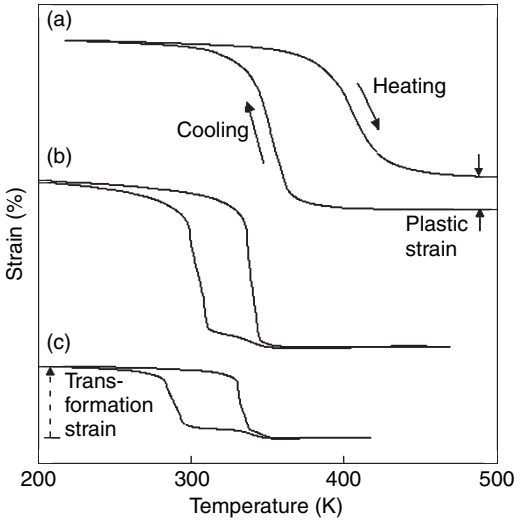

Figure 8 Effects of heat treatment and film composition on strain–temperature curves under a constant stress of 400 MPa for Ti-rich Ti–Ni thin films: (a) Ti-50 at.%Ni film annealed at 773 K for 1 h; (b) Ti-47.9 at.%Ni film annealed at 723 K for 1 h; and (c) Ti-45.2 at.%Ni film annealed at 773 K for 1 h.

that of the Ti-50 at.%Ni thin film, and no permanent strain after a cooling–heating cycle, which is comparable to the shape-memory behavior of the Ti-45.2 at.%Ni thin film. Annealing temperatures higher than 773 K, however, caused the appearance of plastic strain and the decrease of transformation strain. Obviously, the fine microstructures shown in **Figure 7(d)** are effective to improve the shape-memory behavior (Kajiwara *et al.* 1996).

Basically, Ti-rich Ti–Ni thin films exhibit higher transformation temperatures than Ni-rich thin films. In bulk alloys, however, the shape-memory behavior of Ti-rich Ti–Ni alloys has not been utilized and even not studied, since they are very brittle due to coarse grain boundary precipitates formed during casting. In contrast, the shape-memory behavior and mechanical properties of thin films are drastically improved by peculiar fine structures, as is obvious from **Figures 6** and **7**. Therefore, Ti-rich Ti–Ni thin films seem to be more attractive than Ni-rich Ti–Ni thin films from the viewpoint of practical use as well as fundamental aspects.

Ternary SMA thin films (Miyazaki *et al.* 1997) such as Ti–Ni–Cu, Ti–Ni–Pd, Ti–Ni–Hf, and Ti–Ni–Zr are also fabricated by sputtering. Substitution of Cu for Ni decreases temperature hysteresis, while substitution of Pd for Ni increases martensitic transformation temperatures with narrow temperature hysteresis, as in bulk materials. These characteristics are effective to achieve a high-response actuation. Recently, it was reported that a Ti–Ni–Zr thin film shows a perfect SME under a high stress at temperatures above 373 K, though bulk alloys with the same composition are so brittle that the shape-memory behavior has not been measured (Sawaguchi *et al.* 2004). The diversity of SMA thin films is one of the advantages of thin-film SMA actuators.

Besides ordinary SME, two-way SME (Kuribayashi 1990) has also been reported. Furthermore, a perfect superelasticity (Miyazaki *et al.* 1994) has been achieved in the form of thin film as well.

As discussed above, the shape-memory behavior of sputter-deposited thin films is different from that of conventional bulk alloys and is sensitive to heat treatment, composition, and bias stress. This makes it difficult for mechanical engineers and researchers to use SMA thin films. The information on shape-memory behavior of sputter-deposited thin films is, however, available in several material science journals (Ishida and Miyazaki 1999, Ishida *et al.* 1996, 2001, Sato *et al.* 1998b) and establishment of the database is in progress.

1.03.3.5 Mechanical Properties of Sputter-Deposited Thin Films

The measurement of stress–strain curves has been performed for shape-memory thin films with equiatomic, Ni-rich, and Ti-rich compositions (**Figure 9**) (Ishida *et al.* 2000). A Ti-50.0 at.%Ni thin film shows an elongation of more than 50%, while a Ti-51.5 at.%Ni thin film containing a large amount of

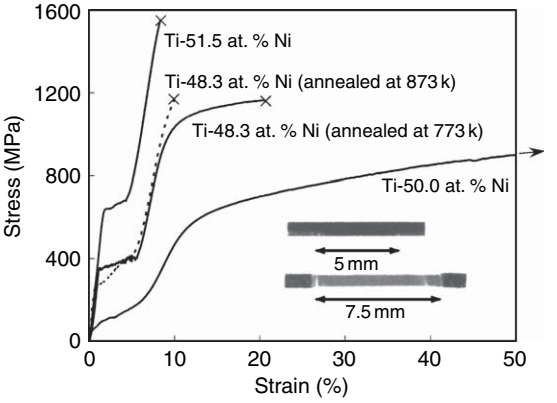

Figure 9 Stress–strain curves of Ti-48.3, 50.0, and 51.1 at.%Ni films. (X means fracture.) The inset shows the Ti-50 at.%Ni films before and after deformation.

Ti_3Ni_4 shows a fracture stress of 1.6 GPa. These values are comparable to those in bulk materials. Furthermore, a Ti-48.3 at.%Ni thin film annealed at a low temperature (773 K) shows an elongation of almost 20%. It is known that a bulk material with the same composition does not show any plastic deformation. This improvement of plasticity is attributed to suppression of grain boundary precipitation, since a Ti-48.3 at.%Ni thin film annealed at a high temperature (873 K) shows grain boundary precipitation, resulting in no plastic deformation. In general, the yield stress for plastic deformation of thin films seems higher than that of bulk materials, owing to the small grain size (<4 μm). The grain size of bulk materials is typically several tens of micrometers.

It has been found that the advantages of crystallized thin films with respect to structure are (1) small grain size, (2) formation of unique metastable precipitates, and (3) suppression of coarse grain boundary precipitates, which bring out stable SME and reliable mechanical properties compared with the conventional shape-memory bulk alloys.

1.03.3.6 Thin-film SMA Microactuators

Ordinary SME is one-way, in that a deformed shape in the martensite phase recovers the original shape in the parent phase. To achieve reversible actuation, a bias force is required to deform the film in the martensite phase, as discussed in Section 1.03.3.2. Depending on the source of a bias force, thin-film SMA microactuators can be classified into four types: (1) bimorph, (2) freestanding, (3) two-way SME, and (4) differential types, as shown in **Figure 10**. For bimorph actuators, the bias force is provided by a thermal stress exerted from the substrate, while for freestanding actuators, there is an external source of stress such as bias pressure and a spring. The bimorph actuators can produce large deflections at low forces while the freestanding ones are capable of exerting large forces over a substantial stroke. In general, the bimorph actuators are used for microgrippers (**Figure 13**), micromirrors and so on, whereas the freestanding actuators are used for microvalves (**Figure 14**) and micropumps (**Figure 15**).

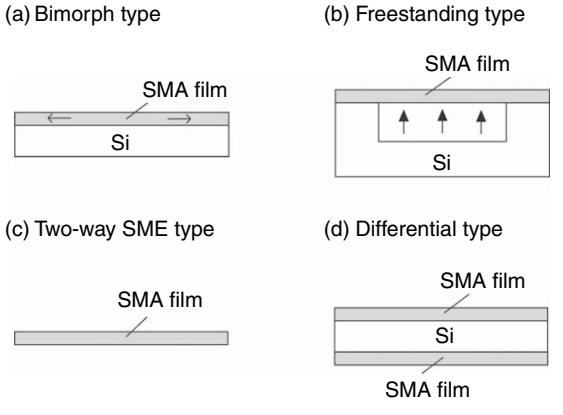

Figure 10 Various types of thin-film shape-memory alloy (SMA) microactuators.

Two-way SME utilizes the two-way SME. Two way means spontaneous shape change on both cooling and heating, thus displaying a repeatable shape change without a bias force. This effect is, however, obtained by aging under constraint, which is difficult to incorporate into the MEMS fabrication process. Further, control of the shape changes and recovery forces on both cooling and heating is difficult. For these reasons, this type of actuators is rarely used.

In differential-type actuators (Benard *et al.* 1998), the two SMA actuators work antagonistically, i.e., if one actuator is heated to shrink, the other actuator at room temperature extends. The advantages of these actuators are a large force and a large efficiency of energy conversion, but the problem is thermal isolation between the two actuators.

1.03.3.7 Technical Issues in Thin-film SMA Microactuators

The application of SMA thin films as microactuators produces additional challenging problems. The understanding of stress evolution and relaxation in thin films during annealing and micromachining is inevitable to prevent detachment of films and to control the actuation of SMA thin films especially for bimorph-type actuators (Grummon and Zhang 2001). The stress in SMA thin films consists of intrinsic and extrinsic stresses; the former is caused by deposition and crystallization, while the latter comes from differential thermal expansion. In addition to the stress in films, characteristics of the film/surface interface, such as the presence of reaction products, affect the film adhesion.

Film thickness is an important parameter in designing a thin-film SMA actuator. **Figure 11** shows the effect of grain size-to-film thickness ratio on the shape-memory behavior and mechanical properties of thin films. It is apparent that both of them are affected by the surfaces if the film thickness is less than 4 μm, which corresponds to a mean grain size of this film (Ishida and Sato 2003).

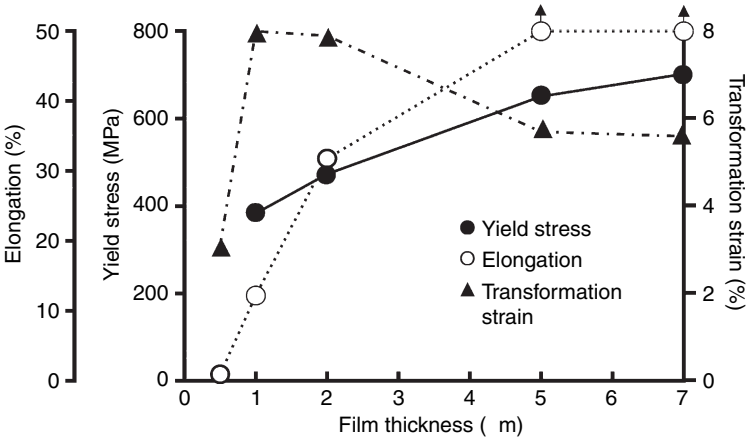

Figure 11 Thickness effects on shape-memory behavior and mechanical properties of Ti-50 at.%Ni film.

1.03.3.8 Microfabrication of SMA Thin Films

The possibility of integrating TiNi SMA thin films into silicon micromachining process was first demonstrated in 1990 (Walker *et al.* 1990). They deposited a Ti–Ni thin film onto a polyimide layer, wet etched the Ti–Ni thin film to make a serpentine shape, and released it by reactive ion etching (RIE) of the sacrificial polyimide layer. **Figure 12** shows the fabrication process of the microvalve shown in **Figure 14(b)** (Ishida and Martynov 2002):

(1) The backside of a Si wafer is anisotropically wet-etched to produce a thin membrane of silicon (~40 μm) for supporting an island of silicon, which eventually becomes the poppet of the valve.
(2) A layer of TiNi is sputter-deposited on the Si membrane and subsequently annealed for crystallization.
(3) A layer of gold is sputter-deposited on top of the TiNi layer, for facilitating masking in TiNi wet etching and for providing electrical contact to the conductive path of the actuator.
(4) The Au and TiNi films are patterned with wet etchants.
(5) The gold on the active parts of the actuators is removed.
(6) The remaining silicon is etched out to release the poppet and active parts of the SMA actuator.
(7) Finally, a microvalve is assembled (see **Figure 14(b)**).

The main issues to be addressed to integrate the sputter-deposited TiNi film into a silicon micromachining process are the following:

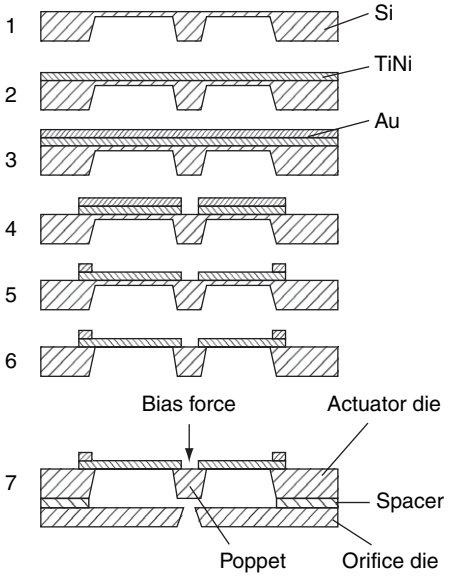

Figure 12 Micromachining steps of the microvalve are shown in (b): (1) backside Si etching; (2) deposition of TiNi film followed by crystallization annealing; (3) deposition of gold; (4) patterning and etching of gold and TiNi films; (5) removal of gold on the active parts; (6) etching of Si to release TiNi films; and (7) assembling. (Source: Ishida A, Martynov V V 2002 Sputter-deposited shape-memory alloy thin films: Properties and applications. *MRS Bull.* **27**, 111–14; reproduced with permission from MRS Bulletin.)

(1) Compatibility with the high annealing temperature (above 773 K) of SMA films
(2) Patterning methods for SMA films
(3) Selective release of SMA films from the substrate
(4) Compatibility with bonding process
(5) Internal stress and adhesion of SMA films

As described earlier, an amorphous film of TiNi is crystallized above 773 K, which causes no problem with a silicon wafer, but may not be compatible with materials that become unstable at high temperatures. Deposition of crystalline films onto heated substrates may avoid this problem. Hou *et al.* (1995) demonstrated the feasibility of producing crystalline SMA films on polymeric substrates by heating the substrate.

For etching of Ti–Ni thin films, $HF/HNO_3/H_2O$ solutions are usually used. A solution of $HF:HNO_3:H_2O=1:1:4$ allows selective etching of a Ti–Ni film deposited on a Si substrate (Makino *et al.* 2000). The problem of this etchant is undercut and backetching, since this process is isotropic etching (Gill *et al.* 2001). When compared with this chemical etching, electrolytic photoetching shows some advantages such as a high etch rate, good surface finish, and near vertical sidewall. As an electrolyte, 5% sulfuric acid in methanol (Kohl *et al.* 1996) and lithium chloride in ethanol (Mineta and Makino 2005) have been reported. RIE (3 sccm of $SiCl_4$ gas, 5 mTorr, 250 W, 20 °C, 90 min) is applicable to the etching of Ti–Ni (Nakamura *et al.* 1997). Ion milling (Gill *et al.* 2001), liftoff (Nakamura *et al.* 1996), and laser machining (Davies *et al.* 2002, Kohl *et al.* 1995) have been also reported for etching of Ti–Ni thin films. These methods can produce a vertical sidewall and avoid back-etching unlike wet etching.

On the other hand, an SMA film should not be damaged during etching of silicon. Though potassium hydroxide (KOH) and ethylene diamine pyrochatecol (EDP) are the most common anisotropic etchant of silicon and are commonly used in fabricating devices with SMA thin films, they (especially KOH) are known to attack the TiNi thin film (Krulevitch *et al.* 1996). To avoid this problem, RIE or deep RIE (Fu *et al.* 2005, Gill *et al.* 2002) is employed. Makino *et al.* (2001) measured the etch rates of Si, TiNi thin film, as well as those of SiO_2, Cr and positive photoresist layers as mask material during RIE in SF_6 at 30 sccm, with 100 mTorr, and at an RF power of 100 W. The result showed that silicon was etched at about 480 nm min^{-1} whereas no etching was observed for TiNi thin films. As mask material, the Cr layer showed superior results, whereas the SiO_2 layer and the photoresist were etched at about 1 and 60 nm min^{-1}. This method allows only Si to be etched without etching of a TiNi thin film.

A bonding temperature is also selected carefully so that the SME is not damaged. A high-temperature process causes the coarsening of the structure of a SMA film, resulting in an increased plastic strain after a thermal cycle. Makino *et al.* (2000) carried out anodic bonding between a TiNi film and a Pyrex glass at 623–673 K for 1–3 h in vacuum and diffusion bonding between two TiNi films under a bonding pressure of 210 MPa at 473–673 K for 1–5 h in vacuum. They were reported to obtain sufficient bond strengths without damaging the TiNi thin films.

1.03.3.9 Application of SMA Thin Films

So far, a number of microdevices activated with TiNi thin-film microactuators have been reported: microvalves (Kohl *et al.* 1997, 1999), micropumps (Benard *et al.* 1998, Makino *et al.* 2001, Xu *et al.* 2001), microreley (Johnson 1999), micromirrors (Fu *et al.* 2005, Johnson and Martynov 1997), out-of-plane spacers (Johnson and Martynov 1997), microgrippers (Roch *et al.* 2003, Wang *et al.* 2002), and microclips (Mineta *et al.* 2005, Takeuchi 2000). **Figure 13** shows an SMA-actuated microgripper fabricated by Krulevitch *et al.* (1996). The size of the microgripper is 1000 μm × 200 μm × 380 μm. Thermal stress between the Ti–Ni–Cu film and the Si substrate provides a bias force. The recovery force of the SMA films deflects each side of the microgripper up to 55 μm for a total gripping motion of 110 μm when the SMA films are heated to 70°C. When fully open, the force exerted by the film corresponds to a 13 mN gripping force at the tip of the gripper. The maximum switching rate for fully opened to fully closed is approximately 100 Hz in air, with an input power of 30 mW in air and 150 mW in water.

The microvalve with a thin-film SMA actuator was first reported in 1992. **Figure 14** shows the

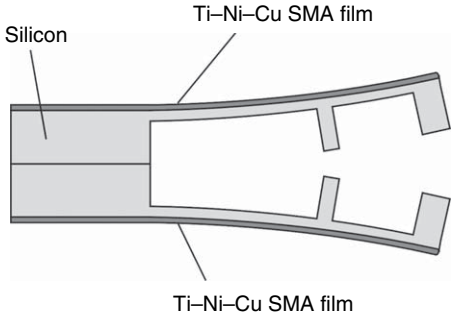

Figure 13 Microgripper driven by shape-memory alloy (SMA) film. (Source: Krulevitch P, Lee A P, Ramsey B R, Trevino J C, Hamilton J, Northrup M A 1996 Thin film shape memory alloy microactuators. *J. Microelectromech. Syst.* **5**, 270–82.)

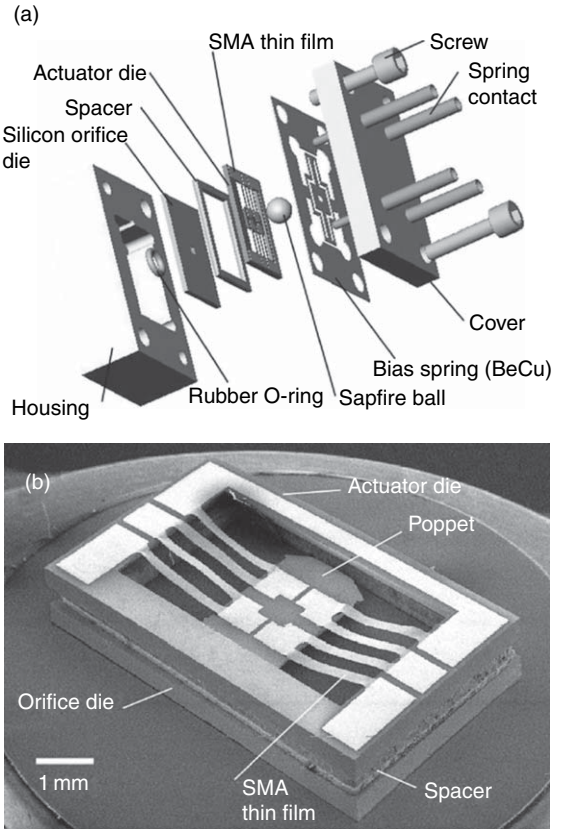

Figure 14 Microvalve driven by shape-memory alloy (SMA) film: (a) exploded view and (b) subassembly of micromachined parts. (Source: Ishida A, Martynov V V 2002 Sputter-deposited shape-memory alloy thin films: Properties and applications. *MRS Bull.* **27**, 111–14; reproduced with permission from MRS Bulletin.)

microvalve manufactured by the TiNi Alloy Company (Johnson 1999). It consists of an actuator die with a poppet controlled by eight TiNi thin-film strips of 3.5 μm thick and 250 μm wide (**Figure 12(b)**), a silicon orifice die, a spacer, and a bias spring. All the elements are assembled in a plastic package (**Figure 12(a)**). The bias spring forces the poppet towards the orifice, so when the current is off the TiNi strips supporting it are elongated allowing the poppet to move down and close the orifice. Resistive heating of the SMA thin films causes it to transform from the martensite phase to the parent phase. By this transformation, TiNi strips recover the original length, lifting the poppet against the bias force and opening the valve. When the current is turned off again, the TiNi strips supporting the poppet are cooled down, transform into the martensite phase, and are easily deformed by the bias spring causing the valve to close. The device has a poppet displacement of ~100 μm and bias force of 0.5 N. It is operated with an electric current of 50–100 mA. The response time is about 10 ms; maximum flow is up to 2000 sccm at 0.13 MPa. This valve survives more than two million cycles.

Recently, a micropump actuated by an SMA thin-film diaphragm was fabricated by Shin *et al.* (2005). **Figure 15** illustrates a cross-sectional view of a pumping chamber. The NiTi membrane of radius of 7 mm is placed above the inflow and the outflow ports. The o-ring and the faceplate clamp the membrane onto the chamber body, leaving a small cavity between the NiTi membrane and the chamber body. Under a bias pressure, the membrane deflects upward at room temperature. When heated, the membrane transforms from the martensite phase to the parent phase and the deflection decreases. The net volume change under the membrane produces a flow rate. In this pump, hot liquid is forced out of the cavity on heating and cool liquid enters the cavity on cooling. This forced cooling mechanism increases the operating frequency of this pump up to 100 Hz, leading to a large flow rate. Their device, which is cubic with a side length of 2 cm and which has NiTi membranes at each of its four faces, achieved a high flow rate of 152 $cm^3\ min^{-1}$ and an output force of 100 N.

Figure 16 shows some devices fabricated by Ishida *et al.* (2005). **Figure 16(a)** shows a microgripper. A similar device was reported by Gill *et al.* (2001). **Figure 16(b)** and **16(c)** shows a microconveyer and a legged robot. The microconveyer can transport an aluminum plate of 48 mg. The microrobot can walk with a load on its back. The walking speed is 400 $\mu m\ s^{-1}$ under a voltage of 8 V and a frequency of 1 Hz. The operation principles of the

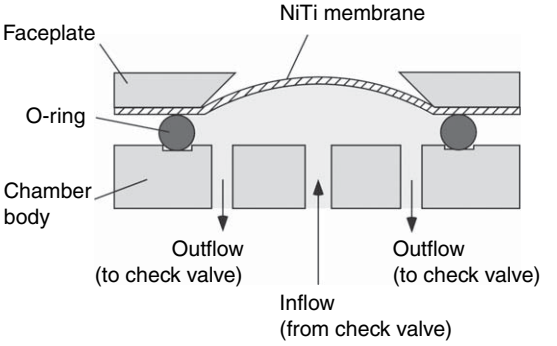

Figure 15 Micropump. (Source: Shin D D, Mohanchandra K P, Carman G P 2005 Development of hydraulic linear actuator using thin film SMA. *Sens. Actuators A* **119**, 151–6.)

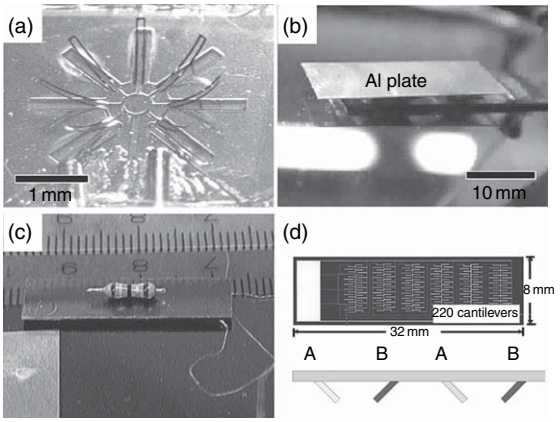

Figure 16 (a) Microgripper; (b) microconveyer transporting aluminum plate; (c) legged robot carrying resistance; and (d) mask pattern for the legged robot and operation principle.

microconveyer and the microrobot are the same, and are shown in **Figure 16(d)**. These devices consist of two groups of actuator arrays arranged oppositely, as shown by the A group and the B group in the figure. By driving the actuator arrays asynchronously, the device can obtain a dynamic motion. The microrobot in **Figure 14(c)** has six pairs of cantilever arrays arranged in a row, each array consisting of 18 cantilevers. Thus, 216 cantilevers (200 μm in width and 1000 μm in length) were fabricated within an area of 25 mm × 8 mm for the walking robot. Integrating many actuators onto a single silicon chip produces many advantages such as enhanced overall function of microsystems, low fabrication cost, and mass productivity. In this respect, shape-memory thin films are desired actuators in comparison with piezoactuators, since they are easier to etch for a fine pattern. Furthermore, the robustness of shape-memory thin films is an important factor for making a microrobot, since the main problem associated with the fabrication of silicon robots has been to achieve sufficient strength in the movable parts.

1.03.3.10 Future Perspectives

Understanding of SMA thin films and development of SMA microactuators have greatly advanced in recent years. Early difficulties of film fabrication such as porosity and oxygen contamination have been solved and composition control technique has shown an advance. Schematic and in-depth study revealed that sputter-deposited thin films possess stable SME and reliable mechanical properties even superior to those of bulk alloys. Further development of ternary alloy thin films is still underway. Microfabrication techniques have also been developed by many researchers. The fabrication technology of microdevices using SMA thin films is, therefore, ready to be transferred to manufacturing. Medical applications and microfluidic components are potential markets. However, in order that shape-memory thin films are widely accepted as promising microactuators, development of device design technique based on the material database is necessary. A complicated device design to introduce a bias force and a complicated behavior of a thin-film SMA actuator as a function of bias stress, heat treatment, and composition make it difficult for mechanical engineers to use SMA thin films as a common actuator. The issue of film adherence remains to be addressed and it sometimes causes a problem in processing. A relatively low frequency and efficiency may be crucial disadvantages in some applications. Even with these disadvantages and problems to be solved, shape-memory thin films are considered to contribute to advances in MEMS in which large force and stroke are essential. In the near future, they will find practical applications owing to their unique properties, which cannot be replaced with other actuating mechanisms.

Biographies

Kazuki Takashima received the B.Eng. degree in Metallurgy from Kumamoto University, Japan, in 1978 and the M.Eng. and Ph.D degrees in Metallurgy from Tokyo Institute of Technology, Japan, in 1980 and 1984, respectively. He is currently a professor of Department of Materials Science and Engineering, Kumamoto University, Japan. His research interests include the evaluation of mechanical properties of microsized materials for MEMS applications.

Akira Ishida is the leader of the actuator function group in the sensor materials center at the National Institute for Materials Science in Tsukuba, Japan. His most recent research involves martensitic transformations, physical vapor deposition, mechanical properties of thin films, and microelectromechanical systems (MEMS). He has also studied superalloys, hot corrosion and coating, and hard coatings formed by ion plating. He has received Ph.D. degrees in materials science from Osaka University.

1.04 Polymers

Ponnambalam Ravi Selvaganapathy, McMaster University, Hamilton, ON, Canada

Glossary

Alkanethiol A class of organic compounds that consist of a carbon chain (alkane) attached to a sulfur-based chemical group (thiol). These compounds have a known propensity to form self-assembled monolayers on gold surfaces.

Autoclave A device that uses high-pressure steam to kill microorganisms and clean medical equipment.

Base pair (bp) Constituents of the DNA strand. The common nucleic acid bases such as adenine (A), guanine (G), thymine (T), cytosine (C), and uracil (U) pair selectively with each other in nucleic acids. The A–T (or T–A) and C–G (or G–C) base pairs form the ''rungs'' of the DNA double helix, holding the two complementary strands together.

Cationic polymerization A process in which the active end of the growing polymer molecule is a positive ion. The polymerization proceeds via a radical chain reaction with intermolecular transfer of the radical center.

Collagen An insoluble fibrous protein, which is the principal component in connective tissue. It provides the rigid framework for tissue and cells. It is found in tissues, cartilage, and bones. Collagen is formed when tropocollagen molecules polymerize.

Da (Daltons) Atomic Mass Unit. It is used to express atomic and molecular masses. It is defined as 1/12th of the mass of one atom of carbon-12.

DMD Digital Mirror Display. These consist of thousands of MEMS mirrors whose angle could be individually controlled, hence producing an image.

DNA Deoxyribonucleic acid, a high molecular weight molecule composed of two chains coiled into a double helix. DNA is an universal component of living matter. It is located on the chromosomes in the cell nucleus, and it consists of nucleoproteins. The set of DNA molecules forms the chromosomes, which contain all the information of the genetic code.

EDM A process for machining metal parts by a very rapid succession of electrical discharges in an insulating liquid. The tool, usually in the form of a wire, is taken over the workpiece according to a design and the part is formed.

Genomic sequencing Process of elucidating the sequence in which base pairs occur in a particular strand of DNA.

Lewis acid An electron pair acceptor. This substance acts in a similar manner as H^+ ion in accepting a pair of electrons.

LIGA Abbreviation for lithography, electroforming, and molding, which are the fundamental process stages of this technology. The lithography method used is X-ray deep lithography, which used to define high aspect ratio structures in polymers. Electroplating in this mold creates a master, which can be used for precision replication.

LoC Lab-on–a-chip devices that were first developed in the early 1990s that miniaturized and automated the sequence of steps required to perform complex but repetitive laboratory-based analysis of biomolecules.

PCR Polymerase chain reaction, a method that produces several million copies of a single fragment of DNA in several amplification cycles.

III–V materials Elemental materials that occupy groups III and V of the periodic table of the elements. The combination of these materials in a crystalline structure produces semiconducting properties, which is used in electronics.

φX-174/HaeIII A DNA marker sample with DNA fragments ranging in size from 72 to 1353 bp. This is widely used to determine the size of unknown fragments of DNA.

1.04.1 Introduction

Miniaturization of laboratory-based analytical techniques into tiny lab-on-a-chip (LoC) devices has the capability to dramatically improve performance, throughput, and the cost associated with these methods (Dittrich and Manz 2006). This in turn has far-reaching consequences in areas as diverse as medical diagnostics, drug delivery, drug discovery, analytical chemistry, and molecular diagnosis. It was observed that miniaturization of the analysis equipment reduced the need for a large volume (expensive) of samples and reagents. Similarly it reduces the time of analysis significantly as unit operations like heating, mixing, and metering can be performed more accurately and quickly with smaller volumes. Once the

operation sequence of an analysis is determined and miniaturized, these devices can be produced in thousands and can be used to perform thousands of parallel analysis leading to higher throughput. Miniaturization and the microfabrication techniques used allow precise replication of these devices leading to repeatable performance, which is critical for comparing the analysis by different operators. This eliminates the human factor in the analysis and increases confidence in the analysis (Selvaganapathy *et al.* 2003).

Polymers are ideally suited – and hence are widely investigated – for use in LoC devices for biomedical and microfluidic applications because of their low cost, chemical inertness, low electrical and thermal conductivity, suitability for surface modification, and compatibility with biological materials. Biomedical devices including sensors and LoC systems are required to be disposable to avoid cross contamination between samples. Polymer substrates cost ~2 cents per square centimeter while glass costs ~10–20 cents per square centimeter (Becker and Gartner 2000). Other microfluidic applications typically involve a large footprint of several square centimeters and cannot be conveniently miniaturized without loss of performance (Becker and Gartner 2000). The low cost of polymeric materials and their processing techniques are the twin advantages that provide the impetus for developing processing technologies for the microfabrication of polymeric microelectromechanical systems (MEMS)/microfluidic systems. This chapter discusses some of the widely used polymers in MEMS, their properties, and their fabrication methods.

1.04.1.1 Polymers and Their Classification

Polymers are macromolecules of high molecular masses (higher than 1000 Da and having more than 100 repeat units) made from smaller molecules called monomers. Polymerization is the process of producing polymers from monomeric units through chemical reactions. These reactions can lead to linear polymers or cross-linked polymers depending on the position of the reaction groups in the monomer and the cross-linker. The latter case leads to a large 3D network structure. The process is also statistically dependent and hence a range of polymer chain lengths are produced. Hence polymers usually do not have a defined melting temperature but soften above a range called the melt interval. A wide variety of polymers from different starting monomers have been polymerized, and they are classified according to their structures and behavior (Nicholson 1997).

Polymers have traditionally been classified according to their response to thermal treatment. Thermoplastics (such as polyethylene and polystyrene) are mostly linear or branched polymers that melt upon the application of heat and resolidify when cooled. They do not have cross-linking and hence their thermal behavior is reversible – they undergo the same phase transition without hysteresis. Above the glass transition temperature (T_g), these materials become plastic and they can be molded into specific shapes that they retain at lower temperatures.

Elastomers (such as polydimethylsiloxane (PDMS)) are weakly cross-linked polymers. They can be easily stretched and revert back to their original shape upon release. Since they are cross-linked they do not melt before reaching their decomposition temperature. Thermosetting polymers (such as bakelite and vulcanized rubber) are heavily cross-linked and hence the molecular movement for elasticity is not possible. They are normally rigid and brittle and do not soften significantly at higher temperatures. The key parameter of interest in microfabrication is the glass transition temperature (T_g). This is the temperature below which the polymer solidifies and becomes hard and brittle. Thus, the polymer can be heated above T_g and molded using a mold insert. Then the mold can be cooled to below the glass transition temperature and the plastic component demolded.

1.04.2 Microfabrication

Microfabrication originated in the semiconductor industry as a process for constructing, layer by layer, using different materials, the structure of a transistor and its interconnections. Materials are deposited or removed from a planar substrate using thin-film deposition or etching techniques, producing structures in the order of 0.1–5 μm. The definition of regions for selective removal or deposition is done using photolithography. These techniques have been modified and adapted to produce high aspect ratio microstructures in the order of 20–200 μm using methods broadly classified as bulk and surface micromachining. Bulk micromachining describes processes that involve microfabrication aimed at selective removal of material from the substrate. One popular example is wet etching of silicon. Other methods like dry etching using the Bosch

processes (Larmer and Schilp 1996) or other micromachining methods like LIGA (German acronym for X-ray lithography (X-ray Lithographie), Electroplating (Galvanoformung), and Molding (Abformung)) process (Ehrfeld *et al.* 1988) produce structures with high aspect ratios (~10). Surface micromachining involves processes aimed at selective addition of thin films of a sacrificial material (to produce topology) and several structural materials. The substrate is not affected during the processing and provides only a stable base layer. The sacrificial material is removed at the end of processing to produce a 3D structural feature. These microfabrication techniques generally use silicon and III–V materials as the working materials primarily due to their origin and their development in the semiconductor industry. Since the early 1990s (Manz *et al.* 1990) traditional semiconductor microfabrication techniques have been adapted for the construction of LoC devices in silicon and glass (Harrison *et al.* 1993, Liang *et al.* 1996). These devices perform a complex series of chemical and biochemical reactions and unit operations such as metering, mixing, and pumping in the microscale. Genomic sequencing, drug discovery, and disease diagnostics have been the main drivers in this effort to produce LoC devices, which enabled the low-cost, high-throughput, low-reagent consumption analysis to be performed faster and more efficiently.

However, silicon as a substrate and structural material has several disadvantages. Silicon-based devices have high substrate electrical and thermal conductivities. Special insulation layers (oxide, nitride, or polymers) have to be provided in the instance of electrokinetic pumping, which is a widely used actuation mechanism in microfluidic systems. Similarly, thermal insulation or isolation islands have to be provided for microreaction chambers to prevent heat transfer between chambers or interaction with biomolecules in the microchannels. Glass provides excellent isolation properties, but it is very difficult to machine high aspect ratio complex 3D structures. Polymers, in contrast, are moldable to complex shapes and dimensions and have isolation properties comparable to glass.

Silicon also interacts with the biomolecules and fluids in the channels, leading to adhesion, accumulation, and fouling. Typically, surface modification (silanization, polyelectrolyte assembly, atom-free radical polymerization) is performed to prevent interactions. However, surface modification leads to extra processing cost, is variable in performance, and degrades over time. Polymeric materials, in contrast, can be made inert to interaction with biomolecules (e.g., polyethylene glycol) and can be modified to have a uniform surface property for electroosmotic flow (EOF).

Polymers are better suited for these applications because of their low cost, chemical inertness, low electrical and thermal conductivity, suitability for surface modification, and compatibility with biological materials. Further, biochemical analysis has been traditionally performed in either glass equipments that could be autoclaved or in plastic that could be disposed after use. However, the processing techniques used in the semiconductor industry – such as dry etching, sputter deposition, chemical vapor deposition – are high-temperature processes, and hence they are generally unsuitable for polymeric processing. Microfabrication of LoC and other MEMS/microfluidic devices therefore require the development of techniques for polymer microfabrication and replication, which are cheap and cost-effective for producing thousands of low-cost disposable devices. Polymeric materials are also available in a compliant form at low temperatures, which allows other techniques such as hot embossing, injection molding, and casting to be used for microfabrication. These are bulk micromachining techniques where the substrate made of the polymer is fashioned as a negative replica of the master, which retains its structural integrity at these temperatures. Fabrication costs of molded microparts are insensitive to the complexity of design. Once a mold insert (master) has been made, several thousand parts can be molded with little effort. The replication can be performed outside the clean room, while still obtaining a resolution of the device that is similar to that in photolithography. This reduces the cost of the devices significantly – making the technology applicable for disposable biomedical devices. An excellent review of these alternative microfabrication technologies, their applications, and limitations has been published in Heckele and Schomburg (2004). Surface micromachining techniques have also been adapted to suit low-temperature processing for polymeric materials. These allow construction of devices with multiple materials and construction of devices with complex functionality. A brief description of the different methods widely used to structure 3D objects in the microscale is given in the subsequent sections.

1.04.2.1 Injection Molding

Injection molding is a well-established technique in macroscopic production of products such as CDs and DVDs. Hence the machines, technology, and process know-how have been rapidly adapted for microscale molding (Hanemann *et al.* 2000, Larsson *et al.* 1997). A number of groups have demonstrated the feasibility of replication in thermoplastic polymers of microstructures (Despa *et al.* 1999, Larsson *et al.* 1997, Madou *et al.* 2001, Piotter *et al.* 1997, 2001, Weber *et al.* 1996). An injection molding process starts with the formation of molds. Silicon micromachining (Manz *et al.* 1990), LIGA process (Ruprecht *et al.* 1995), SU-8 photolithography (Jian *et al.* 2001), and microEDM are used to produce microscale features, which serve as mold inserts. The mold cavity with the mold inserts is evacuated and heated to a temperature above the glass transition temperature (T_g) of the polymer. A horizontal injection unit heats the polymer and injects the viscous melt into the mold cavity. The entire cavity is then cooled below T_g and subsequently the molding part is demolded. **Figure 1(a)** shows the process flow. Injection molding is the most ideal technique adapted to industrial production due to short cycle times (~minutes). The quality of surface features within the fabricated device is entirely dependent on the quality and the precision of the mold insert.

1.04.2.2 Hot Embossing

Hot embossing refers to the replication of a microstructure from a hot mold insert (master) onto a thin film of thermoplastic material. **Figure 1(b)** depicts the process. In this method, a thermoplastic film is inserted into the embossing mold with mold inserts on either side. The tool is evacuated and the mold inserts are pressed against the thermoplastic film with great force. The film and the mold insert are heated above T_g. The plastic fill is squeezed from the elevated parts and fills the valleys and generally confirms to the contours of the mold inserts. The setup is cooled and the mold insert is removed from the plastic (Heckele *et al.* 1998).

Unlike injection molding, hot embossing requires the polymer flow only over short distances. Two major effects of this are the reduction in stress and the faster cycle time. Hot embossed parts have very low stress as there is only local modification of the surface of the film. Hence these are ideal for membrane structures and optical components. Since the flow is local, the viscosity of the film need not be reduced as much as in the case of injection molding. This reduces the need to heat the film to a high temperature thereby reducing the heating and cooling times. The stress and temperature effects reduce shrinkage during cooling and enhance demolding. Thus, microstructures with high aspect ratios and thin structural features, like membranes, can be fabricated using hot embossing as compared to injection molding (Heckele and Schomburg 2004). Since high aspect ratio structures (>10) can be replicated very easily in thin films (1–100 μm), this technique has been adapted to replicate patterns on photoresist films using a process called nanoimprint lithography.

1.04.2.3 Casting

In this process a material is introduced into a mold in its liquid state, allowed to solidify inside the mold, and then removed, thus producing a replica of the microstructured master. **Figure 1(c)** illustrates the process. Techniques similar to those described earlier for producing injection molding mold inserts are used to produce the microstructured master. Casting materials used could be hot, liquid metals or meltable plastics (such as thermoplastics). A variation of this process is what is termed as reaction casting. Here the plastic – instead of being melted and cast into the mold – comes as two parts, which are mixed together. The mixing with heat or UV light input coldsets the polymers through cross-linking – increasing its viscosity by several orders of magnitude. The initial low viscosity of the two-component mixture allows the polymer to flow and wet the entire surface of the mold insert and accurately replicate the shape. This process is typically used for nonthermoplastic materials such as thermosetting plastics (bakelite), epoxies (Sethu and Mastrangelo 2004), and elastomers (PDMS) (Xia and Whitesides 1998). The essential requirements of this process are that complete mixing and distribution of the two components have to take place and the chemical reaction (cross-linking) has to take place throughout the bulk for uniform strength. This can be achieved only by comparatively long cycle times (~hours). However, features in the scale of a few nanometers can be easily replicated.

1.04.2.4 Stereolithography

Stereolithography is a rapid prototyping technology first developed in the 1980s (Hull 1986) for creating a 3D prototype for automotive and aeronautical

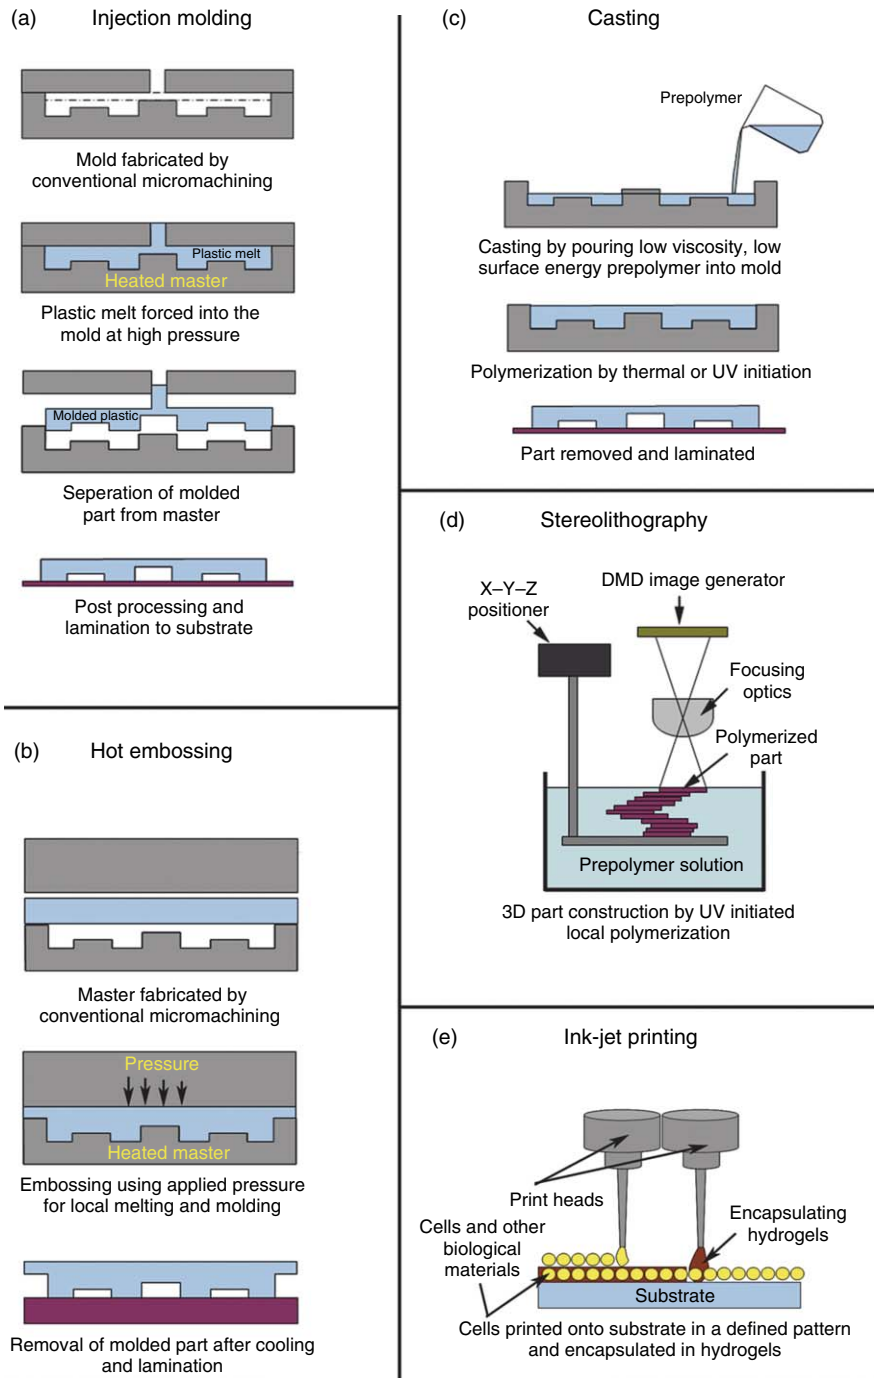

Figure 1 Injection molding, hot embossing, casting, stereolithography and inkjet printing process flow.

applications mainly for fluid dynamic testing and visualization. The object to be formed is deconstructed into a series of 2D layers and reproduced by laser-induced polymerization of a resin. Figure 1(d) illustrates the process. In this, a laser beam is focused on the free surface of a photosensitive liquid, which induces polymerization of the local region of the liquid, transforming it to a polymerized solid. The laser is scanned across the surface with control from a software program to trace a 2D feature. Resolution depends on the laser, the scanning apparatus used, and the diffusion in the photosensitive liquid. The

penetration depth of the laser light into the liquid determines the thickness of the layer. This produces the shape of one layer of the object to be formed. Fresh liquid is spread on top of this photodefined layer and the second layer is produced similarly. The resolution in this technique is ~150–200 μm in three dimensions. The effort to improve resolution and prototype of smaller objects started in 1993 (Ikuta and Hirowatari 1993, Takagi and Nakajima 1993). The thickness of individual layers was reduced by using a glass container attached to an X–Y–Z micropositioner to determine the thickness of the resin with which the light interacts. The laser illumination mechanism along with the shutters for patterning are attached to the X–Y–Z positioner and moved with it. The major problem with this approach is that the polymerized resin adheres to the glass plate. Free surface polymerization is then done wherein the part formed is attached to the X–Y–Z positioner and moved close to the free surface of the resin/air interface. The gap between the part formed and the free surface determines the thickness of the layers (Zhang *et al.* 1998). Increasing the throughput of the method by using optical fibers to split the laser light and to manufacture several parts simultaneously has been investigated (Ikuta *et al.* 1996). Micrometer scale resolutions have been obtained using these methods. LCD displays (Bertsch *et al.* 1997) and digital mirror display (DMD) devices (Bertsch *et al.* 1998) have been used to generate patterns and eliminate X–Y movement and to provide a lithography-type process that decreases the time to generate layers and increases throughput. However, these methods require the resin to be spread uniformly on the already formed part, time for stabilization of the resist after vertical movement of the part, support for the part, and an inability to form freely moving structures.

Two-photon absorption, a nonlinear optical phenomenon, has been used to produce parts inside the bulk of the resin instead of close to the interface. This eliminates most of the problems mentioned above and, when combined with LCD and DMD masking technology, provides a high throughput method for fabrication (Maruo and Kawata 1998, Maruo *et al.* 1997). Nonphotoreactive materials including ceramics can be fabricated by incorporating them as suspension particles in the photosensitive resin. This, once polymerized, can be fired at a high temperature to burn off the resin, leaving behind a sintered 3D microstructure (Zhang *et al.* 1999). Structures with lateral dimension of ~100 nm have been obtained using this technique (Sun and Kawata 2003). An excellent review of stereolithography and its applications has been published in Bertsch *et al.* (2001).

1.04.2.5 Ink-jet Printing

Ink-jet printing has been widely used for the reproduction of text by propelling microscale droplets of ink through a narrow nozzle. Recently efforts have been made to adapt this technology for the printing of polymeric liquids other than inks. The print head of the ink-jet printer consists of a reservoir with an actuator and a nozzle. The reservoir holds the ink, which is propelled through the nozzle upon actuation. The transducer produces volumetric change either due to the flexure of the piezoelectric material or due to thermal expansion by heating. This creates pressure waves, which force the fluid to move toward the exit. The droplet size is typically of the size of the nozzle (Wallace 1989) and drops with diameters ranging from 20 to 120 μm can be generated. The critical aspects of this method are the composition of the ink and its viscosity. The viscosity should be <20 m Pa s so that the energy imparted by the actuator to the fluid is not viscously dissipated. Hence polymers have typically been printed as melts (such as waxes) or in the colloidal form (Wong *et al.* 1988). Hot melt waxes solidify on contact with the substrate and retain their shapes. Spots (20–40 μm diameter) with drop placement accuracy of 1 μm have been used to fabricate masks for metal layer etching of transistors (Wong *et al.* 2002).

For biopolymers such as DNA, proteins, and cells, this is the only viable method for pattern definition. These polymers are highly temperature sensitive and lose their properties on exposure to other solvents. Ink-jet printers have been used to deliver specific reagents to individual spots on a slide to synthesize a different DNA sequence at each site (Lemmo *et al.* 1997). One of the issues with printing of biological materials, especially proteins and cells, is the loss of functionality due to dehydration on the substrate. This has been solved by printing proteins and cells embedded in hydrogels (Kesari *et al.* 2005). **Figure 1(e)** shows the schematic of the use of ink-jet printing of biological materials such as cells in a hydrogel matrix.

1.04.3 Polymers and Processes

A wide variety of polymers are used to fabricate microstructures using both traditional micromachining processes such as bulk and surface micromachining and nontraditional processes such as injection molding, casting, hot embossing, and stereolithography. Thermoplastic polymers such as polymethylmethacrylate, polycarbonate, polyvinylidenefluoride, polysulfone, polystyrene, polyvinylchloride, polypropylene, polyetheretherketone, polyoxymethylene, and poly-amide have been successfully used to fabricate microstructures using injection molding-, hot embossing-, and casting-based approaches (Heckele and Schomburg 2004). However, the most widely used polymeric materials for MEMS/microfluidics include parylene (*para*-xylylene), PDMS, SU-8, hydrogels, porous polymers, biodegradable polymers, polyesters, polyimide, and paraffin. This section provides a detailed description of the properties of these polymers and their fabrication processes.

1.04.3.1 Parylene

Parylene is the common name for a class of polymers called poly-*para*-xylylene. The basic member of the series, called parylene N, is a completely linear, highly crystalline material. It is commercially available in three forms, which are variations of a basic polymer backbone of xylylene formed by the replacement of 1–4 atoms in the benzene ring as shown in **Figure 2**. Parylene C and D are other variations, which have chlorine atoms at various positions in the basic backbone. The commercialization of parylene coating was initiated with the realization that the dimeric form was stable and with the development of a vapor-phase deposition process (Gorham 1966). It has been used in a wide variety of applications such as encapsulation for microelectronic circuits (Lin and Wong 1992, Olson 1989), as interlayer dielectrics (Selbrede and Zucker 1997), and for strengthening wire bonds (Flaherty 1995) in microchip packaging. Similarly, a number of applications of parylene in microfluidics include microchannels (Man *et al.* 1997; Webster and Mastrangelo 1997), microvalves (Carlen and Mastrangelo 2002, Rich and Wise 1999, Wang *et al.* 1999), membrane filters (Yang *et al.* 1998), and other micromachined devices.

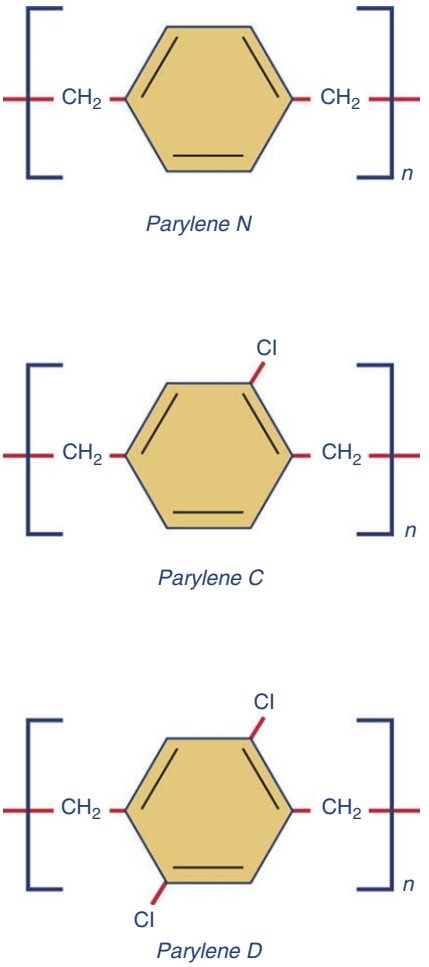

Figure 2 Chemical structure of different kinds of commercially available parylene polymers. Reproduced with permission from Specialty Coatings Systems Inc.

1.04.3.1.1 Polymerization

Parylenes have to be polymerized *in situ* and cannot be formed by extrusion or molding techniques due to their high molecular weight (~500 000), which causes their melting temperature and crystallinity to be high. Parylene polymers are deposited by vapor deposition at room temperature and in vacuum. **Figure 3** shows the schematic of the process flow. The dimer form of parylene, a solid at room temperature, is the source. It is sublimated at 140–160°C and vaporized into the pyrolysis chamber where it splits into two monomers at 680°C. The reactive monomer is then allowed to flow into a deposition chamber where it deposits and polymerizes on surfaces that are below 100°C. The deposition pressure is ~100 mtorr and hence the deposition is conformal. This allows the formation of uniform conformal thin films.

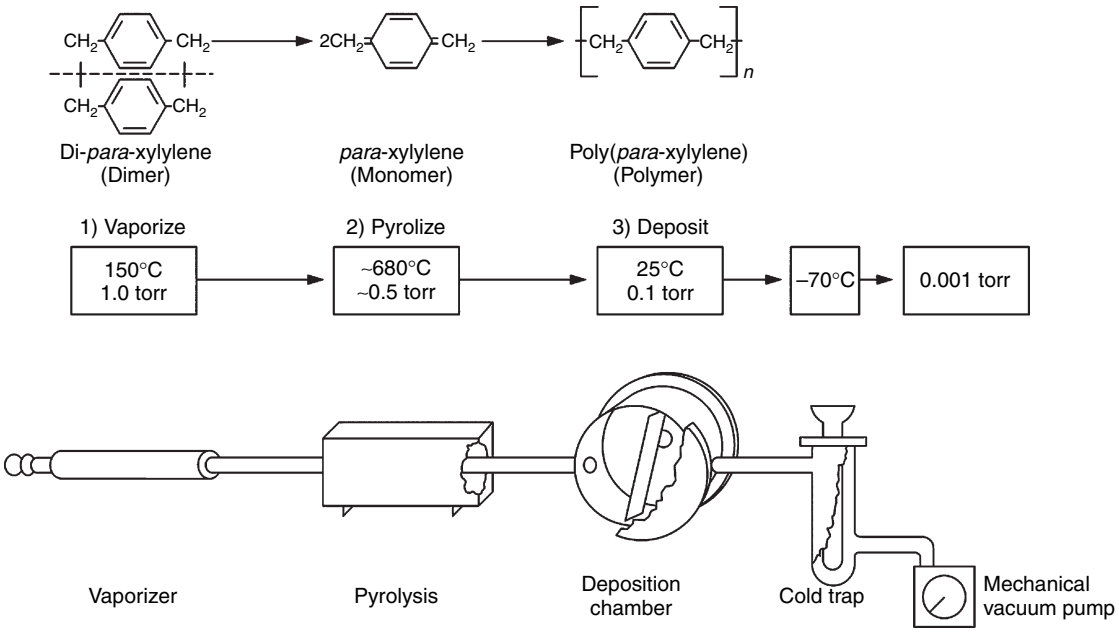

Figure 3 Parylene polymerization process flow. Reproduced with permission from Specialty Coatings Systems Inc.

1.04.3.1.2 Properties

Parylene thin films are extremely conformal even with high aspect ratio structures due to the vapor-based deposition process. Under an operating pressure of 0.1 torr, the mean free path of the molecules is much smaller than the feature size, leading to uniform condensation and excellent control over thickness. Low surface roughness and pinhole-free coating can be obtained for films of thickness >0.5 pm. The films also are chemically pure due to the lack of initiators and catalysts in the polymerization process. The room temperature deposition and polymerization ensure formation of stress-free films. These films have excellent dielectric breakdown properties, especially below 1 μm.

With regard to microfluidic devices, parylenes are clear and possess low autofluorescence allowing visualization of biological and chemical interactions through optical means. They exhibit very little absorption in the visible region and are, therefore, transparent and colorless. Below 280 nm, both parylene N and C absorb strongly. They are chemically and biologically inert and hence resistant to damage by acids, bases, corrosive body fluids, electrolytes, enzymes, and proteins.

The low solubility in organic or other media allows them to maintain the integrity and concentration of the biomaterials and chemicals in organic solvent without significant absorption. Parylenes have superior barrier properties when compared to silicones and other polymeric materials. Their moisture vapor permeability is $1.7 \times 10^{-16}\,\mathrm{kg\,m\,N^{-1}\,s^{-1}}$, which is an order of magnitude lower than for silicones. They resist chemical attack at room temperature and are insoluble in all organic solvents up to 150°C. Parylene C can be dissolved in chloronapthalene at 175°C, and parylene N is soluble at the solvent's boiling point (265°C).

Surface properties of parylene are modified on exposure to strong chemicals. For instance, etchants such as buffered hydrofluoric acid (BHF) and hydrofluoric acid (HF) make the surface more hydrophobic. Chromium etchant solution makes the surface hydrophilic. Substituted parylenes that are capable of reacting with biomolecules to promote strong attachment have been developed recently (Lahann *et al.* 1998). Parylene is biocompatible as evidenced by its use in cochlear implants (Bell *et al.* 1997) as well as for PCR (Man *et al.* 1997) and biochemical reactions (Brahmasandra *et al.* 1998).

1.04.3.1.3 Adhesion

Adhesion of parylene to silicon, SiO_2, and Si_xN_y surfaces is greatly improved by the silanation of silicon dioxide and silicon nitride surfaces. While the silanation of silicon itself will improve parylene adhesion, parylene adheres better to the silicon dioxide and nitride films. Silanation can be done either by dip-coating the silane (vinyltrichlorosilane

in isopropyl alcohol) solution and spin-drying the substrate or by vapor deposition prior to parylene deposition. Adhesion of parylene to most polymers isimproved by exposing the polymer surface to 250-mtorr, 100-W oxygen plasma for 1 min. This plasma treatment etches the surface of the polymer and exposes the active polymer nucleation sites for parylene to bind. Using this treatment, parylene C has been found to adhere to polyimide, photoresist, and polycarbonate. Metals such as Cr, Au, and Ti adhere quite well to parylene while Al does not. Silanation process described above can be used to improve the adhesion of Al to parylene.

1.04.3.1.4 Microfabrication

As mentioned before, parylene films cannot be formed by molding or casting and vapor deposition is the only technique for forming thin conformal films. Solvent-resistant property enables photoresists, developers, and other chemicals to be used directly on parylene. This enables the formation of complex multilayer structures using parylene as a structural material and photoresist as a sacrificial material. No wet etchants are available for parylene. Dry etching in O_2 and CF_4 atmospheres at low pressures produces etch rates of 0.2 μm min^{-1} at 250 W and 50 mtorr (Tacito and Steinbruchel 1996).

A surface micromachined process for construction of parylene microchannels has been demonstrated (Webster *et al.* 1998). The surface micromachined fabrication process is shown in **Figure 4**. In this, the substrate merely provides mechanical support and hence materials other than silicon such as glass, polycarbonate, and other plastics can be used. The process begins with the initial coating of the substrate with a thin conformal parylene layer. Adhesion is usually obtained by plasma treatment as described above. Then, electrodes and other functional parts of the microfluidic and MEMS device are deposited and patterned. Thick (20 μm) photoresist is spun-cast and photolithographically patterned to define the microchannel – its microstructure, shape, and dimensions. A second layer of parylene is then conformally deposited to form the top and sides of the channel. The adhesion of this layer is also assisted by a short oxygen plasma treatment. A thick photoresist layer is used as a mask to etch the reservoir, and contact pad openings are etched using oxygen plasma. A photodefinable silicone rubber (polysiloxane) is used to make reservoir rings. The wafer is partially released in acetone to remove the photoresist mask and treated with an oxygen plasma for a short duration to improve adhesion. The channel is then released in acetone for 36 h without agitation, rinsed and dried, and then immersed in chrome etchant several times to etch the remaining chromium at the bottom of the channel. The release time can be shortened by constant agitation or by heating the acetone. A number of devices such as DNA separation devices (Webster *et al.* 1998), PCR systems (Man *et al.* 1997), cochlear implants (Bell *et al.* 1997), microvalves for drug delivery (Carlen and Mastrangelo 2002, Rich and Wise 1999), and microneedles have been fabricated using these techniques.

1.04.3.2 Polydimethylsiloxane

Polydimethylsiloxane is one of the most widely used polymers in MEMS, especially in microfluidic and bioMEMS. It belongs to a class of polymers called silicones, which are synthetic polymers containing a Si–O backbone. To this backbone, organic groups are frequently attached to the silicon atoms via a Si–C bond. PDMS has a repeating $(CH_3)_2SiO$ unit. Depending upon the number of repeat units in the polymer chain and the degree of cross-linking, the material can be produced in different rheological forms such as fluids, emulsions, lubricants, resins, elastomers, and rubbers (Brook 2000). The low rigidity of the backbone allows the methyl groups to be easily exposed, resulting in low intermolecular interactions of PDMS and also its low surface tension.

1.04.3.2.1 Polymerization

Silicones are made from silicon and methyl chloride in a process known as the direct reaction yielding methyl chlorosilanes. They are distilled, and the dimethyldichlorosilane ($(CH_3)_2SiCl_2$) is hydrolyzed to produce PDMS (Noll 1968). Both linear and cyclic siloxane oligomers are formed simultaneously in the hydrolysis reaction. These are the basic raw materials (monomers) from which a number of useful silicone products can be made through cross-linking.

As mentioned previously, siloxane polymers occur in a variety of common forms – fluids, gels, elastomers, and resins. Fluids are typically linear chains of PDMS, which are terminated with a trimethylsilyl group. Gels are lightly cross-linked PDMS fluids, where the cross-link is introduced either through a trifunctional silane – such as CH_3SiCl_3 giving a branched silicone structure – or through a chemical reaction between a Si-vinyl group on one polymer chain and a hydrogen-bonded silicon in another (Noll 1968). This produces a 3D network that can be swollen with PDMS fluids to produce a gel-like structure. Elastomers are highly cross-linked fluids with very little free fluid in the matrix. Fillers, such as amorphous silica, are frequently added to the matrix to give greater reinforcement to the network and thereby increase its strength.

PDMS in its elastomeric form is generally used for microfluidic and bioMEMS applications. The commercial form is available as a kit with the PDMS base solution and a curing agent to cross-link fluid PDMS with an elastomer by an organometallic cross-linking reaction. The siloxane base oligomers (prepolymer) contain vinyl-terminated end groups ($CH_2{=}CH–$). The base solution also contains a platinum-based catalyst and a silica filler (dimethyl-vinylated and trimethylated silica). The cross-linking oligomers, typically dimethyl-methylhydrogen siloxane, tetrakis (dimethylsiloxyl silane) (TDS) $(HSi(CH_3)_2O)_4Si$), or a copolymer poly(dimethylsiloxane-*co*-methylhydrogenosiloxane) $(CH_3)_3Si–O–[Si(HCH_3)–O]_x–[Si(CH_3)_2–O]_y–Si(CH_3)_3$, contain at least 4–11 silicon hydride bonds each. The curing agent also contains an inhibitor (tetramethyl tetravinyl cyclotetrasiloxane). The platinum-based catalyst catalyzes the addition of the SiH bond across the vinyl groups, forming $Si–CH_2–CH_2–Si$ linkages (Fu *et al.* 2003). The multiple reaction sites on both the monomer chain and the cross-linking chain enable 3D cross-linking, as shown in **Figure 5**. One advantage of this type of addition reaction is that no waste products such as water are generated. If the ratio of the curing agent to the base is increased, a harder, more cross-linked elastomer is obtained. Heating also accelerates the cross-linking reaction.

1.04.3.2.2 Microcontact printing

One of the first applications of this polymer has been in microcontact printing. In 1993, the Whitesides group demonstrated that PDMS inked with an alkanethiol and when brought into contact with a gold-coated surface can form a monolayer of these molecules in the areas of contact (Kumar and Whitesides 1993; Kumar *et al.* 1995). The schematic of the process is described in **Figure 6**. Exact pattern replication by this printing process requires both accurate definition of a pattern and conformal contact of the substrate to facilitate ink transfer from the master. PDMS – due to low surface tension and elastomeric properties – has ideal properties to satisfy both these criteria.

A photoresist layer patterned by conventional optical lithography can be used to produce the master. High aspect ratio patterns have been accomplished using SU-8 epoxy-based photoresist, which after sufficient heat treatment tends to form a stable master capable of numerous replications. The PDMS prepolymer (1:10 mixture of the cross-linker and PDMS base) is cast over this master and allowed to cross-link at room temperature for 1 h and heated to 65°C for 1 h. The PDMS base having low surface energy wets the entire surface down to the molecular level forming an exact negative replica of the relief. The cross-linking of the base then solidifies the material into an elastic monolith. The 1:10 ratio allows easy delamination of the PDMS from the master by peeling. The master is used to produce several PDMS molds, thus replicating micro- and

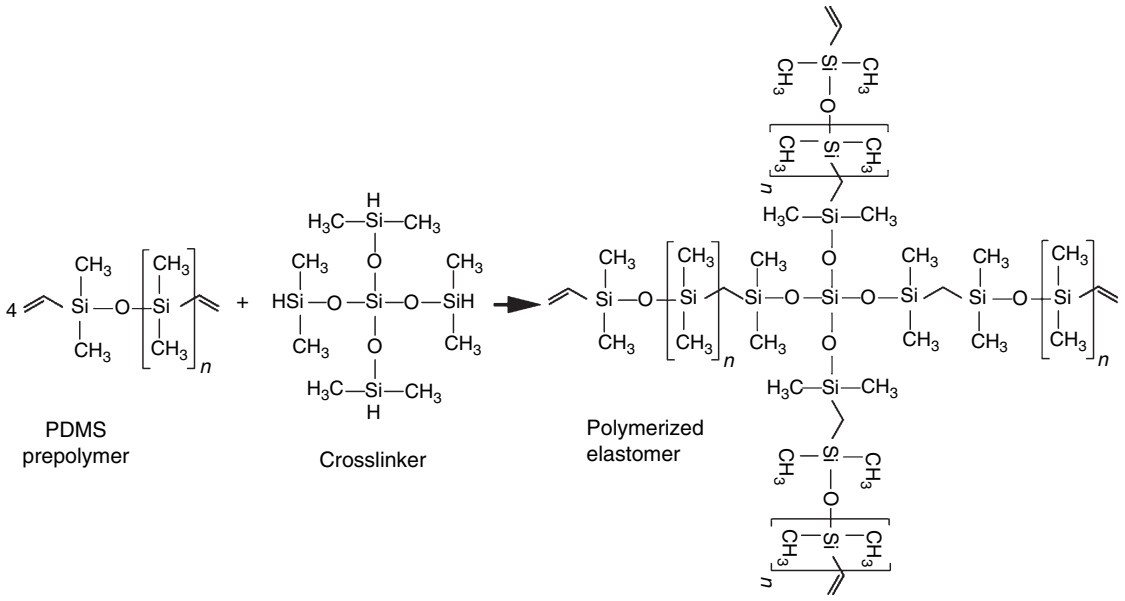

Figure 5 Chemical structure of PDMS and its polymerization.

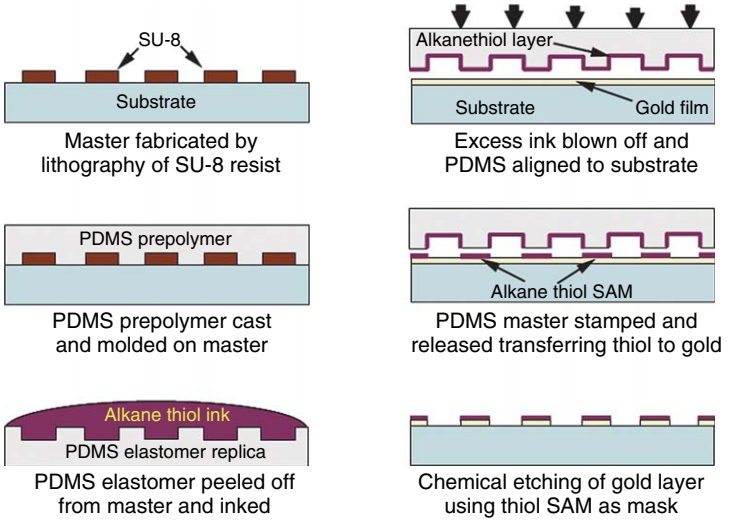

Figure 6 Microcontact printing process.

nanoscale features without expensive clean room processes (Kumar and Whitesides 1993).

This mold can then be inked with alkanethiols either using an ink pad or by solvent evaporation (Xia *et al.* 1996). These methods allow the deposition of a thin layer of the material on the features – either on the elevated surfaces or conformally – thereby maintaining the topography. This inked mold is then stamped on the gold film substrate. The thiol group has a natural affinity for the gold surface and tends to form self-assembled monolayers on the surface. Because of the topography, only those regions that are elevated in the mold imprint thiols on the gold surface. Hence the pattern on the PDMS mold is replicated on the gold surface in alkanethiols. Etching in gold etchant allows the replication of this pattern in gold (Xia *et al.* 1996).

This method allows the direct transfer of a micrographic pattern present on the flexible PDMS layer to be replicated on any substrate without expensive microscale definition processes like UV lithography. A number of different materials have been patterned using this technique, including metals and dielectrics (Joon *et al.* 1995, St. John and Craighead 1996,

Wang *et al.* 1997a). The important feature of using PDMS as the feature replication mold is its flexibility and its ability to achieve conformal contact between the PDMS stamp and the substrate. The mold can be used to replicate patterns on a nonplanar surface. These techniques are able to generate features on both curved (Jackman *et al.* 1995) and reflective substrates and rapidly pattern large areas, which are not possible in conventional lithography. A comprehensive review of microcontact printing (Xia and Whitesides 1998) and its modifications (Deng *et al.* 2000, Huck *et al.* 2000, Jackman *et al.* 1999, Jeon *et al.* 1999, Qin *et al.* 1999, Shah *et al.* 2000) provides greater detail about the process and its applications.

1.04.3.2.3 Microfluidic channels

The method mentioned earlier has been adapted for constructing microfluidic channels using PDMS elastomers as the structural material (Effenhauser *et al.* 1997). Till then microfluidic devices were made of silicon and glass-based substrates (Harrison *et al.* 1993, Liang *et al.* 1996). These were rigid and their fabrication processes require a series of cumbersome and expensive steps using traditional microfabrication techniques. However, the use of a microfabricated template of silicon to cast PDMS and the use of replica molding for high aspect ratio structures reduced the cost of the process (Effenhauser *et al.* 1997). The process is shown in **Figure 7**. **Figure 8** shows the replicated microchannel in PDMS.

In this process, lithographic patterning and wet chemical etching of silicon are used to produce a rigid high aspect ratio (20-μm-high) master. The silicon wafers are silanized in 3% (v/v) dimethyloctadecylchlorosilane in toluene for 2 h to facilitate peeling off the PDMS replica. A 10:1 mixture of PDMS base and its curing agent is poured over the wafer. After curing the PDMS for 4 h at 65°C, the PDMS replica is peeled off the master. Holes serving as reservoirs and providing access to the channels are punched through the bulk material. The device is then placed on a thin slab of PDMS in order to form a closed channel system of four equivalent walls. The hermetically sealed microchannels are readily formed by mere adhesion without applying external force (Effenhauser *et al.* 1997). The chips manufactured using this technique withstood pressures of 1 bar without clamping. The adhesion between the PDMS layers is reversible and the two layers can be separated easily by using a blade. This is useful in cleaning and reusing the microchannels. Buffer solution and separation media are pipetted into the reservoirs, and the microchannels are filled by applying vacuum to one of the reservoirs. Capillary electrophoresis separation of φX-174/HaeIII DNA is performed in this device as shown in **Figure 9** to demonstrate the feasibility of microchannel construction and its use in bioMEMS (Effenhauser *et al.* 1997).

Chem.* **69**, pp. 3451–7, © 1997 American Chemical Society.

However, this process produced microchannels that are hydrophobic and leak under higher pressures. Further, producing a master is expensive, involving single-crystal silicon wafers. A technique for cheaper

production of master using photoprinting (Qin *et al.* 1996, Xia and Whitesides 1998) of the masks and using photolithographic definition of master has been developed (Duffy *et al.* 1998). In this technique, a computer-aided design (CAD) file is printed on a transparency sheet by using a high-resolution laser printer. The file contains the pattern, which determines the regions blocked from exposure to UV light, and the printed transparency is used as a mask in contact photolithography of SU-8 high aspect ratio-negative resists. The transparency mask is 10–50 times cheaper to make and has a fast turnaround time. However, the resolution is limited to the accuracy of the photoprinter (>20 μm) while that of a chrome mask is ~500 nm (Duffy *et al.* 1998). After development, the pattern of SU-8 photoresist is used as the master to cast replicas of PDMS. Apart from providing high aspect ratio patterns, SU-8 has sufficient adhesion to the substrate to provide reliable replication on repeated use. Polyurethane and other epoxies have also been cast on the relief to provide more reliable single-piece masters (Duffy *et al.* 1998). The PDMS processing is similar to the process described for microcontact printing. The difference between the processes is in the type of SU-8 resist used and the height of microstructures formed. Microcontact printing typically can be accomplished with structures that are 5–10 μm high. However, microchannel structures typically require heights in the range of 20–100 μm.

1.04.3.2.4 PDMS bonding

A method to irreversibly bond PDMS to a substrate in order to construct devices to withstand higher pressures has also been developed (Duffy *et al.* 1998). The technique involves oxidizing the surface groups using oxygen plasma. In its natural state the PDMS surface is hydrophobic with CH_3 groups on the surface. This makes the surface inert and hence affects adhesion with other substrates. Surface oxidation of the PDMS in plasma converts some of the methyl groups on the PDMS backbone into hydroxyl groups – changing the surface from hydrophobic to hydrophilic. Bringing the two oxidized PDMS surfaces into conformal contact forms a tight, irreversible seal, improving adhesion of the substrates, and pressure tolerance of microchannels. The Si–OH groups at the surface of the PDMS slabs form a covalent Si–O–Si bond between them. The thickness of the oxidized surface layer is approximately 130–160 nm and consists of SiO_x, i.e., silicon bonded to three or four oxygen atoms. However, the oxidized layer becomes thinner and starts to crack on prolonged plasma treatment (>30 s). If the treated samples are left to age in an ambient atmosphere, they become hydrophobic again. This is due to low

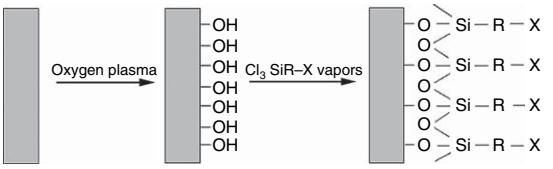

Figure 10 Surface functionalization of PDMS by silyl chloride vapor.

molecular weight PDMS migrating to the surface (Hillborg *et al.* 2000).

An important consequence of oxidizing the PDMS surfaces for microfluidic systems that use electroosmotic pumping is that the walls of the channels present a layer of silanol (SiOH) groups to an aqueous solution in contact with them. These surfaces are charged (SiO–) when the solution is neutral or basic, and so the channels support EOF toward the cathode. These OH groups can be further reacted with different terminal groups in the presence of silyl chloride vapors to form a surface with desirable properties (Xia and Whitesides 1998), as shown in **Figure 10**.

Although plasma oxidation is popular, other techniques such as corona discharge (Efimenko *et al.* 2002) and UV light exposure (Hillborg and Gedde 1998) have also been used to reduce hydrophobicity, particularly to reduce protein adsorption in microchannels.

PDMS surfaces can also be rendered hydrophilic by chemical treatment (Jo *et al.* 2000) using sodium silicate, which produces a permanent hydrophilic surface inside the microchannels. Sodium silicate has been used as a low-temperature adhesive for glass bonding applications (Ito *et al.* 2002, Wang *et al.* 1997b) and it has demonstrated excellent hydrophilic and adhesive properties. Other methods include sol–gel techniques (Roman *et al.* 2005), silanization (Papra 2001), chemical vapor deposition (Lahann *et al.* 2003), atom transfer radical polymerization (Xiao *et al.* 2002), and polyelectrolyte multilayers (Liu *et al.* 2000). Polyelectrolyte multilayers have also been cross-linked to provide greater stability to the surface layer (Makamba *et al.* 2005).

1.04.3.2.5 Multichannel structures

The basic microchannel fabrication technique described above can be modified to produce multiple stacked layers with microscale features embedded in them using a technique known as multilayer soft lithography that combines soft lithography with the capability to bond multiple patterned layers of elastomer. The resulting microstructure is shown in **Figure 11** (Unger *et al.* 2000). Multilayer structures are constructed by bonding

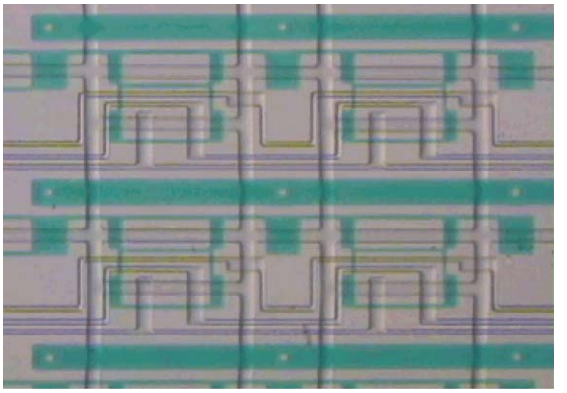

Figure 11 Multilayer microfluidic channels fabricated in PDMS. Reproduced with permission from Liu Y, Fanguy J C, Bledsoe J M, Henry C S 2000 Dynamic coating using polyelectrolyte multilayers for chemical control of electroosmotic flow in capillary electrophoresis microchips. *Anal. Chem*. **72**, 5939–44, © 2000 American Chemical Society.

layers of elastomer, each of which is separately cast from a micromachined mold. This technique exploits the two-component curing process to obtain PDMS elastomers. The bottom layer has an excess of one of the components (PDMS base), whereas the upper layer has an excess of the other (cross-linker). After separate curing of the layers, the upper layer is removed from its mold and is placed on top of the lower layer, where it forms a hermetic seal. Because each layer has an excess of one of the two components, reactive molecules remain at the interface between the layers. Further curing causes the two layers to irreversibly bond. The strength of the interface equals the strength of the bulk elastomer (Unger *et al.* 2000). A monolithic 3D patterned structure composed entirely of elastomer is produced by this process. Additional layers are added by simply repeating the process. Each time the device is sealed on a layer of opposite polarity and cured, another layer is added. Valves and pumps using pneumatic control have been constructed using this approach (Unger *et al.* 2000).

1.04.3.3 SU-8

Photoresists are polymeric solutions whose properties can be selectively altered using UV light. They have been typically used as the selective definition layer on other thin films in semiconductor applications. They have also been used as a sacrificial layer for the construction of microchannels (Man *et al.* 1997). However, it is with the development of SU-8 – a negative tone resist – that photoresists have been used as a structural layer for MEMS and microfluidic applications. SU-8 was developed by IBM (Lee *et al.* 1995) for LIGA

applications. A modified form of this material was used to produce high aspect ratio structures for MEMS applications using conventional lithography (Lorenz *et al.* 1997).

1.04.3.3.1 Polymerization

SU-8 resist consists of EPON SU-8 resin (an epoxy) as its main constituent. The resin is an aromatic hydrocarbon with an epoxide group at either end. The solvent used is γ-butyrolacton. The ratio of the solvent to the resin determines the viscosity and thereby the thickness of the resist layer at a particular spinning speed. The versatility of this resist was evidenced by the fact that thicknesses from 750 nm to 450 μm can be obtained by a single spin using a conventional spinner by varying the solvent/resin ratio (Lorenz *et al.* 1997). The resist also consists of 10 wt.% of photoinitiator, which is a photo Lewis acid generator.

A typical processing sequence of the resist is as follows. SU-8 is spun on a silicon wafer and the solvent is allowed to dry by prebaking at 95°C. The prebake time depends on the thickness of the resist and is typically 15 min for a 100-μm thickness. Exposure of the resist is performed on a UV aligner and the UV light interacts with the photoinitiator, converting it into a Lewis acid. The resin has very low UV absorption and hence a uniform exposure dose, and Lewis acid generation throughout the bulk of the resist can be achieved. The resin then undergoes cationic polymerization induced by the Lewis acid to form a cross-linked epoxy layer in the areas exposed, as shown in **Figure 12**. A dose of 300–400 mJ cm^{-2} at 365 nm is required for complete cross-linking of a 100-μm-thick resist layer. Removal of the unexposed resist is done using propylene glycol monomethylether acetate solution and rinsed in

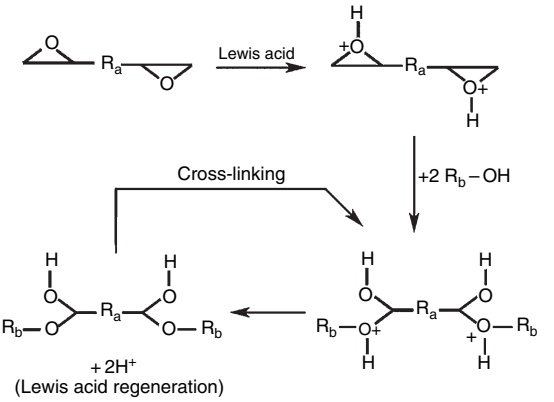

Figure 12 SU-8 polymerization process.

isopropyl alcohol. The development time depends on the thickness and is typically 15 min for a 100-μm-thick resist layer. The resist can be stripped at this stage using hot 1-methyl-2-pyrrolidon solution. Further hard baking of the resist at higher temperatures of 120–200°C for 30 min makes it resistant to metal etchants and other solvents typically used in MEMS fabrication (Lorenz *et al.* 1997).

High aspect ratio structures (>18) with a thickness range from 80– to 1200 μm with conventional mask aligners have been discussed in Lorenz *et al.* (1998). Higher aspect ratios (>60) have been achieved using X-ray sources for LIGA applications (Jian *et al.* 2003). Another feature of SU-8 is that taller structures can be constructed by using multiple layers. A 100-μm layer can be spun, prebaked, and exposed, and this can then be used as a substrate for the next layer. Multiple layers with alignment using different masks can produce complex 3D structures. After the final layer has been exposed and baked, all the layers can be developed at the same time. **Figure 13** shows a number of microstructures fabricated using SU-8

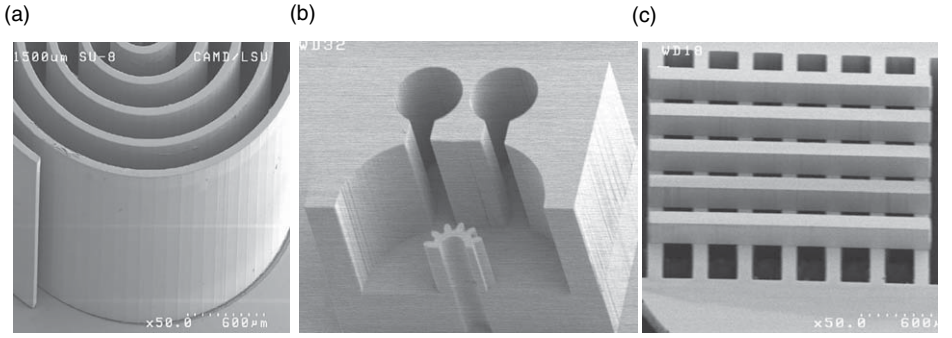

Figure 13 Part manufactured in SU-8: (a) 1500 μm tall microstructure, (b) cross section of engine housing, (c) multi-level 3D microstructures made by the combined use of SU-8 and PMMA resists. including a microrotary engine housing, which has a size of 1.6 mm × 1.6 mm, and three multilevels of 0.3, 0.6, and 0.9 mm, with the smallest feature size of 15 μm (Jian *et al.* 2003).

1.04.3.3.2 Channel fabrication

There are a number of surface micromachining methods for the fabrication of microchannels using SU-8 as depicted in **Figure 14**. One of the early methods involves a process flow as shown in **Figure 14(d)**. Here the SU-8 layer is spun, prebaked, exposed, and developed to produce a pattern of the microchannel. A dry photoresist film – Riston (Dupont) – is laminated over the SU-8 layer. Access holes are then patterned in the Riston layer to provide fluidic connection to the SU-8 microchannel (Heusckel *et al.* 1998).

Another technique, depicted in **Figure 14(a)**, involves the use of a sacrificial material (typically positive tone photoresist) to define the microchannel structure. SU-8 is cast over this sacrificial mold and the access holes are lithographically defined. Then the sacrificial resist is removed to produce an open microchannel (Guerin *et al.* 1997). A variation of the methods is depicted in **Figure 14(b)**. Here a layer of SU-8 is spun, prebaked, and exposed into patterns of microchannels. Then a thin metal layer is deposited on top to protect the unexposed regions at the bottom SU-8 layer from exposure. A second SU-8 layer is then spun, prebaked, and exposed to a pattern to form access holes for the microchannels. Subsequently the second SU-8 layer is developed, the metal layer etched, and the unexposed resist in the first SU-8 layer also developed to produce the channel structure (Guerin *et al.* 1997). The fourth technique, as shown in **Figure 14(c)**, starts with spinning of a double layer of SU-8. A long exposure to a 2-MeV proton beam through a mask is done to produce a

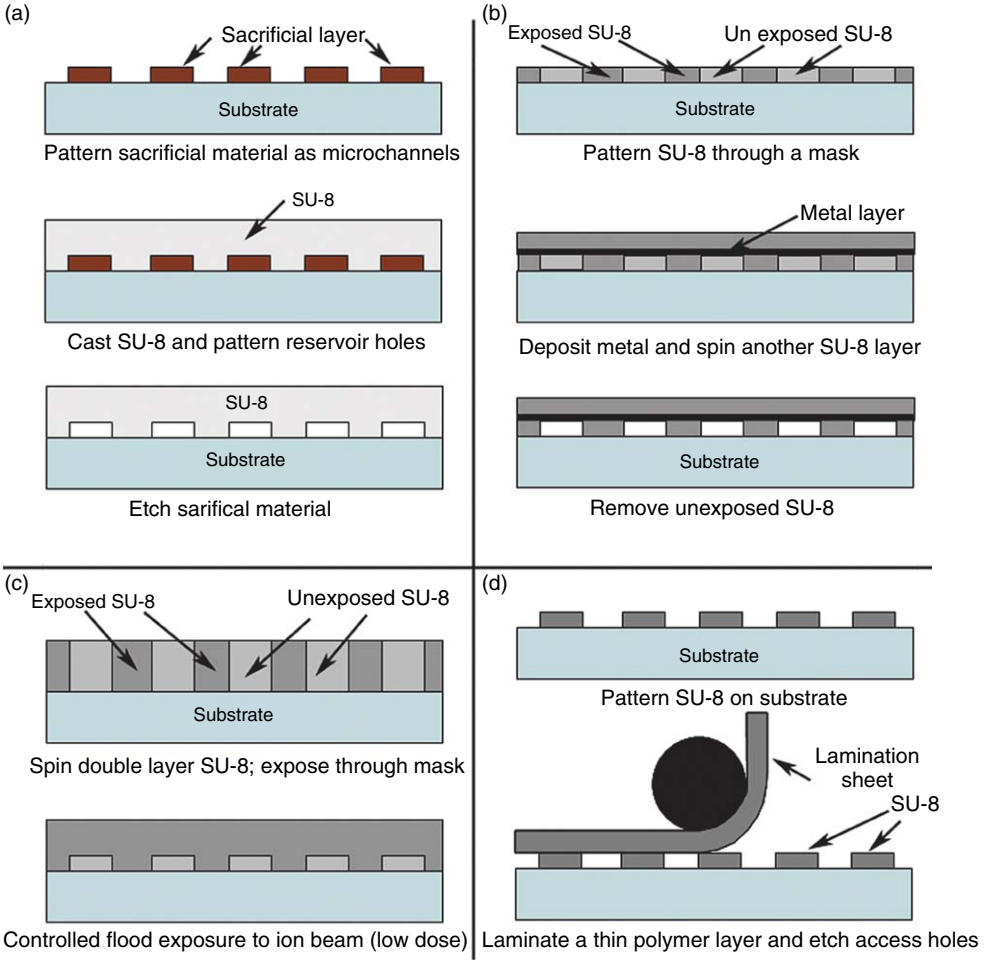

Figure 14 SU-8 microchannels construction techniques.

pattern of the microchannels. In this exposure the entire thickness of the resist is exposed. Subsequently the wafer is flood exposed to a 0.6-MeV beam. These low-energy protons have a thickness range of 10 µm and hence the top layer of SU-8 is exposed while the bottom layer is not. Subsequently the unexposed regions are developed to produce the embedded microchannel structure (Tay *et al.* 2001).

1.04.3.4 Hydrogels

A gel is generally defined as a loose network of cross-linked polymers that retains much of its solvent. They are of two types: physical and chemical. Physical gels may be colloidal suspensions, which aggregate together and adhere to form the gel. These are not held together tightly and can be dispersed again by agitation or mixing. Another type of physical gel is where individual long-chain polymers aggregate either through helix formation or by crystallization. A prime example of this is collagen – a protein that in its denatured state is called gelatin. With a temperature stimulus, individual long-chain gelatin polymers aggregate through helix formation (due to hydrogen bonding or electrostatic attraction). Less rapid aggregation, with the help of fibroblast cells, allows tighter aggregation in the form of a triple helix, leading to strong fibers of collagen.

Chemical gels, on the other hand, are aggregated or gelated with the help of cross-linking reactions between the long polymer chains. An example of this is polyacrylamide, which has been used as a matrix for gel electrophoresis of proteins. Typically, a 1–10% aqueous solution of acrylamide monomer with methylene bisacrylamide as a cross-linking agent at 5–20% of the monomer concentration, a persulfate free-radical catalyst, and a tertiary amine (usually TEMED, tetramethylethylenediamine) as an activator (Heskins and Guillet 1968) is used for gel formation. The activator causes decomposition of the catalyst to produce free radicals that initiate the polymerization. The cross-link density then depends on the ratio of cross-linking agent to monomer. Gels in which water is the solvent are called hydrogels. Any water-soluble polymer can be prepared as a gel by carrying out the polymerization in the presence of a cross-linking agent in an aqueous solution of the polymer (Dusek 1993).

1.04.3.4.1 Responsive gels

Since these gels have a high solvent content, their properties depend upon the balance of polymer–polymer versus polymer–water interactions. Structural change, size variation, and mechanical actuation can be accomplished by slight changes in the polymer–solvent interaction properties initiated by an external stimulus. These kinds of gels are termed as stimuli-responsive hydrogels, and temperature sensitivity is the most common kind where the polymer gel network displays a temperature-sensitive phase behavior at the swelling solvent (Pelton 2000). A linear polymer that displays cloud point behavior (i.e. loss of transparency in a solution of long change hydrocarbon due to aggregation and particulate formation) when heated can be cross-linked to give a temperature-sensitive gel network. A common example is poly(*N*-isopropylacrylamide) (polyNIPAM) or related copolymers. The structure of *N*-isopropylacrylamide (NIPAM) is shown in **Figure 15**. When this gel is heated, it becomes hydrophobic and shrinks by expelling water above a temperature termed as lower critical solution temperature (LCST). At their LCST (32°C) polyNIPAM chains undergo a rapid and reversible phase transition from extended hydrated chains below the LCST to collapsed hydrophobic coils above the LCST (Heskins and Guillet 1968). At room temperature, the gels have high water content, low refractive index difference with water, and few electrically charged groups at the chain ends. At elevated temperatures, the gel volume is several times smaller. The density of electrically charged groups is higher and the refractive index difference with water is greater (Pelton 2000).

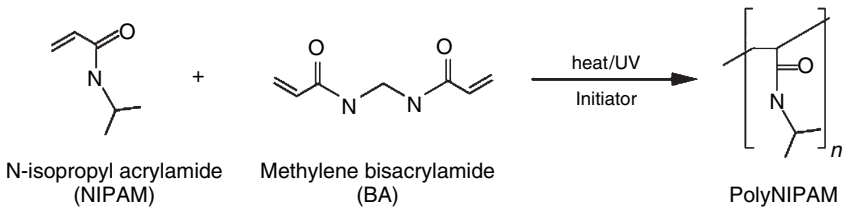

Figure 15 Chemical structure of NIPAM.

MEMS devices utilize transduction principles where a signal in one domain (biological, chemical, mechanical, or fluidic) is converted into another domain. Hydrogels provide a natural phenomenon that can be utilized in microfluidics for intelligent transduction. They are capable of converting chemical signals such as pH to mechanical action such as expansion or contraction. Hydrogels can be tuned to be sensitive to a variety of environmental cues such as pH (Tanaka and Fillmore 1979), temperature (Tanaka *et al.* 1980), electric field (Shiga 1997), glucose concentration (Kataoka *et al.* 1998), and antigens (Miyata *et al.* 1999). The response time for the volume change is proportional to the square of the gel dimension (Gan and Lyon 2001) because diffusion of the stimuli into the bulk of the gel is the key criterion that affects its phase transition. Therefore, faster response can be achieved by reduction in size, making hydrogels attractive materials for microscale actuation.

1.04.3.4.2 Microfabrication

These gels can be formed by photoinitiation, particularly using UV light (Chen *et al.* 1998). This feature makes them suitable for microfabrication through photolithography. One technique for microfabrication involves the use of microchannels to provide spatial resolution (Beebe *et al.* 2000). In this process, microfluidic channels are first constructed using a PDMS elastomer through a casting process as described in Section 1.04.3.2. This method can also be applied to microchannels made of other materials but with sufficient optical transparency. The microchannel is filled with a mixture of monomers and a photoinitiator and allowed to settle to equilibrium. This mixture is irradiated with UV light through a photomask to define the regions in the microchannel for polymerization (Beebe *et al.* 2000). The photopolymerizable liquid consists of acrylic acid and 2-hydroxyethyl methacrylate (in a 1:4 molar ratio), ethylene glycol dimethacrylate (1 wt%), and a photoinitiator (3 wt%) (Beebe *et al.* 2000). Polymerization times vary depending on the light intensity and the photoinitiator and monomer mixture, and is less than 20 s when Irgacure 651 is used as the photoinitiator. When the polymerization is completed, the channel is flushed with water to remove the unpolymerized liquid. This method allows pH-responsive hydrogels of different shapes and sizes to be integrated directly into microfluidic systems (Beebe *et al.* 2000).

1.04.3.4.3 Glucose-responsive devices

In another application, hydrogels responsive to glucose concentration are fabricated using a casting-based approach (Baldi *et al.* 2003) to actuate microvalves. Glucose-responsive hydrogels are synthesized at room temperature in a 200 mg ml^{-1} aqueous solution containing a feed of 18.4 mol% 3-methacrylamidophenylboronic acid, 81.5 mol% acrylamide, and 0.1 mol% methylene bisacrylamide (bis) solution, using ammonium persulfate and TEMED as initiators (Baldi *et al.* 2003). Microfabrication of this gel is done by fabricating a microfabrication mold on top of a membrane as shown in **Figure 16**. The monomer mixture is poured into the cavity, the top layer of which is made of a Teflon sheet. The gel is polymerized by thermal initiation. Then the Teflon sheet is removed and the porous membrane is placed for glucose diffusion. The expansion of the gel in response to glucose concentration regulates the flow in the microchannel. This gel, apart from being sensitive to glucose, is also sensitive to pH, demonstrating a 100% volumetric expansion for pH variation from 7 to 11 and a 30% volumetric expansion for glucose variation from 0 to 100 mM at a physiological pH of 7.4. As noted earlier, the response time of the gel is dependent on its size and valve opening times as low as 7 min have been observed with 30-μm hydrogel layers (Baldi *et al.* 2003).

1.04.3.4.4 Thermally responsive devices

In an interesting photoresist-like implementation, a solution of NIPAM, allyl methacrylate, and azobisisobutyronitrile (photoinitiator) in tetrahydrofuran (THF) solution is spin-cast to 1-μm thickness and photolithographically defined using optical photolithography (Mutlu *et al.* 2003). Higher thicknesses are obtained by casting the prepolymer mixture in a mold and heating the solution at 60°C for 10 min. This reduces the solvent, increases the viscosity, and allows the processing of thicker films. Photolithography and development in acetone produce microstructures with 50-μm resolution (Mutlu *et al.* 2003). Adhesion is promoted by dip-coating and by incubation of the substrate in a solution of 3-(trimethoxysilyl)-propyl methacrylate for 1 day. An in-line microvalve has been fabricated around this hydrogel using parylene microchannels constructed as described in Section 1.04.1. A 2.5-fold increase in polymer volume in water is observed when the water temperature decreases from 25°C to 10°C. Response time is reduced to 7 s primarily due to microfabrication of the hydrogel (Mutlu *et al.* 2003).

Hydrogels have been incorporated into the pores of macroporous polymers to provide both structural stability and thermal responsiveness. The macroporous polymer monolith does not change shape and hence provides overall structural stability, while the hydrogel inside the pore undergoes volumetric change, thereby changing the resistance to flow through the porous material (Yu *et al.* 2003). Response times of 4–5 s are observed with a pressure resistance of 200 psi in the closed state. The LCST temperature at which these phase changes occur has also been adjusted to be between 35°C and 74°C with the same characteristics by varying the proportions of the monovinyl monomers in the polymerization mixture (Lu *et al.* 2003).

1.04.3.5 Polyimide

Polyimide has also been used as a structural material for the construction of microfluidic devices (Goll *et al.* 1996, Metz *et al.* 2001). Commercially available polyimide resin has aromatic heterocyclic chains similar to the structure shown in **Figure 17**. They consist of alternating carbonyl (C=O) groups that act as electron acceptors and nitrogen (N) groups that act as electron donors. This charge transfer complex stabilizes the chain and is responsible for its chemical inertness. This kind of stabilization also happens between the chains and causes structural rigidity and high strength. Polyimide synthesis is a two-step process (**Figure 17**) involving a reaction between a dianhydride and a diamine under ambient conditions in a dipolar aprotic solvent such as *N*,*N*-dimethylacetamide (DMAc) or *N*-methylpyrrolidione (NMP) to yield the corresponding polyamic acid. The acid undergoes cyclization to form the final polyimide.

Photosensitivity can be introduced into the synthesis in two ways, with both depending on prevention of cyclization and hence formation of the polyimide backbone. The first method is to attach a photosensitive group to the carboxylic acid groups and prevent cyclization. The photosensitive group detaches from the polyamic acid upon light excitation. The other method is to use an acid–ion linkage between a photosensitive group and the polyamic acid, which can be broken using light (Hiramoto 1990).

1.04.3.5.1 Microfabrication

For applications in biosciences, polyimides offer advantages over other polymers due to their excellent chemical and thermal stability, low water uptake, and good biocompatibility (Richardson *et al.* 1993). In microfluidics, the initial application of polyimide is as membrane materials for microvalves (Goll *et al.* 1996) and pumps (Goll *et al.* 1997). These studies used commercially available thin polyimide membranes to separate the actuation chamber from the working chamber. Later, photosensitive polyimide (PI-2723, a negative tone organic polymer) was used as a structural material for microchannel construction (Glasgow *et al.* 1999). A thin polyimide layer is spun, prebaked, and patterned on a substrate using optical lithography with the desired geometry and vent channels, but not cured. Next, a thin layer of solvent with dissolved precursor is used to coat a soft-baked layer polyimide on a second substrate. The two halves are placed in contact and cured. Channels with a width of 50–1000 μm and a depth of 3–30 μm have been fabricated for chemical analysis and heat transfer devices (Glasgow *et al.* 1999). Significant stress develops in the structure due to solvent evaporation during the final curing.

An adapted lamination technique is used to produce microchannels with embedded electrodes without the problem of solvent evaporation (Metz *et al.* 2001). The process uses a photosensitive polyimide PI-2732, which is microstructured using optical lithography, and a nonphotosensitive polyimide PI-2611, which is microstructured using dry

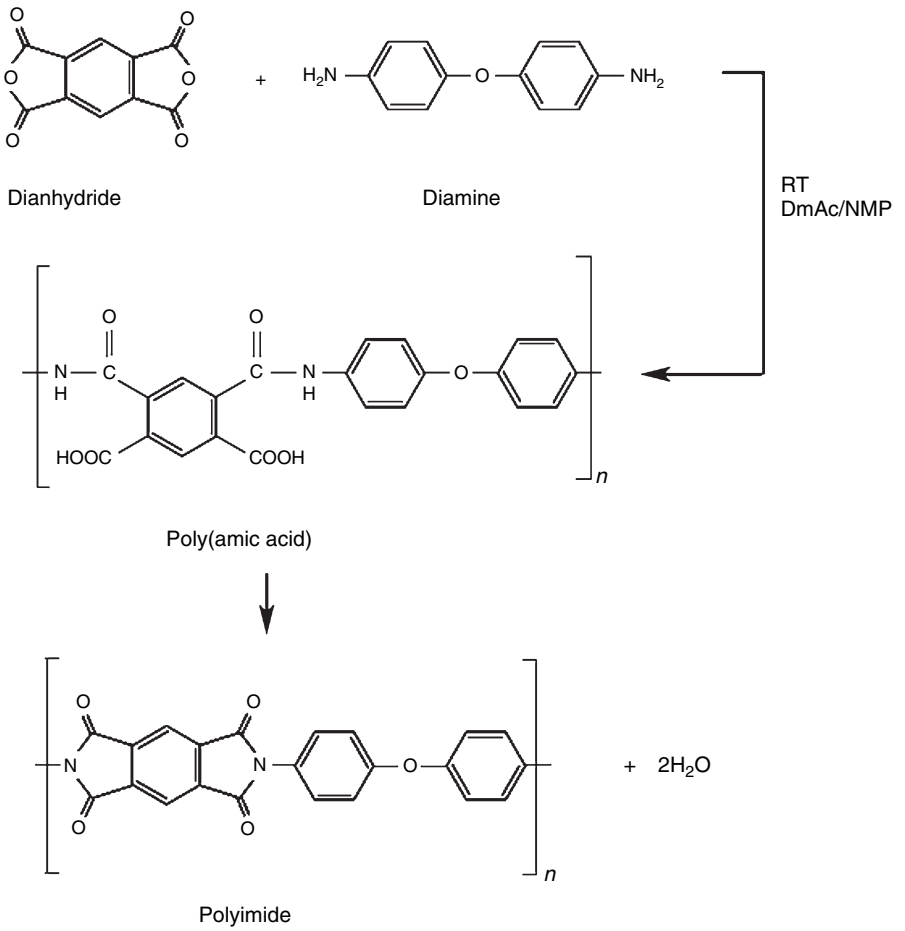

Figure 17 Chemical structure of polyimide.

etching with oxygen plasma with silicon dioxide mask. The process flow begins with the spinning of a 5- to 20-μm layer of polyimide and its curing at 350°C for 1 h. This layer forms the base of the microchannel. A layer of Ti/Pt (50/200 nm) is sputtered and patterned using a positive photoresist. This forms the electrodes inside the microchannels. A second layer of polyimide (5–20 μm), which forms the sidewalls, is spun and partially cured at 100–150°C for 1 h. This layer not only insulates the electrodes but also provides the structure for microchannels. Lamination is done with a nonphotosensitive polyimide layer whose surface is treated with *n*-methyl-2-pyrrolidone (NMP) (swelling agent). The swelling agent causes the partially cured second layer to swell, enabling higher interdiffusion with the lamination layer. A thin Mylar foil (polyimide) is spin-coated with photosensitive polyimide, partially cured, flipped over, and bonded to the substrate by lamination. This layer forms the top of the microchannel. The Mylar layer is peeled off and then the microstructure is laminated again (Metz *et al.* 2001). No interface was observed between the open channel prestructures and the laminated top layer, which indicates good channel sealing as shown in **Figure 18**. The imidization (curing) results in the shrinkage of the polyimide (30–40%), which decreases the height of the film and degrades the sharpness of the sidewalls. The channels thus fabricated withstand pressures as high as 19 bar (Metz *et al.* 2001).

1.04.3.6 Macroporous Polymers

Macroporous polymers were discovered in the 1950s (Abrams 1964; Corte and Meier 1971, Meitzner and Olin 1980). These polymers have a fixed pore size, narrow pore size distribution, extensive cross-linkings, and are structurally stable with their porous structure persisting even in the dry state. The porous

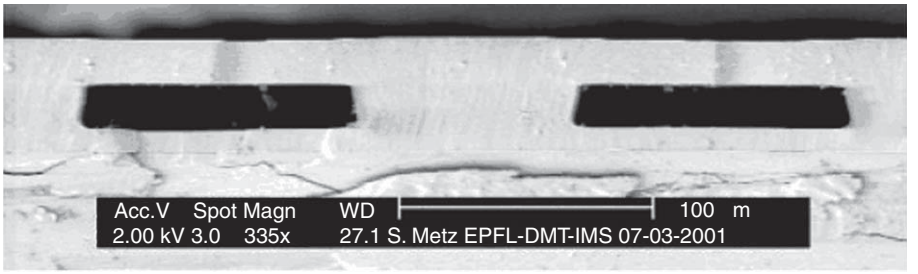

Figure 18 SEM image of microchannels constructed of polyimide. Reproduced with permission from Metz S, Holzer R, Renaud P 2001 Polyimide-based microfluidic devices. *Lab Chip* **1**, 29–34, © 2001 Royal Society of Chemistry.

nature gives them a high surface-to-volume ratio, which is desired in case of catalytic reaction, surface adsorption, chromatography, drug delivery, and electroosmosis.

These materials were initially produced in bead form for applications such as chromatographic packings (Brooks 1990, Yuan *et al.* 1991). The control of pore size and its narrow distribution is accomplished using inert diluents (also called porogens), which phase-separate during polymerization (Svec and Frechet 1995a, Viklund *et al.* 1996). They have also been demonstrated to be effective as monolith support for catalytic reactions (Unger 1990). The fabrication of these monoliths in molded fashion in various tube sizes and tube materials has been discussed in Peters *et al.* (1997a), Svec and Frechet (1995b, c), and Wang *et al.* (1993). These polymers have been used in high-throughput bioreactors with immobilization of various catalytic enzymes on the pores (Petro *et al.* 1996), and now find applications in drug delivery, membranes, and encapsulation of bioreactors (Dusek 1993). The surface properties of these pores formed can be changed from hydrophobic to hydrophilic by addition of grafted side chains (Wang *et al.* 1995). The variation of water permeation in the porous monolith can be controlled with the addition of polyNIPAM side chains (Peters *et al.* 1997b).

1.04.3.6.1 Polymerization

These monoliths can be structured to any given shape by casting the monomeric solution in the mold and by *in situ* polymerization. Microfabrication of these monoliths, using this technique, has been done by using optical lithographic techniques (Mutlu *et al.* 2002). The monomeric mixture consists of ethylene dimethacrylate (EDMA), butyl methacrylate (BMA), and 2-acrylamide-2-methyl-1-propanesulfonic acid (AMPS) as the main monomers, azobisisobutyronitrile (AIBN) as the polymerization initiator, and 1-propanol and 1,4-butenediol as the porogenic solvents. Light initiates radical generation of AIBN and polymerization of the

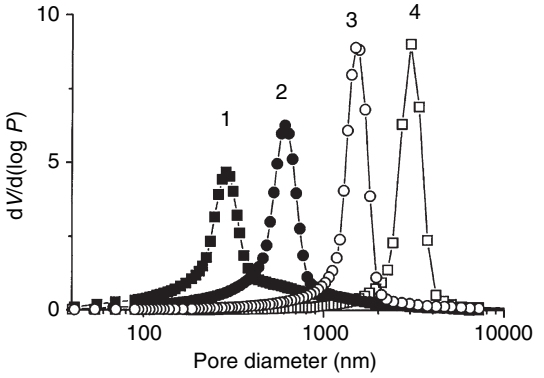

Figure 19 Pore size distribution in porous monolith. Reproduced with permission from Yu C, Svec F, Frechet J M J 2000 Towards stationary phases for chromatography on a microchip: Molded porous polymer monoliths prepared in capillaries by photo-initiated *in-situ* polymerization as separation media for electro-chromatography. *Electrophoresis* **21**, 120–7, © 2000 Wiley.

monomers. Upon polymerization, the polymer phase separates from the porogen phase and polymerizes around the trapped porogens, forming a porous structure. These polymers are usually hydrophobic; however, AMPS ionizes in most pH and hence provides hydrophilicity to the pore surface. The composition of the monomeric mixture determines the pore size and its narrow distribution (Yu *et al.* 2000) as shown in **Figure 19**.

1.04.3.6.2 Microfabrication

The main issues in adapting the technique for thin-film microstructure fabrication are the low viscosity of the monomeric mixture and the effect of oxygen on the polymerization reaction. Low viscosity restricts the use of spinning as a technique for obtaining the defined thickness of films. Very thin layers (~50 nm) and nonuniform distribution of polymer thickness are obtained by spinning. Furthermore, thin layers of the monomeric solution exposed to

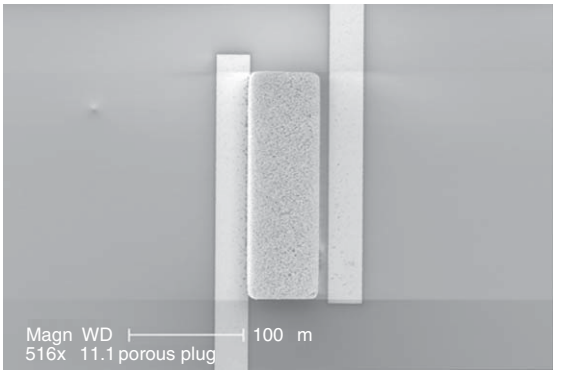

Figure 20 SEM image of a microfabricated porous monolith. MEMS*, Las Vegas, NV, USA, pp. 19–23, © 2002 IEEE.

the atmosphere absorb oxygen, which inhibits polymerization. These issues are solved using a microstructured glass mold, which is etched to a depth of 20 μm (thickness of a thin-film layer) and is used to enclose the monomeric mixture (Mutlu *et al.* 2002). The substrate to which the polymer monolith is to be structured is used as the capping layer. Glass allows polymerization of the monomer using optical techniques. Differential adhesion is obtained by depositing a monolayer of γ-methacryloxytropyl trimethoxy silane as an adhesion layer on the substrate while coating glass mold with parylene (Mutlu *et al.* 2002). Low viscosity causes diffusion of polymers and loss of resolution. Hence flood polymerization and dry etching techniques are used for producing high-resolution structures as shown in **Figure 20**. These structures have been demonstrated to increase the pumping capacity of microelectroosmotic pumps (Mutlu *et al.* 2002) and have potential applications in microscale catalysis, bioreactors, preconcentrators, and filtration units.

1.04.3.7 Biodegradable Materials

Biodegradable materials have traditionally been used as scaffolds for tissue engineering applications (Freed *et al.* 1994), controlled release mechanism for drug delivery (Langer 1990), and in sutures (Frazza and Schimdt 1971). Commonly used biodegradable polymers are polyglycolic acid (PGA), polylactic acid (PLDA), polycaprolactone (PCL), and poly(lactide-*co*-glycolide) (PLGA). The degradation times of these polymers range from 5 months to more than 24 months (Lu and Chen 2004). These polymers have low toxicity and minimal immune response, tunable degradation rates, and excellent mechanical properties suited for tissue engineering applications. The degradation of these polymers is done by hydrolysis of unstable linkage groups in the backbone, yielding degradation products that are capable of reabsorption by the body through metabolic pathways. For example, the degradation product of PGA is glycolic acid, which is a natural metabolite. Suitable unstable groups include esters, anhydrides, orthoesters, and amides. The structures of these polymers allow the manipulation of their degradation rates.

1.04.3.7.1 Polymerization

Synthesis of these polymers is carried out from their stable dimeric form. **Figure 21** shows the chemical structure and the synthesis of the most common of the biodegradable polymers. The dimer is cyclic and hence stabilized. In the presence of heat and an appropriate catalyst, the dimer undergoes ring-opening polymerization and forms linear chains. The chains take the shape of the mold in which the reaction occurs. Other techniques such as injection molding and extrusion have been used for shaping these polymers. An excellent review of the material properties of various classes of biodegradable materials can be found in Gunatillake and Adhikari (2003).

1.04.3.7.2 Microfabrication

A wide variety of microfabrication methods including imprinting or hot embossing (Lu and Chen 2004), soft lithography (Vozzi *et al.* 2003), direct writing (Vozzi *et al.* 2003), stereolithography (Cooke *et al.* 2002), and laser micromachining (Chen *et al.* 2003, Kancharla and Chen 2002) have also been used for structuring biodegradable materials. Photocurable biodegradable versions of PCL have been developed for stereolithographic applications (Matsuda *et al.* 2000). Microfabrication of these photopolymers using lithography has also been accomplished (Leclerca *et al.* 2004).

Compression molding combined with low-temperature bonding of layers has been used to demonstrate the feasibility of producing microstructures, specifically microchannels, using biodegradable materials (King *et al.* 2004). The application of these devices is in tissue engineering of microfluidic vascular networks, which then form the scaffold for seeding and growth of cells to form tissues with the existing blood supply networks. Biodegradable materials are attractive since they provide the initial structural

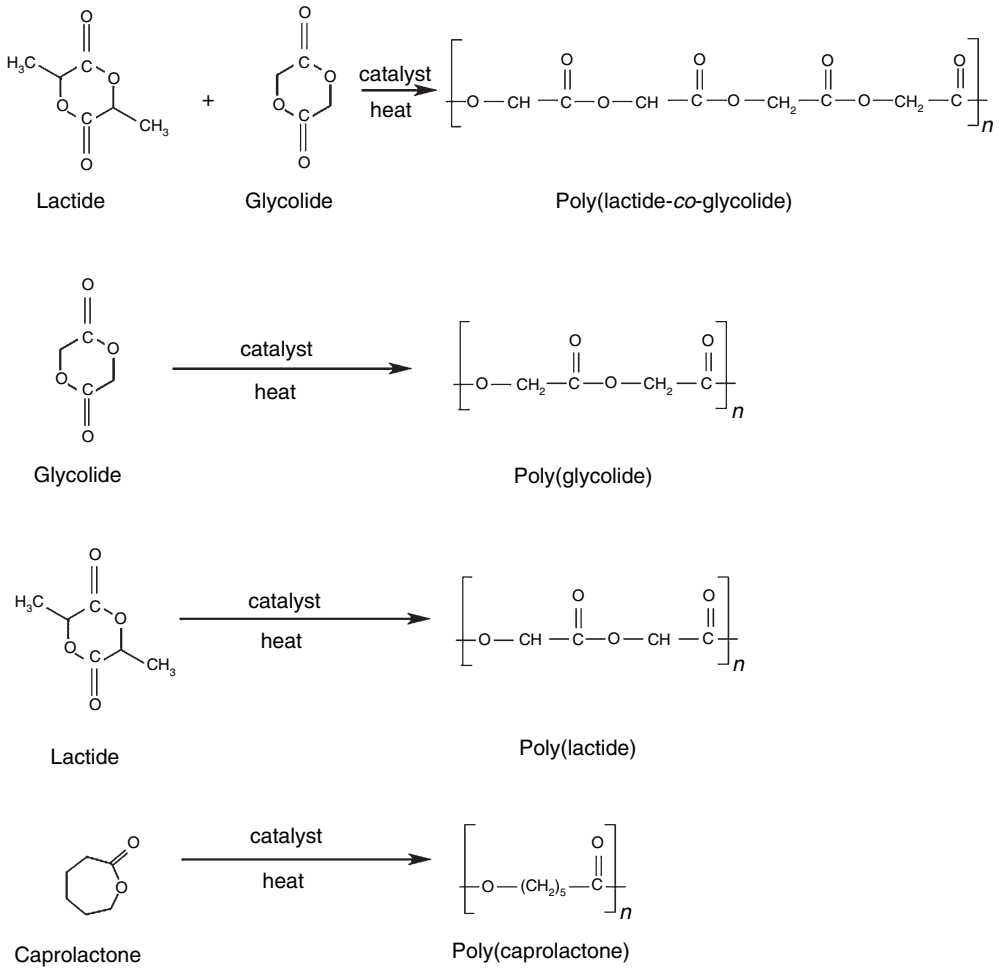

Figure 21 Polymerization process and chemical structure of biodegradable materials.

framework for growth and then wither away when the tissue is able to sustain itself. For molding, the masters containing the fluidic network are produced from PDMS using soft lithography techniques as shown in **Figure 22**. PDMS posts are then attached to the reservoirs in the mold. Another PDMS master with larger holes that are concentric with the attached post is assembled on the first master. PLGA pellets are placed between these two layers and heated to 110°C along with the application of compressive force of 100–500 lbs.

The PLGA becomes a viscous melt and conforms with the microstructure inside the mold cavity. Film thickness of 100–500 μm can be obtained by varying the compression time, the temperature, and the applied force. An unpatterned PLGA film is used to close the microchannel structure using low-temperature fusion bonding at 60°C for 30–60 min. Bonding at temperatures slightly higher than the glass transition temperature maintains structural integrity while still allowing interdiffusion in the areas of contact providing greater bond strength (King *et al.* 2004). Multichannel stacks could be created this way leading to 3D microchannel network as shown in **Figure 23**. A similar method was used to mold PCL material into microchambers for drug delivery (Armani and Liu 2000).

1.04.3.8 Paraffin

Paraffins are saturated hydrocarbon mixtures consisting of alkanes of varying chain lengths. They can be gas, liquid, or solid depending on the pressure and temperature conditions. They occur as simple straight chains or as branched chains. The general chemical formula for straight chain paraffins is

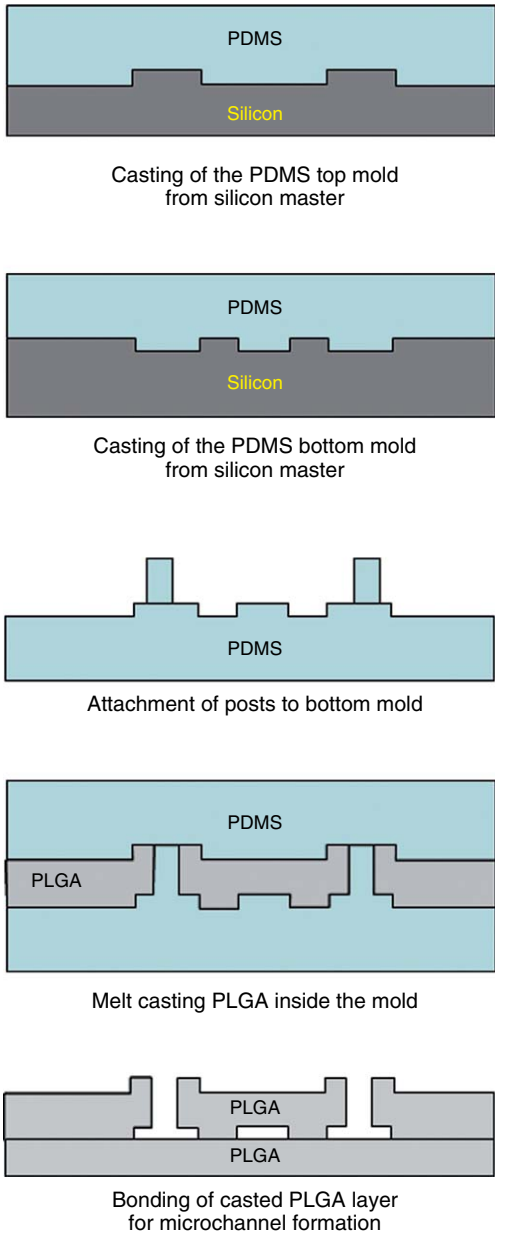

Figure 22 Schematic process flow for the construction of microchannel network in PLGA for creation of vascular networks.

C_nH_{2n+2} and they have different melting temperatures depending on their chain lengths. **Figure 24** shows the range of melting temperatures for paraffins of different chain lengths.

1.04.3.8.1 Properties

Paraffins have low thermal conductivity, low electrical conductivity, and low chemical reactivity, and hence they are ideally suited for microactuator applications. They undergo phase change from solid to liquid, which is accompanied by volumetric expansion. Differences in volume of 5–40% are observed between phases for various paraffins (Carlen 2001). **Figure 25** shows the specific volumetric expansion of a particular paraffin wax under different pressure and temperature conditions. Paraffins are stable up to 250°C; therefore no

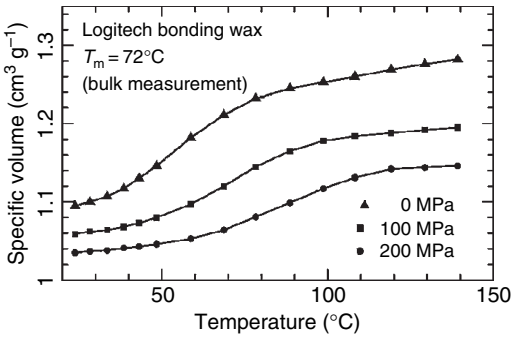

Figure 25 Volumetric expansion of paraffins under varying thermopneumatic conditions. Reproduced with permission from Carlen E T, Mastrangelo C H 2002 Electrothermally activated paraffin microactuators. *J. MEMS* **11**, 165–74, © 2002 IEEE.

boiling occurs even at high temperatures. Pressure loss during actuation is low due to its low viscosity in the liquid phase. Furthermore, liquid paraffins are nonpolar and hence do not mix with the polar liquids such as water, which are commonly used in microfluidic applications. Paraffins are also stable through numerous phase change cycles and their properties remain constant over long periods of time.

1.04.3.8.2 Microfabrication

Phase change actuation has the highest actuation power among all the actuation methods used in microactuators. They provide both high displacements and forces but their integration into microsystems has been cumbersome (Bergstrom *et al.* 1995). Microfabrication of paraffins has enabled ease of integration and development of high-force actuators in the microscale (Carlen and Mastrangelo 2002). Thin films of paraffins have been deposited using a thermal evaporation process. They are easy to evaporate due to their high vapor pressures. Deposition conditions of 5 µtorr and temperature of 150°C provided a deposition rate of 100 nm min^{-1}. Surface roughness of $\leq$42 nm has been measured (Carlen 2001). Adhesion of the deposited film to the substrate was enhanced by silanation and oxygen plasma treatment. Micropatterning of paraffins follows an elaborate procedure because of its dissolution and loss of feature in solvents such as acetone and developer solutions. First, the thin film is encapsulated by a thin layer of parylene. A thin layer of Au is deposited using a cooled-stage sputtering station. The Au layer is patterned using optical lithography and is used as a mask for reactive ion etching (RIE) of parylene/paraffin hybrid layer. RIE under 300 mtorr pressure with 25:75 sccm (CF_4:O_2) at 70-W radio frequency (RF) provided an etch rate of 250–300 nm min^{-1}. It is critical to maintain the substrate at a low temperature in order to maintain the patterned feature on the wafer.

Microactuators consisting of a microheater with a patterned micropatch of paraffin enclosed in a parylene sealed chamber have been developed (Carlen and Mastrangelo 2000), exhibiting a deflection of 2.7 µm at 150 mW. Actuators were assembled into a valve format and a 6-bit microflow controller was developed, which had flow control from 1 to 2 sccm using 5 V, 50 mW power (Carlen and Mastrangelo 2000).

1.04.4 Conclusion

The use of polymers in MEMS and microfluidics has been expanding rapidly since 1996. A number of microfabrication methods, both conventional and nonconventional, have been developed to encompass a wide selection of polymers available. The main driving force is the application of these techniques toward construction of microfluidic devices for medical diagnostics, drug discovery, and analytical laboratory applications. The attractiveness of polymers is their low cost, variety, solvent and biocompatibility, and customizable surface properties. Single devices such as microchannel networks, pumps, and valves have been successfully constructed using the existing polymers and fabrication techniques. The focus of future research is in three main directions:

1. Development of microfabrication technologies for production of huge volumes of disposable devices at low cost.
2. Development of new polymers customized for specific applications in microfluidics.
3. Development of integrated systems involving multiple polymeric materials and fabrication technologies for complex functionality.

The use of polymers has moved MEMS and microfluidics away from its roots in the semiconductor microprocessing industry. Its widespread adoption points toward its popularity and long-term success.

Biography

Ponnambalam Ravi Selvaganapathy received his BS degree in Chemical and Electrochemical Engineering from the Central Electrochemical Research Institute (CECRI), Karaikudi, India, in 1998. He received his MS and Ph.D. degrees in Electrical Engineering from the University of Michigan, Ann Arbor, MI, in 2001 and 2002, respectively. During his tenure at the University of Michigan, he worked on a variety of projects related to MEMS and bioMEMS processes and device development including electrochemical detection in capillary electrophoresis systems, electroosmotic pumping systems, prevention of bubble formation in electrically active microfluidic systems, thermal phase change polymers, development of microfabrication techniques for porous polymers in microsystems, development of a contact-free technique for pH measurement using the Kelvin probe, and investigation of microplasmas as a fluorescence excitation source for DNA. He then worked as a Postdoctoral Research Scientist with Sandia National Laboratories, Livermore, CA, until June 2004, in the area of integrated microfluidic systems. He is presently an Assistant Professor of Mechanical and Biomedical Engineering at McMaster University, Canada. His current research interests include developing active microfluidic components, materials, and fabrication technologies for a number of applications including, medical diagnostics, drug discovery, drug delivery, automated sampling and sensing, and microtools for biology.

1.05 Biocompatibility of Microsystems

Jürgen Rühe and Markus Biesalski, Department of Microsystems Engineering – IMTEK, University of Freiburg, Freiburg, Germany

1.05.1 Introduction

Recent progress in the field of microengineering has opened new horizons for the development of new types of medical devices (Goodsell 2004, Lee and Lee 2004, Santini *et al.* 1999, Staples *et al.* 2006, Voldman *et al.* 1999, Willner and Willner 2001). These devices monitor the well-being of a person for extended periods of time and detect any critical situations such as unusually elevated or reduced level of blood sugar, unhealthy high or low blood pressure, or an unexpected immune reaction. They respond to any severe problem they encounter either by communicating the problem to the patient or by directly alarming an emergency response unit over cellular phone. Smart sensor/microdevice couples will intervene in critical situations or in situations that require a planned intervention, directly through the controlled release of a drug (Santini *et al.* 1999, Staples *et al.* 2006). A little further in the future microdevices will allow the restoration of bodily functions after such functions have been impaired or even destroyed through an accident or by an illness. One of the expectations in this area is that a patient who has been paralyzed through an accident or even lost a limb completely can regain function of the impaired site, so that it behaves similarly to how it did before the accident. In this scenario the patient will just think about what he/she wants to do, and a microsystem that is coupled to the appropriate neuronal cells bridges the destroyed nerve area and excites the necessary muscles or finely moves a prosthesis (Clark 2006, Margalit *et al.* 2002, Rodriguez *et al.* 2000). In other cases, in a patient who has turned blind because of problems related to the eye itself, for example, due to retinal function loss, vision can be restored by directly feeding electrical signals from a small micro camera into the nerve connecting the dysfunctional eye and the brain. While the latter two examples might be a vision for the future and to date only initial steps have been made in this direction, other devices such as cochlear implants (Clark 2006), which improve the hearing of patients who have turned deaf but still have a functional hearing nerve, are already widely in use and have been implanted in a large number of patients (**Figure 1**).

Concepts for the construction of bacterial-scale, remote control submarines comprising nanocomponents, like the one featured in the 1966 science fiction movie, *Fantastic Voyage*, or, more recently with the same topic, in the movie *Innerspace* (1987), have been proposed. These submarines are injected into the

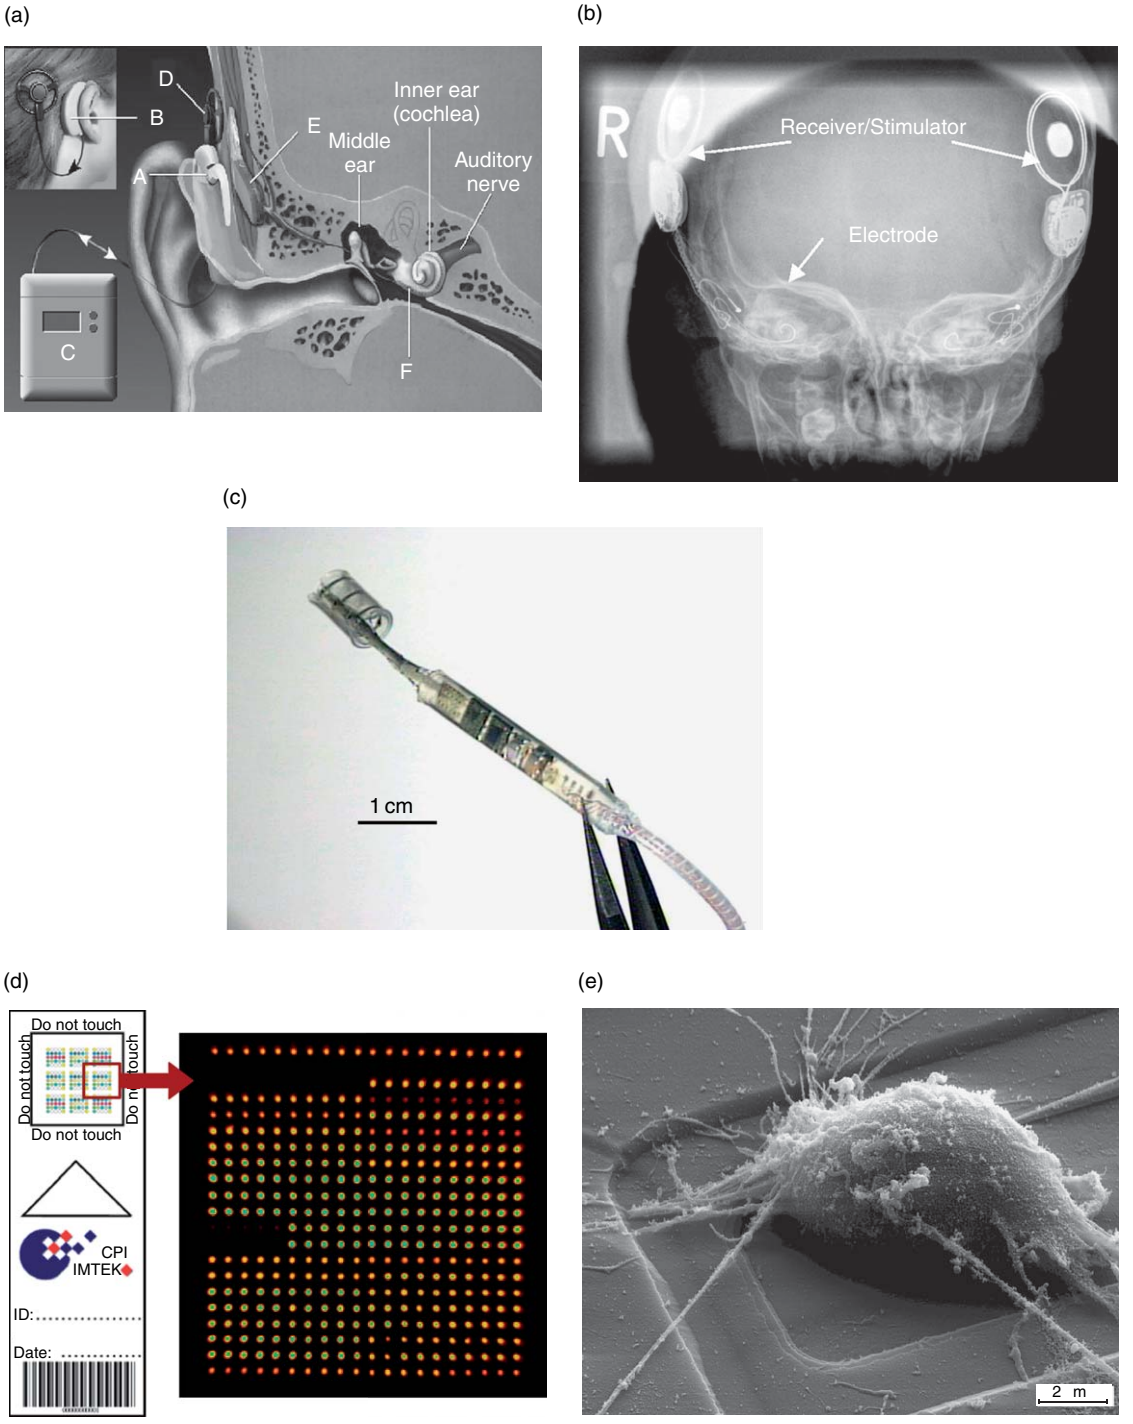

Figure 1 Examples and schematic illustrations of microdevices for medical applications: (a) The structure of the ear and a diagram of the multiple-channel cochlear implant. The components are as given: A, microphone; B, behind-the-ear speech processor; C, body-worn speech processor; D, transmitting aerial; E, receiver stimulator; F, electrode array. (Source: Clark G M 2006 The multiple-channel cochlear implant: The interface between sound and the central nervous system for hearing, speech, and language in deaf people-a personal perspective. *Philos. Trans. R. Soc. Lond. B Biol. Sci.* **361**, 791 [Review].) (b) X-ray micrograph of skull after bilateral implantation of a cochlea implant. (Figures reprinted in part with permission.)

bloodstream of patients and are transported to areas in the body that require examination and treatment. While such ideas belong to the realm of science fiction movies and will continue to do so for many years to come, great progress has undoubtedly been made in several diverse areas of microdevice-driven or microdevice-enhanced applications: Microdevices are already or will in the foreseeable future be employed in a large spectrum of biomedical applications such as minimal invasive diagnosis, monitoring and therapy, drug dosing, and implants, as well as in biochemical diagnostics. Some devices that have been developed and are currently in use are as follows:

- Chip-based bioanalytical devices (DNA, protein, cell chips) that allow high-throughput screening procedures and promise the development of low-cost diagnostic tools (Beier and Hoheisel 1999, Falconet *et al.* 2006, Ramsay 1998, Southern 1996, Zhu and Snyder 2003)
- Bioelectronics including active neurostimulation for the rehabilitation of patients who are suffering from paralysis (Egert *et al.* 1998, Fromherz *et al.* 1991, Scholl *et al.* 2000)
- Implantable sensors (wireless, remote) for readout and monitoring of important physiological parameters (Jain 2003, Kohli-Seth and Orpello 2003, Staples *et al.* 2006)
- Implantable drug dosing systems (Anderson 1994, Cleland *et al.* 2001, Santini *et al.* 1999)
- Smart catheters (Hefti *et al.* 1998, Singer *et al.* 1998)

This list is by no means exhaustive and is meant more as a general illustration of the potential of microdevices. It would be a considerable task to review in depth even the state of the art in one of these areas. For example the generation of biochips has progressed into a large field of scientific research with thousands of publications or patents worldwide. Bioelectronics has similarly developed into a large research area. An in-depth discussion of microdevices in biomedical applications is clearly beyond the goals of this chapter. Here we focus exclusively on the interactions between microdevices and biosystems such as the animal or human body.

If physical parameters of a patient such as blood pressure are measured outside of the body (*ex corpore*), the choice of materials involved in the generation of the microsystem is usually not critical. However, the situation changes drastically if the microsystem is brought into direct contact with the biosystem and the medical devices are implanted into the body of a patient. Arterial blood pressure is most accurately measured invasively by placing a cannula into a blood vessel and connecting it to an electronic pressure transducer. This invasive technique is regularly employed in human and veterinary intensive care medicine, in anesthesiology, and for research purposes, but it can be associated with complications such as thrombosis, infection, and bleeding. With respect to the latter, the choice of material becomes very critical. In the case of implanted devices, the interactions of the microdevice with the biological systems play a crucial role in its performance. During such intimate contact it becomes very important how the body responds to the implanted microsystem and vice versa. These mutual interactions are frequently summarized under the term biocompatibility. In many respects microdevices behave in a very similar way as macroscopic biomaterials, which have been extensively discussed in the literature. However, it should be noted that once a critical size scale is reached, the biosystem directly responds to the structure size. For example Whitesides *et al.* have shown that cells respond strongly to the size of the pattern that is generated at a substrate surface. In their experiments they patterned self-assembled monolayers (SAMs) through μ-contact printing (Kumar *et al.* 1995, Mrksich and Whitesides 1996). Whereas the overall chemistry was the same in all cases, the cells thrived very well on surfaces of one size scale while losing adhesion or even dying on surfaces where the same pattern was generated, but with a different size scale (Mrksich and Whitesides 1996).

A second example, which has already caused several thousand of deaths and forced the restoration or demolition of thousands of buildings worldwide, is the case of asbestos. Asbestos is a silicate mineral, which has wonderful physical and chemical properties and as such has been used as a widespread construction material. While in general silicates in other form and shapes are not toxic, the unfavorable aspect ratio of asbestos fibers has been identified as one of the major reasons for the development of lung cancer (Becklake 1976, Mossman 1989).

1.05.2 Biocompatibility and the Host Response

A useful definition of the term biocompatibility, which is widely used in the biomaterials community today, was given by Williams some twenty years ago (Williams 1986). He defined: "Biocompatibility is the ability of a material to perform with an appropriate

host response in a specific application." This definition is now widely accepted as it describes several important aspects of biocompatibility: Biocompatibility is not an absolute property of a material but must always be seen in the context of an application. While a material might perform very well in one application and one would call the biocompatibility excellent, it might utterly fail in another context. One of the reasons is that some microdevices such as a smart catheter are in contact with the patient for only hours or a few days at most, whereas other devices may be in place and perform their functions for many years, sometimes for the rest of the life of the patient. While a slow leaching out of some adverse/slightly toxic compound might be acceptable for short-term exposure, it might be completely detrimental in a long-term use of the same material. In addition, the long desired lifetime of the implant imposes much stricter restrictions on how critical wound healing and chronic responses become for the evaluation of the biocompatibility of the material.

Furthermore, the definition of biocompatibility given above, expressively points out that all biomaterials cause a host response of some kind. This is very important insofar as most materials cause a nonspecific and rather stereotypic response of the body against the foreign material. Such a response can occur at different levels: for example, a blood–material interaction, an acute inflammation, a foreign body reaction, formation of a fibrous capsule, or a chronic inflammation. An important question is whether the host response against the foreign material is acceptable – in other words, whether it works as intended and presents no harm to the patient, which could not be tolerated (appropriate host response). In the end, the key question is whether the benefits caused by the microdevice outweigh the adverse reactions.

If one looks more closely at the response of the host against the implant, one has to take different levels of host response into consideration:

(1) local response
(2) regional response
(3) global/systemic response

An unfavorable response at one of these levels might render the use of the whole microdevice not suitable. The first-level (local) response describes interactions of the microdevice directly with contacting blood or cells. Here the microdevice might lead to blood coagulation or trigger a direct immune response. The regional response describes how surrounding tissue that is not in direct contact, but close to it, responds to the biomaterial. A global/systemic response of the body can occur if toxic or allergy-inducing compounds are transported through blood or lymphatic vessels and cause reactions of the body against the implanted device sometimes even far away from the actual site of implantation. An example that is widely known and even frequently discussed in public is the so-called metal allergy (Grawkodger 1993, Landsdown 1995), where metal ions are transported through tissue or blood and cause an allergic reaction. While metal ions *per se* do not challenge the immune system of a person as they are way too small to do so, they can form metalloprotein complexes that can cause a strong allergic response locally and also further downstream, at locations where the metals are transported, and are being deposited. In some locations they can accumulate and cause a reaction despite their low concentration in the bloodstream (Landsdown 1995).

The term normal wound healing is commonly used to define a complex cascade of reactions that set in after an injury and that consist of events such as acute inflammation, formation of granulation tissue, and eventual new tissue formation. In brief, the normal healing typically starts with the flooding of blood from injured blood vessels into the injured area. The blood protein fibrinogen is converted into fibrin that promotes the adhesion and activation of platelets, which leads to the formation of a blood clot which closes the wound. Upon the release of chemical signaling molecules (e.g., cytokines), more cells infiltrate the injured area, among them are cells from the immune system (e.g., neutrophils of white blood cells). Macrophages resulting from differentiated monocytes remove foreign materials, bacteria, and dead cells. Upon stimulation, other cells, such as endothelial cells, and fibroblasts are then responsible for building up new blood vessels and extracellular matrix (ECM), thus generating a highly vascularized tissue (granulation tissue). Multiple factors such as the extent and location of the injury, and the loss of basement membrane structures govern the degree of restoration of normal tissue. In most cases the granulation tissue is remodeled into a scar tissue (fibrosis).

If a synthetic material is implanted into a living organism, this process is again accompanied by an injury and/or by a loss of tissue, regardless of the exact details of the medical device. However, now the organism responds in a different way to that outlined above, which is commonly known as foreign body reaction. In case of the presence of a biomaterial, the wound healing response is largely affected by the blood–material interactions, the formation of a

provisional matrix surrounding the implanted material, the extent and degree of cellular necrosis, as well as the extent and degree of the inflammatory response. For a detailed description of the host response of organisms to implanted synthetic materials, the reader can refer to several reviews by Anderson (Anderson 1993, 2001, Anderson *et al.* 1996). Here we will only summarize in brief the important events that take place (**Figure 2**) once a synthetic material (e.g., a prosthesis or a medical device) is implanted into a living organism.

Immediately after implantation, blood proteins, which are among the first components to arrive, adsorb at the surface of the material, typically in a nonspecific manner. Upon adsorption, many proteins change their conformation, i.e., they denature at the surface of the biomaterial. Note that nonspecific interaction of proteins with the biomaterial's interface, including the denaturation of proteins, does not occur in normal wound healing conditions. First, cells (e.g., neutrophils and platelets) approach and adhere to the biomaterial; subsequently, they sense the abnormal protein interface and react in a cascade of reactions in which cytokines signal other cells to infiltrate the area of the implant as well as signal for the differentiation of monocytes into macrophages that start attacking the foreign body (acute inflammatory response). As a biomaterial implant is most likely much larger than the recruited macrophages, chronic inflammation results in the fusion of macrophages into foreign body giant cells that are often present during the lifetime of an artificial implant. The final stage of this foreign body response, typically reached after 2–3 weeks, consists of the formation of a 50- to 200-μm-thick capsule that surrounds the biomaterial implant (Ratner and Bryant 2004). The fibrotic capsule consists of an avascular collagenous tissue, with the ultimate goal to cut off

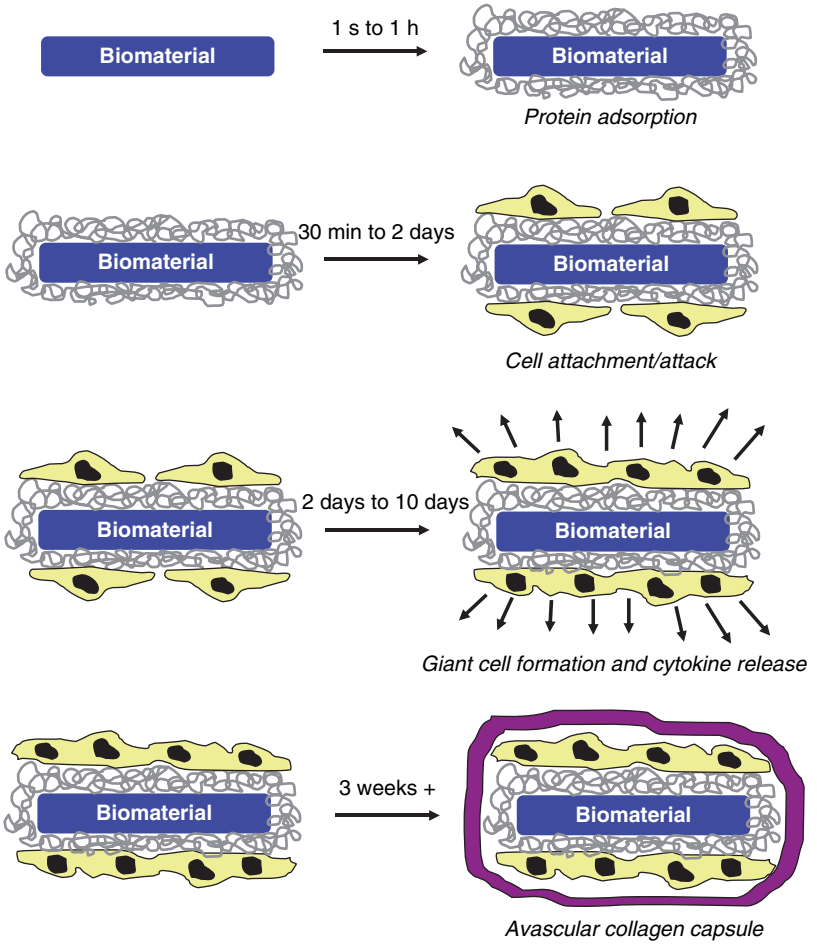

Figure 2 The foreign body reaction as illustrated here is the normal reaction by higher organisms to an implanted synthetic material (e.g., microdevice).

any support (e.g., nutritional supplements) and to wall-off the foreign body. Sometimes, chronic inflammation reduces after the formation of this capsule, and, in principle, the organism accepts the presence of the implant. However, in some cases strong inflammatory responses are still upregulated after weeks, or months, or even years of implantation, and the function of the injured tissue is significantly altered (Anderson *et al.* 1996).

Local responses determine the compatibility of a microsystem in contact with a biosystem. These responses in turn depend on a large spectrum of parameters. Some are directly related to the organism into which the microsystem is implanted, as not all information obtained from one species can be transferred directly to another species. The host response might further be influenced by the age, the gender, and the state of health of the patient and the tissue type and location.

Heart valve implants of porcine origin provide an example of the influence of the age of the patient on biocompatibility (Dahm *et al.* 2004, Schoen and Levy 1999). These materials can be implanted and behave rather well in the human body. They heal well and are next to carbon fiber-reinforced polymers, one of the standard materials for heart valve replacement. However, they have some tendency to become calcified, which causes strong wear to the valve and limits the lifetime of such a device in an adult person to about 10–15 years. As during this time the performance of the valve is very good, one would call the biocompatibility of the material satisfactory. However, when such a material is implanted into children, who have a much higher calcium level in the blood, calcification would occur within months, followed by mechanical destruction and failure. Thus as far as children are concerned, one would call the biocompatibility of the material low.

Some parameters controlling the biocompatibility are directly related to the device itself. Size and shape and mechanical properties such as fracture resistance and elasticity are some examples. Other parameters that are directly related to the surface properties of the implant are:

- Surface chemistry
- Surface roughness
- Surface charges
- Chemical stability/what kind of degradation products are set free
- Porosity
- Bleeding out of chemicals

Interactions of the microsystem and the host are not a one-way street in that the body reacts to the presence of the microsystem. The biosystem also represents an environment, which can sometimes be rather aggressive and highly challenging for microdevices. All biological systems consist of an aqueous solution, which contains a rather high concentration of ions and a wide spectrum of organic molecules. Thus degradation can and will to some extent occur and might change the properties of the microdevice significantly. Another problem that arises from the host response is a possible encapsulation of the microdevice. As already described in more detail above, a fibrous capsule starts to form some days after implantation. The formation of a fibrous capsule, however, may strongly interfere with the functionality of the implant (Brash and Horbett 1987, Ratner and Bryant 2004). If a sensor is implanted into the body, a reliable and accurate measurement of the analyte concentration requires the unrestricted diffusion of the analyte to the sensor at all times. If for example a glucose sensor is implanted into the body to measure the glucose concentration, it is essential that the glucose level at the sensor surface is closely correlated to that in the bloodstream. It is obvious that a barrier, such as the fibrotic collagenous bag surrounding the implanted device after 2–3 weeks, will influence the monitoring of the glucose concentration, as it resembles a barrier to the diffusion of the glucose molecules (**Figure 3**).

Why is the interaction of biological cells and biomolecules with polymers or other artificial materials for biomedical applications so complicated? One complication stems from the fact that biological environments are from a chemical point of view

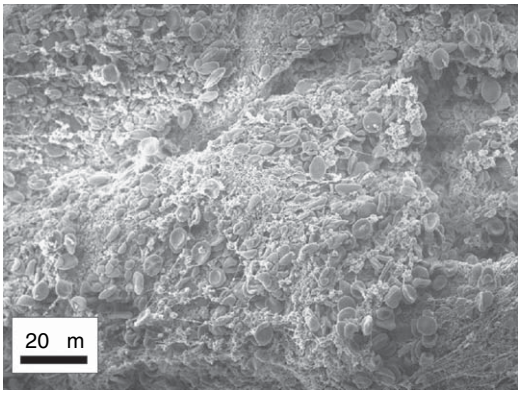

Figure 3 Scanning electron microscopic image of a fibrin network and thrombocytes on the surface of an artificial heart valve. (Picture courtesy: Dr. A. Schlitt, University Hospital, Mainz, Germany.)

rather complex mixtures of a wide spectrum of different compounds. Proteins, polysaccharides, lipids, and low molecular weight electrolytes are all simultaneously present in the biological systems and have all more or less strong interactions with the materials. However, the biocompatibility of implant materials and the success achieved in generating bioanalytical devices such as DNA or protein chips depend critically on the interaction of the surfaces in question with their respective environments.

These complex interactions lead frequently to the formation of more or less thick biofilms at the surface of the implanted material, which alter the surface strongly. As this process is mostly not desired, it is often called surface fouling. The formation of biofilms at the surface of the substrate is a complex process, which starts when the first proteins become adsorbed at the surface. This triggers a whole cascade of signaling events and leads to a strong adhesion of cells. Therefore controlling the adsorption of proteins to the surfaces of the material involved is one of the crucial factors in controlling the adhesion of cells and thus in enhancing the performance of the microsystem. This fact has guided a great quest for the synthesis of biomaterials with controlled surface properties. Before we review some important techniques for surface modification, we will briefly discuss some aspects of adhesion of living cells to surfaces.

1.05.3 Adhesion of Living Cells to Surfaces

For some devices the formation of a fibrotic capsule does not interfere with the functionality of the microsystem. For most applications, however, the encapsulation of the implanted device is very detrimental to its performance. In this case it is important to facilitate the restoration of a healthy tissue surrounding the implant.

In order to achieve this, conditions that allow living cells to attach to the biomaterial's interface, as well as the subsequent buildup of an intact (nondenatured), extra-cellular matrix (ECM), by the attached cells *in vivo*, need to be implemented. In order to design materials that provide the capability to resist nonspecific protein adsorption and to allow the directed attachment of living cells to these materials, it is necessary to understand the basic principles that underlay the adhesion of cells to other cells and to the ECM.

Our understanding of molecular mechanisms that underlay these phenomena has improved tremendously in the past decades. In almost all cases the cell–cell adhesion and cell–ECM adhesion are dominated by specific interactions formed between dedicated adhesion molecules found as transmembrane receptors embedded in the plasma membrane of cells. Five major classes of such receptors, so-called cell adhesion molecules (CAMs), have been identified (Alberts *et al.* 2002, Baszkin and Norde 2000, Lodish *et al.* 2000). Among them are immunoglobulins and cadherins, which interact with their counterparts situated in the neighboring cell membrane and form cell–cell contacts. Selectins bind to glycosylated mucins, and vice versa, and to some growth factors. Integrins are the most important class of CAMs that mainly bind to ECM proteins and interact with immunoglobulins too (**Figure 4**).

Integrins are heterodimers, consisting of two noncovalently linked subunits, called alpha and beta (Alberts *et al.* 2002, van der Flier and Sonnenberg 2001, Humphries 1990, Hynes 2002). Taken together, there are 24 different integrins known to date (Alberts *et al.* 2002, Baszkin and Norde 2000). Most integrins are expressed on a variety of cells, and most cells in turn express several integrins, enabling them to bind to several matrix molecules (Humphries 1990). Most important here being fibronectin and other ECM proteins such as collagens, laminin, and vitronectin.

The process of cell–matrix adhesion consists of a cascade of different overlapping events and is initiated by the interaction of integrin receptors that bind to small peptide ligands in the respective ECM proteins (Alberts *et al.* 2002). One well-known peptide ligand is the minimal cell recognition sequence RGD (R = Arginine, G = Glycine, and D = Aspartic acid) (Giancotti 2000, Giancotti and Ruoslahti 1999, Pierschbacher and Ruoslahti 1984a, b, Ruoslahti 1996, Ruoslahti and Pierschbacher 1987), which is found in many ECM proteins including fibronectin.

As a result of the ligand–receptor interactions, the cell begins to flatten (i.e., spreads) on the surface. Inside the cell, the same ligand–receptor interaction triggers the organization of actin filaments, which are often called stress fibers. Finally, integrin molecules, which cluster together in the membrane to so-called *focal adhesion points*, are attached to both the peptide ligand outside of the cell and the cytoskeleton inside (Geiger and Bershadsky 2001, Pande 2000, Petit and Thiery 2000, Zamir and Geiger 2001). It is important to recognize that the interaction of the peptide

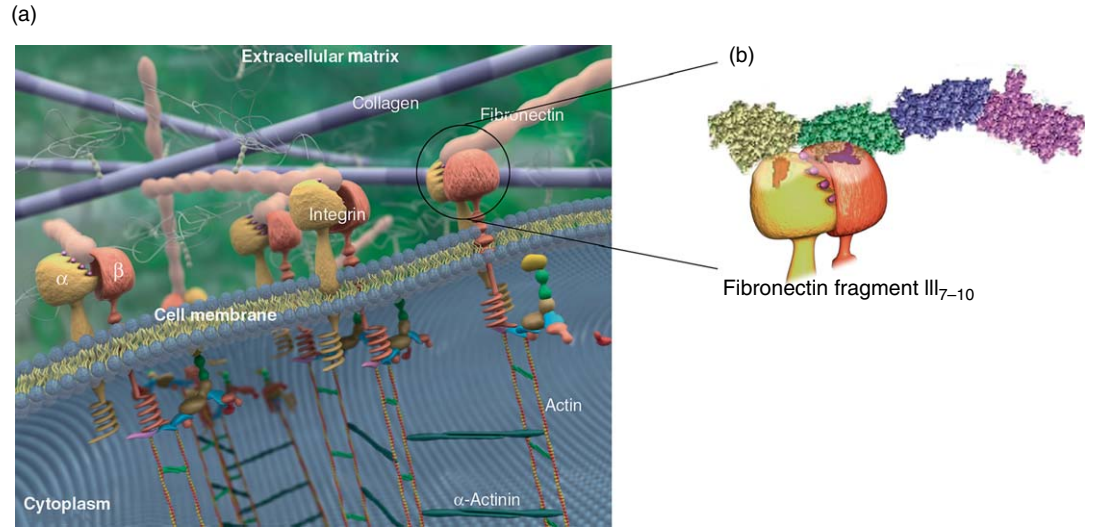

Figure 4 (a) Integrins are composed of two subunits, α and β, and they hold a cell in place by attaching at one end to proteins of the extracellular matrix (ECM) (and in specific to the cell-binding domain of the protein), like fibronectin, and at the other end to the cytoskeleton, the structural framework of the cell. They connect to the cytoskeleton through a highly organized aggregate of proteins, such as actin filaments and α-actinin. (b) Integrins bind to the adhesion domains of the ECM proteins by recognizing specific sites of that domain. A model for the recognition of the fibronectin G**RGD**S site and PHSRN synergy site by an integrin is shown. The four repeats of the fibronectin fragment $III_{7–10}$ are shown in different colors: purple for III_7 to yellow for III_{10}. The synergy site PHSRN in III_9 repeat is marked in blue and the G**RGD**S in III_{10} in red. The minimal amino acid sequence RGD in fibronectin and other cell adhesion proteins is the most important recognition site for about half of all known integrins. The synergy site is also required for high-affinity binding. (Source: Tirrell M, Kokkoli E, Biesalski M 2002 The role of surface science in bioengineered materials. *Surf. Sci.* **500**, 61.)

ligands with integrin receptors not only ensures the structural integrity of living cells but also signals a number of events inside the cell that have an influence on the metabolism, the differentiation, the proliferation and the immune response (Albeda and Buck 1990, Ruoslahti and Pierschbacher 1987, Travis 1993).

As the interaction of cells with microdevice surfaces is quite complex, a very precise tailoring of the surface properties of the involved materials is required. Thus various strategies have been developed to generate surfaces, which have tailor-made chemical composition and which allow the incorporation of functional groups.

1.05.4 Surface Modification of Microdevices

1.05.4.1 General Remarks

Various strategies have been developed in the past to obtain materials for microsystems applications with biocompatible properties. To obtain such a material (biomaterial), one can follow basically two different strategies. One is to generate a material that has all the desired bulk properties and still interacts in a satisfactory way with its surrounding environment. Such an approach leads to the ideal material but requires usually the screening of huge numbers of different materials, as frequently either one or the other requirement is not completely met and the material does not perform as desired. An alternative strategy for generating a biocompatible material is to optimize the bulk properties of the materials as far as possible, regardless of the surface properties and then modify the material's surface according to the requirements of the biological system to which it is exposed. Such a surface modification can be achieved through a chemical treatment process or through the deposition of a biocompatible coating.

The latter strategy has the advantage that the bulk and surface properties of the material become decoupled, and the use of a material is at first approximation independent from its surface properties. If, for example, a compound exhibits very good properties in contact with blood or tissue but has rather weak mechanical properties, it can still be applied as a coating material in mechanically challenging situations. On the other side, a material that has excellent bulk properties but has a strong

thrombogenic potential might still be useful when it is appropriately coated as long as the coating controls all the interactions with the blood.

It is well known that coatings influence the surface properties of a material strongly. Even layers that are just a few angstroms thick can alter the surface properties of a material in such a way that the chemical nature of the underlying material becomes completely hidden and the surrounding environment does not feel the presence of the material at all. The interaction of the whole system with the surrounding environment is then solely governed by the coating (stealth effect). In addition, such biofunctional coatings are by no means very cost effective, as the modification with appropriate proteins requires only little amount of these otherwise very expensive materials.

For the generation of biocompatible coatings on microdevices, a number of techniques are employed, e.g.:

- Adsorption of proteins/polymers
- Plasma treatment
- Formation of SAMs
- Chemical attachment (grafting) of polymers

1.05.4.2 Coatings Based on Physically Attached Polymers and Proteins

The simplest way to coat a substrate with a (biocompatible) coating is to deposit a biocompatible material directly on the surface of the substrate. Examples that are very popular in the literature are coatings containing poly(ethylene glycol) (PEG), with poly(lysine), or one of the serum albumins such as bovine serum albumin (BSA) or human serum albumin (HSA). The deposition of the material is most simple and can be achieved by dip coating, spin coating, spraying, casting, or through adsorption from a dilute solution of the macromolecules.

However, it should be noted that all chains, which are attached to the surface through physical interactions, are held at the surface through rather weak forces. While this is a favorable situation in cases when only a temporary coating is desired, it is in other cases problematic as the coating will slowly bleed off the surface and the properties of the coating decay. Under unfavorable conditions the films can be totally dissolved. This dissolution cannot be avoided as the concentration of the coating material in the contacting solution is zero. Accordingly, the surface concentration in equilibrium will also be zero and only a slow kinetics will prevent the complete disintegration of the film.

In many cases, even more problematic for the integrity of the surface coating is the displacement of the involved molecules by molecules present in the contacting environment. Especially if they show stronger interactions with the surface than the constituents of the coating. Molecules from the environment can compete efficiently for sites at the surface with polymer molecules and displace them from the surface. This aspect is especially important for production and storage of the devices. A somewhat frequently encountered problem is that the amount of material that can be deposited depends on the history of the sample, i.e., on the conditions to which it had been exposed prior to the coating step.

One way to avoid dissolution of the coatings material is to crosslink it, so that an infinite network is formed. In the biomaterials community, frequently the terms gel or hydrogel are used instead of polymer network. A gel is by definition a polymer network that is swollen by solvent and a hydrogel a polymer network that is swollen by water. 'Infinite' in this context means that the molecule forming the network is of the same size as the object itself. Networks can, by definition, not dissolve but only swell. If they swell, they will show at first a very strong buckling of the surface. What then happens, depends on the strength of interaction of the material and the substrate. If the interaction is weak, the strong mechanical forces caused by the osmotic pressure of the swelling network will lead to a complete or partial delamination of the network from the surface. If the adhesion forces are strong, just strong crumpling of the gel will result.

When inert surfaces that do not swell in the biological environment are desired, a deposition from the vapor phase can be envisaged. Examples are parylene deposition or deposition of siloxane molecules from the gas phase or the initiation of a crosslinking polymerization in the gas phase. As long as no creeping of solution under the network occurs in such systems, which would lead to delamination of the whole network from the surface, the coatings are very robust and stable.

Especially in biological environments, competing adsorbates can win out against physically deposited polymer chains/biomacromolecules and completely displace them from the surface. This is the case if the interactions of the contaminants with the surface are much stronger than those of the coated material with the same substrate. Under these circumstances

the polymer molecules of the coating will no longer stay in direct contact with the substrate but will be located on top of a thin layer consisting of the molecules that had displaced them. Displacement of already adsorbed polymer chains is a particularly serious issue if polar substrates are employed and are exposed to polar contaminants, a situation most frequently encountered in biological environments. As already discussed, the contacting liquids are in such systems from a chemical point of view complex and contain many molecules that show a strong interaction with surfaces. For example as far as proteins are concerned, if two proteins have a similar affinity to the surface (similar enthalpy of adsorption), the larger molecules will always displace the smaller ones for entropic reasons (entropy of mixing of the molecules with the aqueous solution). However, if short-term improvements of the biocompatibility of a device are required, physical deposition of polymers or biomolecules such as proteins will be the method of choice.

1.05.4.3 Plasma Treatment of Surfaces

Plasma, corona, or glow discharge processes are frequently used for the modification of surfaces (Inagaki 1996). In such processes the substrate is brought between two electrodes in a gas atmosphere at a reduced pressure. If now a voltage is applied, a cold plasma is formed inside the chamber, consisting of electrons, ions, and radical ions and neutral radicals originating from the gas molecules or atoms. In addition, visible and UV light are emitted. The UV light has a considerable energy and can induce further photochemical reactions. The highly reactive species formed, react with each other, with the wall of the reactor, and with the substrate. Typically, the gas in the plasma chamber is not static but is continuously flown through the chamber.

As far as the substrate is concerned, depending on the conditions during the plasma process, especially on the nature and concentration of the reactive species in the plasma and the energy input, either surface etching or the deposition of plasma polymers can be the predominant reaction. Through etching with, for example, argon or water plasma, reactive sites can be introduced into the surface and the surface can be cleaned from contaminants sticking on it. A surface that is otherwise chemically rather inert and not easily functionalized can be provided with a functional group through a short activation etch. After the introduction of the functional groups, the reactive species formed in the plasma process react with oxygen, once the sample is taken out of the plasma chamber to ambient conditions (**Figure 5**). As a word of caution, however, it should be mentioned that such a strategy for hydrophilization of an otherwise totally inert surface is only rather short lived. It is inherent to such techniques that with time the sample ages and more and more of the functional groups, that had been successfully created during the surface reaction, are lost. This is especially the case if the substrate is exposed to higher temperatures. This effect, commonly called hydrophobic recovery, is partly caused by a contamination of the surface with airborne organic molecules originating from the environment, but the most important aspect is a diffusion of the functional groups away from the surface into slightly deeper regions of the sample.

The driving force for this surface reconstitution is the tendency of any surface to minimize its surface free energy. Although the diffusion coefficient of polymer segments that are well below the glass transition temperature is rather slow, it should be noted that diffusions over very short distances, i.e., only a couple of angstroms, are required to cover all functional groups with low surface energy materials (Andrade *et al.* 1985). In addition, there is also evidence that surfaces are regions of enhanced mobility of polymer segments (Prucker *et al.* 1998). However, if the surface is directly modified after the plasma process, a simple functionalization of otherwise very inert materials can be achieved.

Under appropriate conditions during plasma deposition of organic compounds, layers of highly crosslinked polymers (plasmapolymer) are formed from fragments of the monomers that are present in the plasma. Appropriate conditions refers here to the amount of energy imparted into the gas molecules, which depends both on the energy input and the flow conditions. As monomers, any organic compound that has a sufficiently high vapor pressure under the reaction conditions can be used, even saturated alkanes such as hexane. The reaction mechanism for buildup of the plasmapolymer layers is rather complicated and is based on the fragmentation of the monomers in the gas phase into mono- and biradicals that eventually recombine to form the crosslinked plasmapolymer layer (Yashuda 1981). But even after deposition of the polymer layer, the presence of ions, free electrons, and high-energy irradiation can alter the chemical structure of the material already deposited. Thus the structure of the polymer layer has often no visible connection to the monomer used, and it is not possible to generate structurally well-

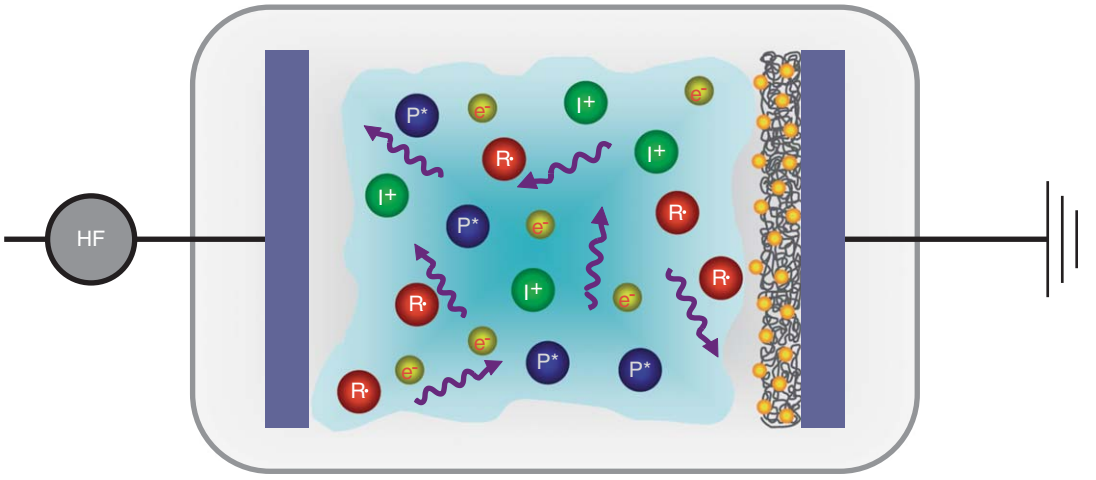

Figure 5 Schematic illustration of a plasma polymerization process.

defined functional monolayers. However, it is possible to deposit in a very efficient manner inert layers consisting of fluorinated units or polymers that resemble more or less glassy carbon. Thus, plasma processes are a very simple and cheap way to generate inert surfaces. If appropriate reaction conditions (low energy input, pulsed plasma) are applied, some monomers can also be used to generate layers containing reactive groups. Such layers can be used in postplasma reactions for the buildup of functionalized surfaces. Examples are plasmapolymer layers containing amine, carboxylic acid, or epoxide groups.

1.05.4.4 Self-Assembled Monolayers

An alternative that can overcome some of the problems of the processes described in the previous section, is to covalently attach the molecules of the coating to the surface of the substrate to be coated. In such cases removal of the coating is only possible at the expense of breaking one or several of the chemical bonds that connect them to the surface. As this requires very high amounts of energy, such a process occurs only under rather drastic conditions. An additional attractive feature of all situations, where molecules are chemically attached to the substrate, is that chemical surface reactions in general are independent from the finer details of the geometry of the substrate, which is a situation, especially favorable for microsystems. Thus even substrates with a rather odd topography such as sharp needles, cavities that are connected to the outside only through a tiny hole, or the inside of narrow microfluidic channel can be coated. This holds true irrespective of the finer details of the immobilization reaction.

Apart from studies where a blocking of the surface with alkyl or fluoroalkyl groups is desired, most silanes employed in microsystems engineering are α, ω-functionalized. One end of the molecule carries a reactive site, which causes the immobilization reaction. The other end carries functional groups such as amino, active ester, or epoxy groups, which can be used for the binding of complex moieties involved in improving the biocompatibility of the surface (**Figure 6**).

Reactive groups that allow to couple the molecules to the surface most frequently consist of silane, thiol, disulfide, or phosphonate groups. Silanes are mostly used in the form of alkoxy or chloro silane compounds and are used to modify oxidic surfaces. When di- and trifunctional silanes are used, self-condensation can occur, which leads to the formation of thicker layers, which represents in a way a siloxane network attached to the surface. Such layers are,

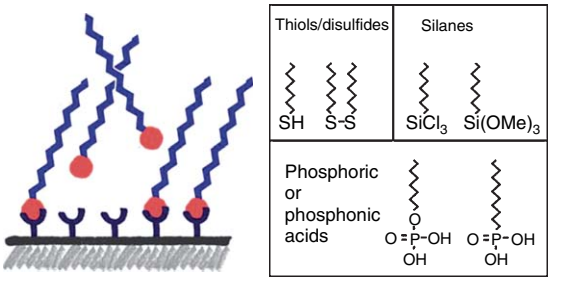

Figure 6 Schematic illustration of the self-assembly process and examples of anchor groups used for the modification of surfaces with self-assembled monolayers (SAMs) of organic molecules.

strictly speaking, not monolayers. This difference is important for a detailed understanding of the surface chemistry; however, in practical terms, this difference is more semantic than of real practical value as far as qualitative results are concerned. If, for example, a glass surface is to be made hydrophobic using a fluorinated silane, the difference between a clean monolayer and a thin surface-attached network of these compounds is marginal. However, if quantitative results are required, for example, when DNA molecules are immobilized on an SiO_2 surface and then used for a further quantitative analysis, the network formation process leads to difficulties in process and quality control of the so-generated biochips (Southern 1996). Silane monolayers are for this reason a little more difficult to form. If clean monolayers are desired, the immobilization reaction must occur in the strict absence of water. However, silane monolayers on SiO_2 surfaces are very stable and can be removed from the surface only when the substrate starts to dissolve, which is the ultimate stability limit for surface coatings anyway. One of the most popular ways in the bio-oriented community is the attachment of functional groups via γ-aminopropylsilanes immobilized to oxidic surfaces (e.g., glass-substrates). This is the case, despite that it has been known for many years that the (basic) amino groups exhibit a strong interaction with the acidic silanol groups on the surface. If, however, some of the molecules are bound only through acid–base interactions instead of formation of a siloxane bond, this will lead to a slow bleeding of the silane compound. In addition, anyone who has experience with amines, knows that alkyl amines have a strong tendency to photo-oxidation, which transforms the amine group into nitroxides and other oxidation products, so that the shelf lifetime for such monolayers is rather limited. Aminosilane monolayers are popular as they allow a very simple additional functionalization. This is especially important as the reactive groups in silanes do not tolerate many functional groups. For example, hydroxy or acid groups are not compatible with reactive silanes.

The sulfur compounds mentioned above (thiols and disulfides) can be used to modify metal, especially noble metal surfaces. Particularly gold substrates have been very popular with these compounds. Monolayers on gold have been a very common subject of study, because they are most easily prepared. Dipping the gold substrates into the thiol or disulfide solution followed by a quick wash with pure solvent is sufficient for the generation of high-quality and in some cases even 2D crystalline monolayers (**Figure 7**).

Thiol and disulfide groups have the additional great advantage that they tolerate a wide spectrum of functional groups, and the buildup of complex surface architectures is greatly facilitated. As the substrate is a noble metal, electrical or electrochemical measurements are also possible as long as the oxidation potential is kept in a moderate range. At electrochemical potentials higher than -1.1 V, the sulfur-containing monolayers are completely removed from the surface (Widrig *et al.* 1991, Yang *et al.* 1997).

On the downside, the binding energy of the compounds to gold surfaces is not so very high. Thermal desorption studies place the bond strength somewhere between a real chemical, say carbon–carbon bond and a hydrogen bond, so that under some circumstances thermal energy is sufficient to remove the molecules (Delamarche *et al.* 1994). In addition, thiols and disulfides have a strong tendency to oxidize under ambient conditions with the formation of sulfites and ultimately sulfates. The latter, however, have a much weaker interaction with the substrate surface, so that the oxidation leads in the end to a bleeding of the compound and a strong reduction in the quality of the monolayer.

The surface immobilization reactions, with very few exceptions, are based on condensation reactions. One of the few exceptions is the immobilization of alkanes on SiH-terminated silicon surfaces. Despite the huge number of publications on thiol monolayers, the mechanism of the attachment of the compounds is not entirely clear. The present model discusses a gold oxide (Widrig *et al.* 1991). The surface reactions occur more or less spontaneously when surface and reagent solution or vapor are brought into contact and stop once a monolayer is formed as the reactive

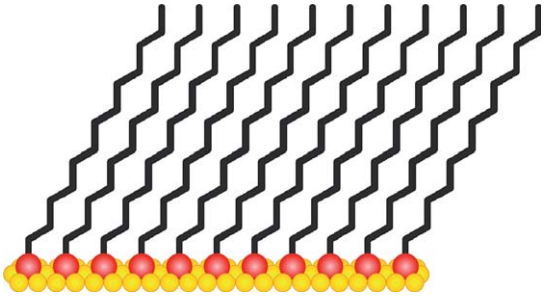

Figure 7 Schematic illustration of a self-assembled monolayer consisting of an *n*-alkanethiol ($CH_3(CH_2)_nSH$) attached to a gold surface.

sites at the surface are consumed. Thus the term self-assembled monolayer is commonly used. SAMs clearly represent the most important technique for surface modification at least as far as oxide materials such as glass, silicon, alumina, titanium dioxide, and similar compounds or metals (especially gold) are concerned. A variety of other compounds such as nitrides contain also a thin layer of oxide at the surface. Such surface modification processes are technically very important (priming of surfaces) and many thousand research papers have been published on the generation, analysis, and application of such layers.

1.05.4.5 Immobilization of Polymers

For the immobilization of polymers to substrate surfaces, essentially four different strategies can be employed:

- Chemisorption of polymers (grafting to)
- Chain attachment through immobilized monomers (grafting through)
- Surface-initiated polymerization at the surface *in situ* (grafting from)
- Chemical attachment and simultaneous network formation

In the first process, specific polymer molecules that carry functional groups which allow the surface attachment are required. In the next two processes, the surface-attached chains are formed at the surface *in situ*, i.e., the substrate is exposed to conditions in which a polymerization reaction is carried out, i.e., the presence of monomer is required (**Figure 8**).

1.05.4.5.1 Chemisorption

One important strategy for the attachment of polymers to a biomaterial's surface is the chemisorption of an appropriately functionalized polymer (Ben Ouada *et al.* 1988, Bridger and Vincent 1980, Krenkler *et al.* 1953, Laible and Hamann 1980, Tsubokawa *et al.* 1989, 1990). In such a case the polymer either contains a functional moiety that can react with an appropriate site in a SAM or carries an anchor group either as an end group or in a side chain. This can then react with appropriate sites at the substrate surface. In either case a monolayer of polymer molecules is obtained, which is chemically bound to the surface. This strategy is in principle closely related to the formation of SAMs described above. In agreement with what has been said before, such endfunctionalized polymers are available; the attachment of the polymers is from a chemical point of view rather simple. This condition sounds rather trivial, but it is not so. The synthesis of polymer chains with reactive end groups is restricted to certain classes of polymers, mostly polymers that can be obtained by polycondensation. In case of polymerization processes occurring as chain processes, the reactive group is typically protected during the polymerization reaction. Only in very few cases a polymerization reaction can be carried out in the direct presence of reactive groups. In most cases either an initiator or a monomer containing the protected moiety is employed during the polymer generation. After the chain formation is complete, the protection group is cleaved off in a polymer-analogous reaction so that the reactive site is retrieved. While a number of polymers having functional groups in the side chain are available, not quite as many that contain a reactive side at one of the chain ends are available.

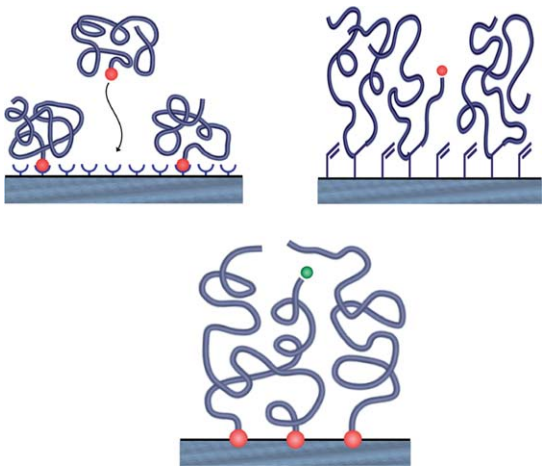

Figure 8 *Top left*: Schematic illustration of different processes used for the attachment of polymers to surfaces – Grafting-to process. *Top right*: Grafting via incorporation of surface-bound monomeric units. *Bottom*: Grafting from or surface-initiated polymerization.

While the attachment of terminally functionalized polymers to the surface leads to layers where one group is connected to the surface, side chain attachment usually leads to multiple attachment points and both very tight binding and a rather flat conformation of the polymer chains. In the latter case the functional groups either on the same chain or on different molecules compete for the reactive sites on the surface. Accordingly, the amount of polymer that can be immobilized depends strongly on the reaction conditions, especially on the concentration of the

polymer in solution. If the concentration is rather low and the rate of the surface attachment reaction is high, the molecule will after initial contact rapidly bind at many different sites to the surface. Accordingly, the molecule obtains a rather flat conformation and uses up many surface sites. If the formation of the chemical bond is irreversible under the reaction conditions, the overall number of molecules that can be attached remains rather low and only relatively thin film can be attached. At high polymer concentration, however, many different molecules are simultaneously present at the surface and compete in a very efficient way for surface sites, so that the overall graft density becomes higher and the thicker monolayers are obtained.

One aspect that is inherent to grafting-to processes and of which one has to be aware is an intrinsic limitation of the film thickness and accordingly the number of functional groups per surface area that can be obtained by such an approach (**Figure 9**). Films generated by chemisorption from solution are limited to (dry) thicknesses of typically 1 to 5 nm. This limitation has both kinetic and thermodynamic origins. With increasing coverage of the surface with attached chains, the polymer concentration at the interface quickly becomes larger than the concentration of the polymers in solution. Additional chains, which are to become attached to the surface, have to diffuse against this concentration gradient that ever increases with increasing graft density of the attached polymer. This diffusion slows down the immobilization reaction further and further as the reaction proceeds. Thus the rate of the attachment reaction levels off rather quickly (exponentially!) and another polymer is linked to the substrate only at an extremely slow rate due to this kinetic hindrance.

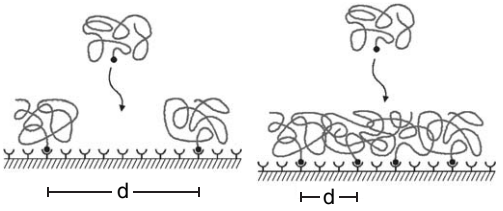

Figure 9 *Left*: Schematic illustration of the grafting-to process. Chains that are to be attached to the surface can easily reach the surface at low grafting densities. *Right*: The attachment process comes virtually to an end as soon as the surface is significantly covered with polymers, as the already attached chains form a kinetic barrier against which incoming polymer chains have to diffuse to reach the surface.

Indeed, it has been shown both theoretically and experimentally that once the surface-attached coils overlap, the attachment of other polymer molecules takes place only on a logarithmic time scale and very quickly time frames of thousands or even millions of years would be required to add a few more nanometers of polymer to the layer. Accordingly, as far as practical reaction times are concerned, films generated by this technique are intrinsically limited to the film thickness. Even if this kinetic limitation is somehow circumvented (e.g., by resorting to high polymer concentrations, which de-emphasize the importance of the diffusion of polymer molecules), the attachment of chains to a strongly covered surface becomes unfavorable also for thermodynamic reasons. At high grafting densities the surface-attached polymer chains are in a rather stretched conformation due to the presence of strong segment–segment interactions as will be discussed in greater detail later. A chain that now attaches to the surface has to change from a coil conformation in solution to a stretched (brush-like) conformation at the surface. The entropy loss during this process, however, is only compensated by the establishment of one chemical bond, namely, the one connecting the polymer to the surface. The higher the graft density of the chains at the surface, the stronger will be the entropy penalty that rapidly precludes the attachment of more chains.

An intrinsic limit to what layer thickness can be reached sounds a bit negative, but it also has its positive side. As the layer thickness is given more or less by the surface concentration of the segments of the already attached chains, the chemical peculiarities of the system do not matter. Thus a very robust system that gives the same result under many different conditions is obtained. As long as the desired film thickness conforms to this regime, i.e., is between 0 and about 5 nm, such a system is from a practical point of view great as the same film thickness is always obtained.

A new way of covalently attaching polymers, which has been described recently, is through a photochemical reaction. Here photoactive moieties are self-assembled at the surface of the substrate. During irradiation of the immobilized molecules with UV light, a photochemical reaction sets in, which leads to a covalent binding of polymers or other macromolecules (DNA, proteins, and sugars) at these surfaces. The binding is achieved through a radical coupling reaction. This reaction can occur with almost all organic molecules and is followed by a very simple and versatile immobilization process.

1.05.4.5.2 Immobilization using surface-attached monomers

Another straightforward technique for the attachment of polymers to surface, which allows to generate a large variety of functional surfaces, is to add a monomer-modified substrate to a solution in which a polymerization reaction is carried out (Dmitrenko *et al.* 1990, Hashimoto *et al.* 1982a, b, Kopf *et al.* 1996, Trachenko *et al.* 1986, Zajac and Chakrabarti 1995). For the performance of the surface-attachment reaction, the monomer units are initially self-assembled at the surface. During the polymerization reaction, which occurs in the contacting solution, statistically every once in a while a surface-attached monomer is incorporated into a growing polymer chain. However, as soon as one surface-attached monomer is incorporated, the growing polymer is becoming permanently attached to the surface. If several monomer units on the surface are incorporated, this will not change the general picture, but the conformation of the polymer molecule will change (**Figure 10**).

As far as the polymerization mechanism is concerned, the surface-attachment reaction is a two-step process: During polymerization a macroradical first attacks a monomer immobilized on the surface (grafting-to reaction). In the second step more monomer units are added, so that the chain grows further (grafting-from reaction). However, careful studies of the polymerization mechanism have shown that the grafting-to step represents the bottleneck of the reaction and thus limits the polymer immobilization.

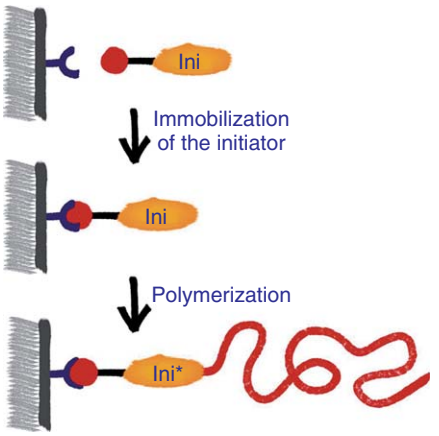

Figure 10 Synthetic strategy for the generation of polymer brushes via surface-initiated polymerization. An initiator molecule is deposited on a surface by means of self-assembly process via the reaction of an anchor group to suitable surface functional sites. Subsequently, chains are grown from the surface using the immobilized initiation sites.

Accordingly, very similar layers are obtained by using immobilized monomers as through the chemisorption of preformed chains.

However, if this poses no problem, it is one of the simplest techniques to generate surface-attached layers, especially as no polymer functionalized with an anchor group needs to be synthesized.

1.05.4.5.3 Growing polymer chains at surfaces

Interesting systems with rather unusual molecular architecture of the polymer chains, and accordingly unusual physical properties quite different to those in films described above, can be obtained if the polymer chains are grown at the surface of the substrate *in situ* (Advincula *et al.* 2004, Pyun *et al.* 2003, Rühe and Knoll 2002, Zhao and Brittain 2000). For the synthesis of such systems the initiator species is self-assembled at the surface of the substrate either directly or using a functional monolayer and attaching the initiator in a surface-analogous reaction. The initiator monolayer is then used to kick off the growth of polymer chains from the surface. Depending on the initiator graft density and the reaction conditions, dense or less dense lawns of long or short polymer chains can be grown. Here the term dense refers to the graft density of the polymer chains and is not related to the material density. Depending on the chemical nature of the initiator, the polymerization reaction can be started by applying heat or light or by carrying out a chemical reaction such as a redox process. As the reaction proceeds, more and more monomer units are added until either the chain growth process is terminated or a transfer reaction to monomer or solvent occurs. Such transfer reactions lead only to the formation of free polymer that is washed away in an extraction step and that does not contribute to the film formation. Depending on the reaction mechanism and on the rate of chain growth versus the rate of chain initiation, all polymer chains are either grown simultaneously or at different periods of time (**Figure 11**).

This way, monomolecular layers of polymer molecules with film thicknesses of more than 2000 nm in the dry state have been obtained. In this case polymer molecules with number-average molecular weights of several 10^6 g mol^{-1} are attached at distances of anchor points of less than 3 nm. Whereas similar graft densities can be easily reached, such high molecular weights can be achieved only under certain favorable conditions and not with every monomer. The growth of polymers from the substrate surface is accordingly ideally suited if layers ranging from a few nanometers

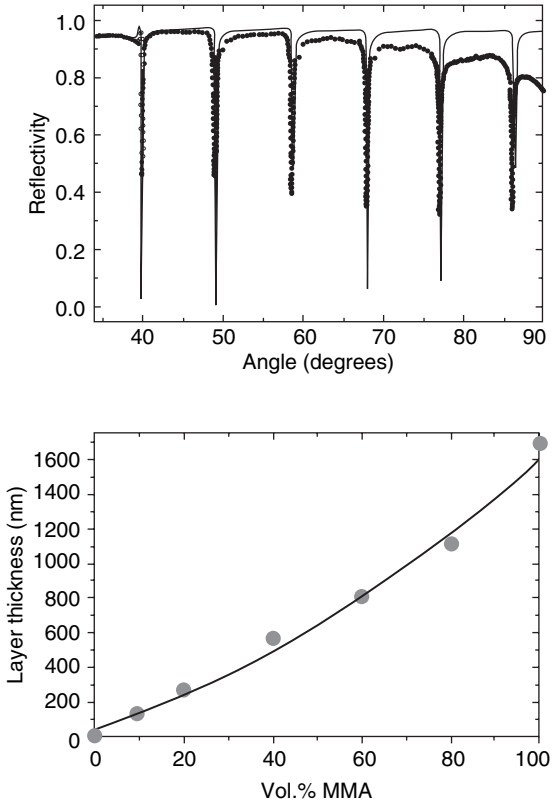

Figure 11 *Top*: Optical waveguide mode spectrum (symbols) obtained from a polymethyl methacrylate (PMMA) brush deposited on an evaporated SiO_2 layer. The solid line corresponds to a model-fit calculation based on a Fresnel formalism assuming a 2200-nm-thick polymer layer. The sample was prepared in neat MMA at 50 °C. *Bottom*: Dry thickness of a PMMA brush as a function of the monomer concentration used in the polymerization feed. Polymerizations were carried out at 60 °C for 18 h (solvent: toluene).

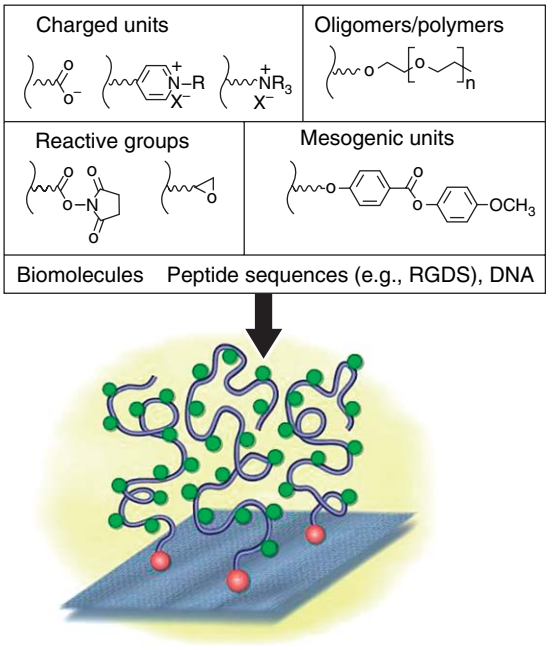

Figure 12 *Top*: Examples of functional groups incorporated into polymer brushes. *Bottom*: Schematic illustration of a functional polymer brush.

to a few hundred nanometers are desired. Especially to the high end of layer thicknesses, some limitations exist as neither the graft density nor the molecular weight of the surface-attached chains can be pushed beyond certain limits.

Polymer chains that are attached to a surface at a high graft density assume a brush-like conformation. The repulsion between polymer segments leads to a strong stretching of the polymer chains away from the surface. This chain stretching causes very unusual properties insofar as polymer brushes cannot be penetrated by other macromolecules in solution, exhibit strongly reduced friction, or show an autophobic wetting behavior (i.e., cannot be wetted even from chemically identical chains) (**Figure 12**).

Surface-initiated polymerization reactions work for any polymer that can be obtained by a chain growth reaction such as free and controlled radical polymerization, carbocationic polymerization, anionic polymerization, and ring-opening metathesis polymerization. As pointed out earlier, the growth of the polymer chains can be achieved on arbitrarily shaped surfaces (planar, curved, and irregular surfaces, and nanoparticles) and is ideally suited for growing chains on complex microstructures. Depending a little on the details of the chosen reaction mechanism, chain growth processes allow for the generation of polymers from a wide spectrum of different monomers.

1.05.4.5.4 Chemisorption and simultaneous network formation

All of the three strategies described above for the covalent attachment of polymer monolayers to microdevice surfaces can also be used for the covalent attachment of polymer networks/gels (**Figure 13**). In polymer networks all the chains form one gigantic molecule with infinite molecular weight. Through network formation, layers with infinite thickness can be obtained, the only limit being the availability of crosslinkable material. To form these networks, either the polymer chains have to be modified with reactive units, which allow a reaction of the polymer molecules with each other, or bi-, tri-, or multifunctional monomers have to be used in

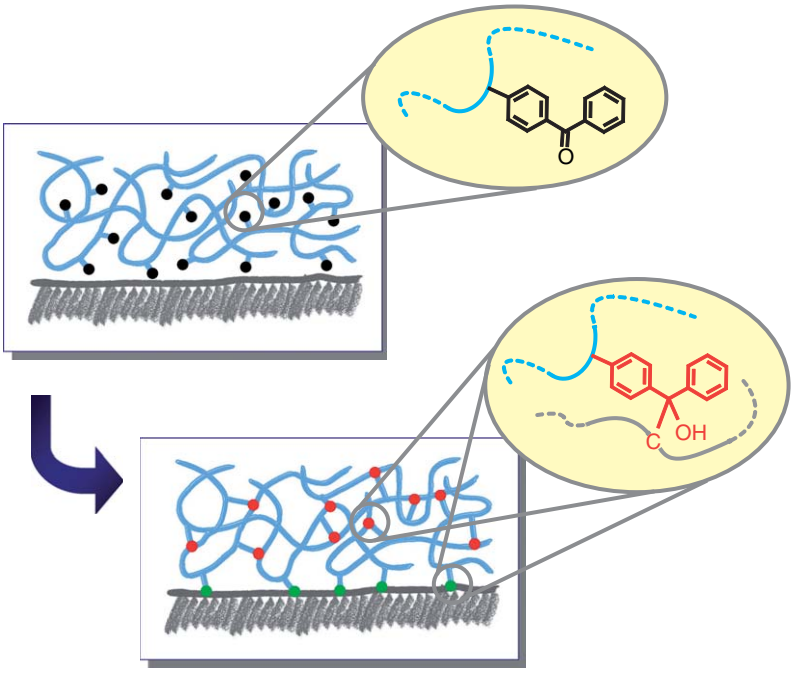

Figure 13 Schematic illustration of the formation of surface-attached polymer networks (polymer gels) by photochemical crosslinking benzophenone moieties built in into polymer molecules; during formation, the network is simultaneously attached to the surface.

a polymerization reaction. To obtain a chosen finite thickness of the layer of the coating, the thickness of the layer containing the polymer or monomer that is to be crosslinked has to be confined. Examples of such reactions are the photochemical crosslinking of benzophenon group-containing polymers and the grafting-through reaction using trifunctional methacrylates (Prucker *et al.* 2003, Toomey *et al.* 2004).

1.05.4.5.5 Surfaces that resist the nonspecific adsorption of proteins

As nonspecific adsorption of proteins to microdevice surfaces is a very important factor for the functioning of these devices, a brief mention will be made about the generation of surfaces that resist nonspecific protein adsorption, regardless of how they were synthesized and whether the molecules were chemically or physically attached to the surfaces.

In order to develop surfaces that resist the nonspecific adsorption of proteins (i.e., nonfouling surfaces), a large number of physicochemical and biochemical studies have been carried out on the fundamentals and the applications of protein adsorption to the material's surface (Brash and Horbett 1987, Hern and Hubbell 1998, Horbett and Brash 1995, Jenney and Anderson 1999, Jeon *et al.* 1991, Kunz *et al.* 1999, Lehmann and Ruehe 1999, Sigal *et al.* 1998, Szleifer and Carignano 2000, Xu and Marchant 2000, Yang *et al.* 1999). Despite its large impact on the aforementioned local reactions of a biological host to an implanted biomaterial, and extensive research efforts, the details of the mechanism of nonspecific protein adsorption have not yet been completely understood. However, it is believed that parameters such as van der Waals interactions, electrostatic forces, and H-bonding govern unspecific adsorption (Ratner and Bryant 2004, Sigal *et al.* 1998, Szleifer and Carignano 2000).

Interesting examples of nonfouling surfaces are materials that have been surface-modified with PEG (Andrade *et al.* 1996, Harris 1992), polymer hydrogels (Andrade *et al.* 1996, Elbert and Hubbell 1996, Griffith 2000, Hern and Hubbell 1998, Horbett and Brash 1995, Hubbell 1999, Jenney and Anderson 1999, Jeon *et al.* 1991, Kunz *et al.* 1999, Peppas *et al.* 2000), polymer brushes (Lehmann and Ruehe 1999, Szleifer and Carignano 2000, Xu and Marchant 2000, Yang *et al.* 1999), or more complex architectures (Shen *et al.* 2002, Siegers *et al.* 2004). PEG is a water-swellable, nontoxic, and biocompatible polymer, and its use in biology and medicine has been widely reviewed in detail in the literature (Amiji and

Park 1993, Andrade *et al.* 1996, Jenney and Anderson 1999, Llanos and Sefton 1993). A different name for essentially the same polymer, which is more common in the polymer science community, is poly(oxyethylene) (PEO). Various schemes have been developed to attach PEG molecules to surfaces, through SAMs, as block copolymers, as comb-polymers, and so on.

Although PEG is widely employed to coat surfaces of biomedical devices and is the material of choice for many applications, it is also known to exhibit thermal instability (Gordienok *et al.* 1986) and rapid auto-oxidation either through O_2 in the presence of transition metal ions or enzymatically *in vivo* (Andrade and Hlady 1986). Thus the quest for stable, nonfouling surfaces that resist the nonspecific adhesion of protein to surfaces is still an ongoing battle.

1.05.5 Engineered Biomaterials Directing the Adhesion of Living Cells

One approach to address the challenge of designing biomaterials that specifically interact with living cells is the coating of a material with whole proteins, such as laminin, collagen, or fibronectin. Although all these proteins carry ligands that promote the attachment of cells, there are some limitations that these strategies have in common. For example, proteins need to be isolated from organisms and purified. Proteins may induce unwanted immune responses, and proteins are often subject to enzymatic degradation, which limits in particular their long-term applications. Finally, protein attachment to a biomaterial's surface may induce conformational changes in the protein itself, which elicits again unwanted foreign body reactions.

Since the discovery of small peptide ligands found in the cell adhesion-promoting ECM proteins, scientists have started to manipulate cellular behavior by engineering these small peptide ligands into a variety of biomaterials, e.g., by directly grafting these ligands onto solid surfaces or by immobilizing them into/onto polymeric materials and surface coatings. A detailed overview of the different strategies that have been followed to date has been recently published by Tirrell *et al.* (2002) and Hersel *et al.* (2003).

In principle, there are several important fundamental parameters that determine the specificity and binding affinity of synthetically formed biomimetic surfaces. An important parameter is the conformation of the peptide ligand, which is presented at the surface. For example, human melanoma cells attach and spread on surfaces presenting the RGD ligand in a looped conformation (similar to the naturally occurring conformation in fibronectin) in a concentration-dependent manner (Pakalns *et al.* 1999). In contrast the same cell type spreads indiscriminately on carboxyl-coupled RGD and does not spread on amino-coupled RGD surfaces (Pakalns *et al.* 1999).

Another very important parameter is the surface density of RGD peptides, i.e., the surface concentration of the bioactive ligand (Arnold *et al.* 2004, Fittkau *et al.* 2005, Hern and Hubbell 1998, Irvine *et al.* 2001, Maheshwari *et al.* 2000, Massia and Hubbell 1991, Pakalns *et al.* 1999). A surface concentration of 1×10^{-15} mol cm^{-2} of GRGDY ligand, which was covalently grafted to the surface of otherwise poorly adhesive glass substrate, was sufficient to promote fibroblast cell spreading. However, focal contact formation was only observed at concentrations of at least 10×10^{-15} mol cm^{-2} and higher (Massia and Hubbell 1991). Hence, a minimum RGD density of 10×10^{-15} mol cm^{-2}, corresponding to a lateral (stochastic) spacing of about 140 nm between peptide ligands, is necessary to render the cells attached in healthy conditions.

Another parameter that influences the extent of cell adhesion is ligand (peptide) clustering at the nanoscale level (Maheshwari *et al.* 2000). Griffith and coworkers applied a number of star-like peptide-modified polymer molecules to surfaces, thereby forming a surface coating that on the one side resists protein adsorption and on the other side promotes the ligand-directed adhesion of living cells. By varying the number of peptide ligands per star molecule, and by mixing these bioactive peptide-polymer materials with nonmodified polymer stars, the authors were able to address different situations, where the bioactive ligand is presented either in clusters (more than one peptide ligand per polymer molecule) or homogenously on the surface (Maheshwari *et al.* 2000). The clustering of the YGRGD ligand significantly reduced the average ligand density required to support fibroblast cell migration, whereas nonclustered ligands supported cell attachment but did not promote full spreading (Maheshwari *et al.* 2000). Cell behavior also can be influenced by creating a biofunctional surface in which the accessibility of the ligand is used as the control parameter. Therefore, selective masking of a peptide ligand by PEG chains of varying length on a biomimetic surface is another new method of controlling the surface bioactivity (Dori *et al.* 2000).

Finally, the use of peptide synergy sites copresented with the bioactive ligand can have an influence on the extent of cell attachment to artificial surface-modified materials (Mardillowitch and Kokkoli 2004, Mardillowitch *et al.* 2006).

As one can infer from the data available on cell adhesion on peptide-modified artificial surfaces, the impact of many of these parameters on the cellular response is still not very well understood, and quantitative results reported so far vary significantly. For example, as outlined above, the minimum concentration of peptide ligand for cell adhesion and spreading varies over a very broad range from about femtomoles per centimeter square (Massia and Hubbell 1991) to almost nanomoles per centimeter square (Dori *et al.* 2000, Maheshwari *et al.* 2000), depending on the cell lines used and the design of the artificial matrix.

With respect to the latter, both top-down (e.g., the postsynthetic modification of materials with peptides) and bottom-up strategies (e.g., the self-assembly of preformed peptides and peptide-hybrid molecules) for various devices or template surfaces have been the locus of ongoing interest. Significant efforts have been devoted to research on peptide-modified polymers (Hersel *et al.* 2003). However, in many of these cases, the exact peptide surface distribution and the amount of peptides that finally interact with the integrin receptors have not been quantitatively proven yet. Recently, Arnold *et al.* (2004) have used peptide-modified gold nanoparticles adsorbed to solid substrates in order to investigate the function behind molecular arrangement of single-integrin receptors in cell adhesion. Because of the size of the gold clusters used ($D < 8$ nm), the authors claim that only one integrin binds to each of the particles. The authors propose a universal length scale of 58—73 nm, i.e., distance of individual integrins, as optimum for integrin clustering and activation (Arnold *et al.* 2004).

Another way to present the peptide ligands on artificial surfaces that possess a very high amount of control of the ligand has been introduced by the design of so-called peptide-amphiphiles (Baronas-Lowell *et al.* 2004a, b, Berndt *et al.* 1995, Biesalski *et al.* 2005, 2006, Dori *et al.* 2000, Fields *et al.* 1998, Malkar *et al.* 2003, Mardillowitch and Kokkoli 2004, Mardillowitch *et al.* 2006, Pakalns *et al.* 1999). Peptide-amphiphiles can be synthesized by attaching distinct peptide motifs onto a synthetic amphiphile using solid-phase organic chemistry, and subsequently, these molecular building blocks can be self-assembled into various planar and 3D architectures (monolayers, bilayers, micelles, and vesicles) with excellent control over peptide presentation, which allows the detailed analysis of parameters such as the ligand conformation (Pakalns *et al.* 1999), the ligand accessibility (Dori *et al.* 2000), or the order and conformation of the applied amino acid sequence (Baronas-Lowell *et al.* 2004a, b, Malkar *et al.* 2003, Pakalns *et al.* 1999) on the cellular behavior on such model surfaces. Moreover, in a recent study, Fields and coworkers have shown that a mixed peptide-amphiphile surface can be used to promote endothelial cell adhesion while inhibiting the attachment of other cell types that are commonly found in inflammatory responses (Baronas-Lowell *et al.* 2004a, b). Such bioactive bilayer films offer advantages as model systems; however, the potential use of such layers as surface coatings for biomedical applications is limited because of the poor stability of such architectures in air and organic solvents. A possible way to overcome such problems has recently been introduced by the preparation of so-called polymerizable peptide-amphiphiles, where a covalent bond is formed between adjacent amphiphiles in order to stabilize both spherical (i.e., vesicles) (Biesalski *et al.* 2005) and planar bioactive architectures on solid supports (Biesalski *et al.* 2006) (**Figure 14**).

Although the most common cell-binding domain that has been used is the RGD sequence, other non-RGD-containing cell-binding domains exist (Ruoslahti 1996), such as the peptides YIGSR and IKVAV in laminin (Vukicevic *et al.* 1990), REDV and LDV in fibronectin (Mould *et al.* 1991), DGEA in collagen I, and various heparin-binding domains (Dalton *et al.* 1995). In one example it was shown that a more complete cell attachment, spreading, focal contact formation, and organized cytoskeletal assembly were obtained by providing the cell with both the RGD ligand and heparin-binding domains of fibronectin (Dalton *et al.* 1995) or bone sialoprotein (Healy *et al.* 1999, Rezania and Healy 1999).

1.05.6 Conclusions

In the coming years, microdevices will become an important addition to medical technology and revolutionize some areas of medicine completely. This revolution will occur along several avenues. Microengineered devices will create new diagnostic

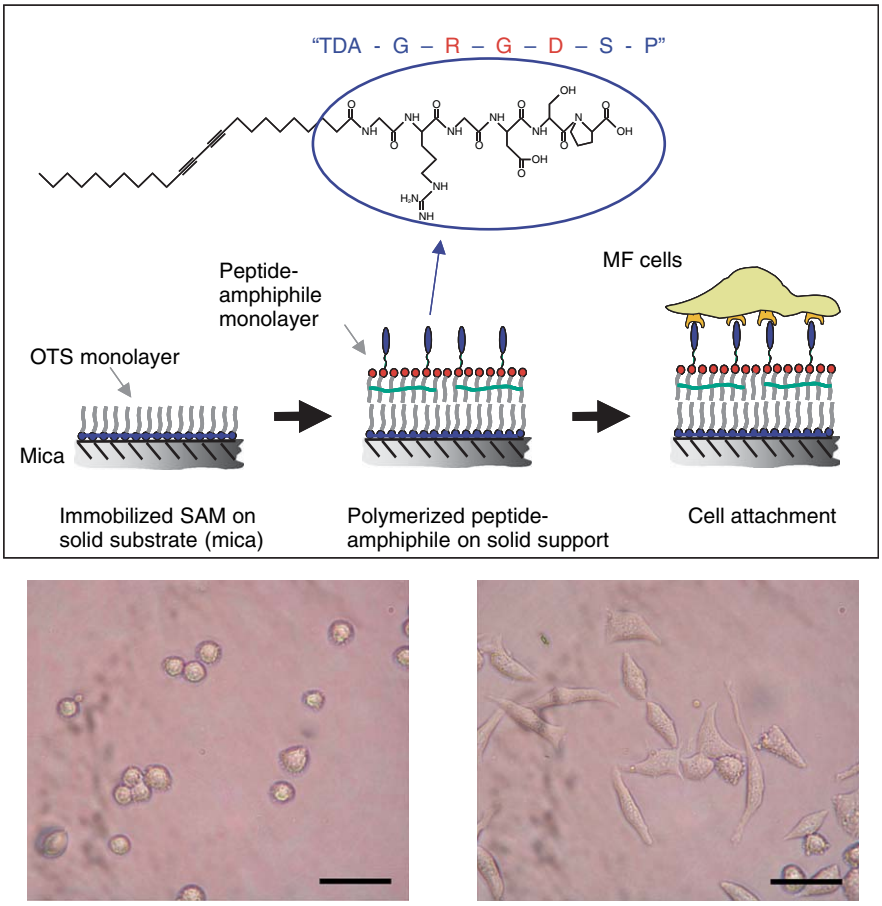

Figure 14 *Top*: Schematic description of a strategy for the buildup of biomimetic surfaces that direct cell adhesion on solid surfaces using self-assembled, polymerized peptide-amphiphiles. The structure of the bioactive polymerizable amphiphile (TDA-GRGDSP) carrying the bioactive RGD peptide sequence is schematically shown as inset. *Bottom left*: Mouse fibroblast (MF) cells adhere but do not spread at surfaces that expose no bioactive ligand. *Bottom right*: Cells adhere and spread in a concentration-dependent manner on surfaces that expose the ligand. tools and improve the long-term monitoring of patients. They will improve medical diagnosis and help avoid the occurrence of critical situations that could cause the patient harm or even death. In some areas it can even be envisioned that microdevices allow to merge diagnostics and therapy and create a new field for which the term theranostics has already been coined. Microdevices will allow to restore body functions that have been impaired or destroyed by acute or chronic illness or through an injury.

However, the intimate contact between the microdevice and the body of the patient also puts very stringent requirements on the biocompatibility of the devices as the contact of the devices with the body might occur for prolonged periods of time. The response of the biosystem against the implanted device might cause harm to the patient or, vice versa, the biological environment to which the microdevice is permanently exposed to might damage or even destroy important functions of the microdevice. Thus the surface engineering of the materials involved in the construction of the microdevices will in the future become more and more important, as surfaces with engineered properties allow to control the interactions of the device with the biosystem.

The creation of tailor-made surfaces of microdevices allows to improve the biocompatibility of such devices significantly. The biocompatibility of the device, however, is critical to the success of the

whole microdevice development project. As long as no appropriate material is found, the whole project has to halt regardless of success in other areas.

In the past biocompatibility was to a great extent related to empirical studies only and various materials had to be screened to find an appropriate one. For such studies the device was exposed to biological environments of increasing complexity and the response was studied. This rather unsatisfactory situation of a more or less educated guessing is currently giving way to a deeper understanding of the interactions of a biosystem and a microdevice. On the one hand, surface analytical tools have improved a great deal and made a more in-depth understanding of complex interfaces of biomaterials with biosystems possible. On the other hand, a number of strategies have been developed, which allow a long-term modification of the surface chemistry of the device, so that adverse reactions can be avoided and specific benign responses can be induced. As a consequence, device surfaces become more and more tailored toward a specific application and mimic a biological system more closely. However, before the goal of truly biocompatible microdevices is reached, very significant research efforts are required, as still many aspects of the interaction of biomaterials and biological environments are poorly understood. Accordingly, any R&D project geared toward biomedical applications of microsystems must tackle this challenge.

Biographies

Jürgen Rühe studied chemistry at the Universities of Münster and Mainz, where he received his Ph.D. degree in 1989 for work carried out at the Max-Planck-Institute for Polymer Research. After a postdoctoral stay at the IBM Research Laboratories in San Jose, California, he returned to Germany and in 1991 started to work at the University of Bayreuth as a 'Liebig'-fellow of the VCI and a fellow of the German Research Council (DFG) in the area of polymers at interfaces. In 1995 he completed his Habilitation and rejoined the MPI of Polymer Research where he held an associate professor position. In October 1999 he accepted a full professor position at the Department for Microsystems Engineering (IMTEK) of the University of Freiburg, where he heads the Laboratory for Chemistry and Physics of Interfaces. He has been visiting scientist at UCSB, Georgia Tech, RIKEN (Japan) and Cambridge University (UK). In 1999 he received the chemistry award of the Academy of Sciences, Göttingen, and in 2001 the Max-Buchner Award of the DECHEMA society. His research interests are focused on the development of new methods for the generation of tailor-made surfaces and micro- and nanostructured thin films, as well as towards the application of such surfaces in various fields of microsystems engineering, especially for chip-based bioanalytical devices and biomedical technologies.

Markus Biesalski studied chemistry at the University of Mainz. In 1999 he received his Ph.D. from the University, Mainz, working at the MPI for Polymer Research. From 2000–2002 he was a postdoctoral fellow in Chemical Engineering and Materials, at the University of California, Santa Barbara. In 2002 he returned to Germany as an Assistant Professor, working at the Department for Microsystems Engineering (IMTEK, University of Freiburg). In July 2002 he received a young investigator award of the German Research Council (DFG), and since then he is heading an 'Emmy-Noether Research Group' at the IMTEK. Since 2004 he is a member of the 'Eliteförderprogramm' of the Landesstiftung Baden-Württemberg, Germany. His research interests focus on the design of molecularly defined peptide-polymer hybrid materials for the use in technological and biomedical applications, and as biophysical model systems.

1.06 Harsh Environment Materials

Erhard Kohn, University of Ulm, Ulm, Germany

1.06.1 Harsh and Hostile Environments

Harsh and hostile conditions are found in various environments and may be firstly associated with high temperature or aggresive media. But they are also found in extreme conditions like high pressure and shock cycling, during exposure to high-energy radiation, or while monitoring chemical reactions.

Of course, the material used in these environments needs to withstand these conditions and the materials associated with applications in harsh environment are ceramics, refractory metals, and highly stable oxides often in heterogeneous configurations. Transducer functions have been realized by a combination of materials like ceramics serving as passive, highly insulating substrate and refractive metals for the electrically active elements. In microsystems, the choice are semiconductors for two reasons: firstly, the modulation of electrons and holes over many decades results in high efficiencies and secondly, the monolithic integration with a system allows direct conditioning of sensors signals enabling smart sensors, or allows direct integration of driver circuits. Therefore, for 30 years microsystems have been designed around semiconductors, namely Si. Again, mainly two reasons have made Si-based microelectromechanical systems (MEMS) successful. Firstly, it is a fact that the processing technology of microsystems can be fully compatible with the complementary metal oxide semiconductor (CMOS) technology, to a large extent the MEMS technology being an extension of the microelectronics technology into the third dimension. Secondly, there is the availability of large surface areas with high quality of the materials. Thus, Si-based MEMS are found in automotive electromechanical applications, in printing with the electorthermal or piezoelectric ink-jet, in mobile communication as radiofrequency (RF) MEMS, and in biochemistry as biochip. Nevertheless, Si is limited by its materials properties. At high temperature above approximately 400°C, its high intrinsic carrier concentration will prevent it from using its semiconducting properties (Colinge 1998). It will also loose its elasticity, eventually giving way to plastic deformation. In liquids it may corrode or be etched like in hot KOH. Under high-energy radiation particle bombardment, the crystal properties may be degraded irreversibly.

Applications, which cannot be used with Si-based devices, are found in many different areas, however, are always confined to very specific cases. They are therefore to date not developed for a mass market. However, this may change in the future, when high-energy processes need to be controlled more and more efficiently. An example is sensing in combustion and jet engines in excess of 300°C, or monitoring and cleaning of exhaust gases at even higher temperatures. Here high-temperature stability is required as well as chemical inertness. Electrodes can be used for water disinfection, without the need of hazardous chemicals. In wastewater treatment highly corrosion-resistant electrodes, which can trace heavy metals or oxidize poisonous molecules, are preferred. In high-energy physics experiments, nuclear power plants, and space missions, radiation-resistant materials with a long life to damage are needed, which can be used for high-energy particle and neutron detection. This short summary tells already that various different materials properties matter, besides the semiconducting characteristics. It should also be mentioned that in a semiconductor with a bandgap of 5.5 eV like diamond the intrinsic carrier concentration at 1000°C is approximately that of Si at room temperature (RT). High-temperature operation of semiconductors will therefore most likely not be limited by their ideal electronic properties.

Nevertheless, the ability of transistors and diodes to tolerate harsh environments, like a high temperature, is a strong indication for the usefulness of the semiconductor materials system in question. Although the bandgap will determine the ultimate temperature limit of its electronic properties, the chemical stability will be the limit to degradation. The materials discussed here are therefore wide bandgap semiconductors with high chemical stability, sometimes called

hard or ceramic-like semiconductors and will center around SiC, GaN, AlN, and diamond, where especially GaN-based devices are heterostructures in a materials matrix of (In, Al, Ga)N. Table 1 lists the highest temperature, at which devices realized in these materials systems have been operated.

On the one hand, this chapter will concentrate on the transducer properties of such highly stable semiconductor materials and their supplementary materials like contact metals and dielectrics for passivation, namely refractory metals and metal oxide dielectrics. On the other hand, all four semiconductors are still rather restricted in their use as electronic material, especially lacking the possibility of an effective CMOS-like configuration. Thus, attempts for systems integration and packaging will also be considered.

For microsystems, wafer processing and bulk as well as surface machining technologies need to be developed, borrowing heavily from the Si-MEMS fabrication routines. Thus, all major device structures developed in SiC, GaN, AlN, and diamond have also been realized on Si substrates.

1.06.2 Materials Requirements

Because sensing is in general a very heterogeneous field, in the following, various materials aspects are discussed in comparison to Si and other alternative materials.

1.06.2.1 Overview of General Materials Properties

An overview of the electromechanical properties of materials suitable for MEMS technologies in harsh environment is given in Table 2.

In microsystems the materials are either bulk substrates or thin films. As bulk substrates, they are mainly single crystal and the ideal material parameters may apply. As thin films, they are often deposited onto foreign substrates, which are highly mismatched. These are therefore often polycrystalline, nanocrystalline, or amorphous. Then, the materials properties may deviate essentially from the ideal case. In harsh and extreme environments, however, the material should display close to the ideal properties, and amorphous films often do not meet this requirement. Therefore, they will be discussed only occasionally. Films used in microsystems must be smooth enough to allow lithography with micrometer size resolution. If not grown single crystalline, they must therefore either be polished or grown nanocrystalline.

SiC, on the one hand, has been used mainly because of its high mechanical strength and high-temperature stability and is the only material, which has already been implemented in a number of commercial high-temperature sensors. Diamond, on the other hand, possesses many exceptional and good properties, but is difficult to process and the development has only led to few device applications up to now, mainly in particle detection and electrochemistry.

GaN-based heterostructures have been used mainly as deep ultraviolet (DUV) and radiation detectors. But it has for a long time lacked a substrate, which can be bulk machined. Only recently with GaN-on-Si first results have become available concerning piezoelectric applications. Semiconducting AlN is still in the early stage of its materials development, and microsystems based on the semiconducting properties of AlN have not yet been reported.

1.06.2.2 Mechanical Properties

SiC and diamond are both materials with a large Young's modulus (YM). Therefore, high forces need to be applied for deflection of a beam or membrane; the limit being the fracture strength. The ratio of YM

Table 1 Maximum temperature of operation of wide bandgap semiconductor devices

Si	MOSFET	400°C	Colinge (1998)
GaAs	HEMT	500°C	Schmid *et al.* (1998)

and fracture strength is therefore an important figure of merit.

For SiC, a YM of 300–700 GPa is obtained depending on its quality (Fu *et al.* 2005).

For GaN epitaxial films, values of the YM between 250 and 350 GPa have been determined by nanoindentation (Jian *et al.* 2003).

For diamond nanocrystalline films, the YM is mostly between 800 and 1000 GPa, and the fracture strength is between 2 and 4.5 GPa (Espinosa *et al.* 2003, Hernandez-Guillen *et al.* 2005). Thus, while a near ideal stiffness can be obtained, the fracture strength is less than half of the single crystal value (**Table 2**). On the other hand, no plastic range and no hysteresis are observed, when bending cantilevers up to fracture. Plastic deformation is only seen with very high forces inflicted by nanoindentors used to determine the hardness. The high elasticity combined with the high fracture strength may be illustrated in **Figure 1**.

Another important feature is the thermal stability of the mechanical properties. For SiC ceramics the YM has been measured up to 1000°C. It is nearly constant up to approximately 600°C, slowly decreasing for higher temperatures (Wolfenden 1997). With respect to diamond, no change has been observed in direct measurements up to 600°C (Werner *et al.* 1997a), and changes are also not observed indirectly up to at least 650°C, inferred from a constant threshold

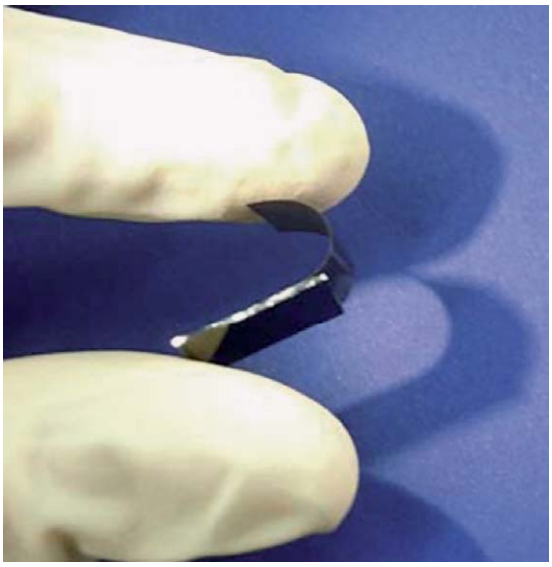

Figure 1 Bending of a freestanding diamond cantilever of approximately 20-μm thickness.

voltage of electrostatically driven cantilever switches (Adamschik *et al.* 2000a) (see also Section 1.06.6.2). In contrast, at this temperature, deviations from Hook's law can already be expected for Si.

A third aspect is the thermal expansion or contraction between growth temperature and the temperature of operation. This may be especially important for membrane structures on Si or SiC, which are operated within a large temperature range or for thermal–electric (bimetal) and piezoelectric actuator stacks. As the coefficient of thermal expansion of all materials is not constant for the temperature range in question, membranes may experience compressive as well as tensile stresses in certain temperature ranges (which on the other hand may be balanced by built-in stresses in the film). **Figure 2** shows the difference in thermal stress between RT and 1200°C for Si, SiC, AlN, and diamond materials combinations. Growth temperature for diamond chemical vapor deposition (CVD) film deposition may be between 600°C and 900°C; that of CVD 3C–SiC between 1100°C and 1300°C as discussed below. The stress between diamond and Si is less than 1 GPa and below the fracture strength of both the materials. Thus, thick crack-free diamond/Si stacks can be realized. However, thick diamond films on Si often lead to a concave wafer bowing and a high dislocation density in the Si substrate, which is mostly caused by a vertical stress profile built into the film during growth (von Kaenel *et al.* 1997).

1.06.2.3 Thermal Properties

Thermal conductivity and heat capacity are important for the dissipation of thermal losses generated during operation under heavy load. In the case of the bubble ink-jet, the thermal properties may determine the overdrive capability or frequency limit of operation. In case of a bimetal actuator, it may limit the speed of recovery.

Two aspects matter: firstly, the direct heat transport through the microstructure and, secondly, the heat extraction through the substrate. Therefore, both the thin-film properties and the bulk properties are important. In general, the thermal conductivity will be reduced with smaller grain size, and nanocrystalline materials have to be evaluated carefully with respect to their granular structure. In **Figure 3** the thermal conductivity is plotted for ideal, single-crystal diamond, AlN, GaN, SiC, and Si, and compared with Cu. Because the thermal conductivity of Si is lower than that of SiC and diamond, but is still the substrate in most cases, it is important to design the thickness of the top SiC or diamond layers according to the heat spreading requirements.

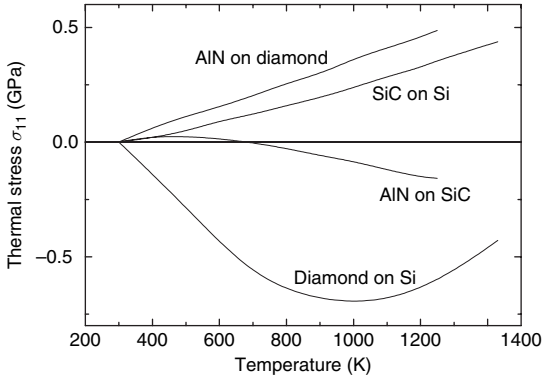

Figure 2 Thermal stress developed for diamond on Si, AlN on diamond, SiC on Si, and AlN on SiC, which may develop between growth at high temperature and temperature of operation. (Source: Aleksov A, Kubovic M, Kasu M, Schmid P, Grobe D, Ertl S, Schreck M, Stritzker B, Kohn E 2004. Diamond-based electronics for RF-applications. *Diamond Relat. Mater.* **13**, 233–40; Slack G A, Bartram S F 1975 Thermal expansion of some diamond like cystals. *J. Appl. Phys.* **46**, 89–98; Okada Y, Tokumaru Y 1984 Precise determination of lattice parameters and thermal expansion coefficient of silicon between 300 and 1500 K. *J. Appl. Phys.* **56**, 314–20.)

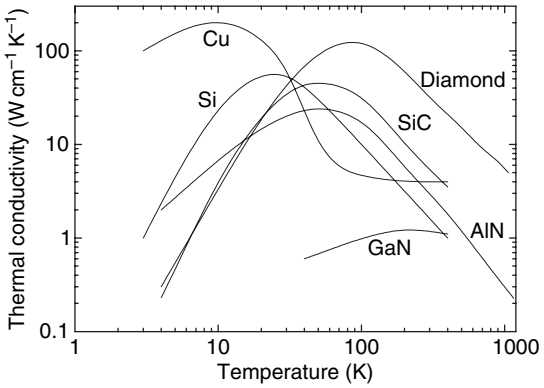

Figure 3 Thermal conductivity of SiC, GaN, AlN, and diamond in comparison to Si and Cu. (Source: Siechel E K, Pankove J I 1975 Thermal conductivity of GaN. *J. Chem. Solids* **38**, 330; Slack G A, Tanzilli R A, Pohl R O, Vandersande J W 1987 The intrinsic thermal conductivity of AlN. *J. Chem. Solids* **48**, 641–47; Glassbrenner C J, Slack G A 1964 Thermal conductivity of silicon and germanium from 3°K to the melting point. *Phys. Rev.* **134**, A1058–69; Slack G A 1964 Thermal conductivity of pure and impure silicon, silicon carbide, and diamond. *J. Appl. Phys.* **38**, 3460–6.)

From **Figure 3** it may be seen that diamond is most effective for a heavy duty operation around RT, but the difference to Cu becomes less important for an operation in a hot environment. Aspects of the chemical high-temperature stability are discussed in Section 1.06.2.4.

1.06.2.4 Chemical Properties

The chemical stability may be considered in three different ways, the chemical stability of the bulk material with respect to phase stability and decomposition, the chemical stability of the surface with respect to corrosion and etching, and the ability to form reliable interfaces, for example, for adhesion of molecules.

1.06.2.4.1 Silicon carbide

SiC is an exceptional stable material subliming at approximately 1800°C. It can only be etched in KOH at around 600°C and is thus stable at the etching conditions for the Si substrate (in KOH at approximately 70°C). Dry etching can be performed in F-based plasma chemistries as also used for Si, however, with lower etch rate. The surface is oxidized to SiO_2 (also forming CO) and the passivation behavior is similar to that of Si, however, and is stable up to high temperatures. The electrochemical stability is higher than that of Si, but it can be etched electrochemically in HF (Mikami *et al.* 2005).

1.06.2.4.2 GaN, GaN heterostructure, and AlN

GaN dissociates in an atmosphere at approximately 650°C, forming Ga oxide (mainly Ga_2O_3) and N_2 (Pisch *et al.* 1998), and Ga_2O_3 itself is stable up to a high temperature above 800°C (Fleischer and Meixner 1992). The stability is still improved, when it is capped with AlGaN and InAlN. Indeed, AlGaN/GaN high electron mobility transistors (HEMTs) have been operated up to approximately 750°C and InAlN/GaN HEMTs up to 1000°C (in vacuum) without loosing their spontaneous polarization and piezopolarization (Daumiller *et al.* 1999, Medjdoub *et al.* 2006). GaN can have two surfaces, Ga face and N face, with a highly stable Ga face and a rather reactive N face, respectively. Usually, device films are grown with a Ga face. In this case, in atmosphere, the top layer is terminated with oxygen.

AlN is usually deposited as an amorphous or nanocrystalline film. It can be etched in KOH, depending on the crystalline quality. It is oxidized above 800°C with a higher stability of the Al face than the N face (Gu *et al.* 2005). The etching of GaN-based films is discussed in Section 1.06.5.3.

1.06.2.4.3 Diamond

Diamond is the metastable form of carbon with respect to graphite and its phase stability must be limited. Nevertheless, the barrier for the phase transition is very high and the survival of the diamond phase has been documented at 2200°C in H_2 atmosphere (Kumar 1996). In an inert atmosphere graphitization is observed above 1500°C; however, with respect to nanodiamond powder, the process already takes place above 800°C (Chen *et al.* 1999). Electronic device operation has been demonstrated at 1050°C (Zimmermann *et al.* 2005a). In the liquid, it is highly corrosion resistant and cannot be etched in any wet solution. It can, however, be etched in an oxygen plasma and in an oxygen atmosphere above approximately 750°C. Dry etching in an oxygen plasma is therefore the common way to pattern diamond thin films (Ding *et al.* 2005).

1.06.2.5 Radiation Detector Properties

The field of wide bandgap semiconductors is the solar blind detection of UV radiation and the detection of high-energy particles. For high-energy photon and particle detection, radiation hard semiconductors are needed to replace current Si detectors, which possess a limited lifetime under high-energy fluences (Bruzzi *et al.* 2002). The wavelength cutoff is determined by the bandgap and reaches from 2.6 to 3.3 eV for SiC (depending on the polytype), 3.5 eV for hexagonal GaN, 5.45 eV for diamond, and 6.2 eV for AlN. SiC and diamond are indirect, whereas GaN and AlN direct bandgap semiconductors. The bandgap of AlGaN can be tuned between that of GaN and AlN depending on the composition and indeed AlGaN/GaN heterostructures are the mostly used ones for UV detectors. However, GaN does not possess a natural substrate and growth on Al_2O_3 or SiC and results in a high mismatch and a high dislocation density in the GaN buffer layer. AlGaN with high Al content is difficult to growth with low oxygen content and defect density.

On the other hand, SiC is a mature substrate technology developed for high-temperature electronics. Thus, active layers on hexagonal SiC substrates have become available with low defect density and

SiC starts to compete with Si detectors in the field of X-ray and particle detection (Bruzzi *et al.* 2002).

The basis for diamond detectors have mostly been polycrystalline CVD films with large grain size. Recently, freestanding single-crystal CVD films with a background impurity concentration of only $10^{13}\,cm^{-3}$, an associated electron mobility of $4600\,cm^2\,V^{-1}\,s^{-1}$, a hole mobility of $3800\,cm^2\,V^{-1}\,s^{-1}$, and photo carrier lifetime in the microsecond range have become available (Isberg *et al.* 2002). Therefore, diamond is an alternative for DUV detection below the 225-nm wavelength. However, the substrate size is still limited to approximately 1 cm^2. An overview can be found in Bergonzo *et al.* (2004).

In general, the materials must posses a large charge collection efficiency, boiling down to a high mobility–lifetime ($\mu\tau$) product and collection distance ($\mu F\tau$). In addition, deep level charging and related drift need to be controlled, which involves priming in some cases. Finally, the atomic displacement energy as measured for radiation damage should be high. **Table 3** shows a comparison of some key parameters.

1.06.2.6 Electrothermal Properties

The electrothermal properties may be used in sensor as well as actuator elements. In sensing, the temperature-dependent change in resistance is used in thermistors. The heat generated in a resistor may on the other hand be used in spot heaters like in ink-jets or in a bimetal type of actuator. They make use of the actuation of deep dopants, the barrier characteristics of grain boundaries in polycrystalline materials, and the change of carrier mobility with temperature, mostly in a highly disordered amorphous system. In SiC, sputtered SiC has been used, most likely taking advantage of a disorder and an activation effect (Dulloo *et al.* 1999). In diamond, boron is a deep acceptor and its thermal activation can be used.

SiC and diamond have also been employed as heaters. Here a temperature-independent behavior is desired. But many doping levels in wide bandgap semiconductors are deep. For diamond no shallow doping exists. However, at high concentrations, the activations energy can be essentially reduced by miniband formation (Borst and Weis 1996, Werner *et al.* 1997b). Such resistive heaters have been used in microhotplates and spot heaters. For operation under high thermal load or in aggressive media also, the chemical corrosion resistance, the resistance to cavity damage, and the resistance to fatigue due to thermal cycling are important. To be used in electrothermal actuators, based on the bimetal effect, both SiC (Jiang *et al.* 2006) and diamond (Schmid *et al.* 2003) have been used as materials with low coefficient of expansion combined with a metal of high coefficient of expansion (**Table 4**). Such pairs are diamond/Ni or SiC/NiCr. Here, either the semiconductor or metal can be chosen as a resistive heater element.

1.06.2.7 Electrochemical Properties

The heart of all electrochemical devices are their electrodes. Two different types of electrodes are used. Firstly this is the metal oxide semiconductor (MOS) diode with a chemically active surface, mostly hydroxyl groups on metal oxides like TiO_2. Here potential differences are detected via field effect. These may be related to work function differences generated by redox reactions at the surface active sites or surface charging due to the attachment of charged molecules. This method is mostly used in biochemical analysis with MOS chemical field effect

Table 3 Materials parameters relevant for particle detection – the Wigner energy is the energy needed to create a site vacancy in the periodic lattice

	Material

transistors (ChemFETs) or ion-sensitive field effect transistors (ISFETs) (Bergovel 2003) within a rather narrow range of pH.

Secondly this is the conductive electrode in which a DC current is passed and a redox reaction can be sustained. This is the case in a battery, where the electrode material itself also takes part in the reaction. Another case are inert electrodes supporting electron transfer between the liquid and the solid without etching or corrosion, the classical example being Pt. They are mostly used in electroanalytical chemistry but also in electrooxidation like in water disinfection. An important aspect of such electrodes is the water dissociation reaction. Water is dissociated into H_2 and O_2 at the cathode and anode, respectively, with a dissociation potential of $\Delta V = 1.23\,V$ (potential window for water dissociation). In the reaction, electrons or holes may need to be transferred, with high density available in a metal. In a semiconductor, three possibilities exist for charge transfer: electron transfer via conduction band, hole transport via valence band, and charge transfer via surface states. The energy/potential scale is illustrated in **Figure 4**, where the bandgap lineup of wide bandgap semiconductors is plotted with reference to the potential of the standard hydrogen electrode (SHE) potential (for diamond, see Angus *et al.* 1999). The electron affinity of diamond is positive for an oxygen-terminated surface and negative for hydrogen termination. The electron affinity of AlN is still under debate, depending on the doping level and status of surface oxidation.

However, to conduct current, the semiconductor surface should not be depleted and the semiconductor should therefore be quasi-metallically doped, allowing tunneling across the interface (from the semiconductor side). Thus, the dissociation reaction may still be suppressed, if the transfer states cause band bending preventing tunneling, if the density of active sites is low, and if the surface is shielded from the electrolyte by adsorbed species. However, within

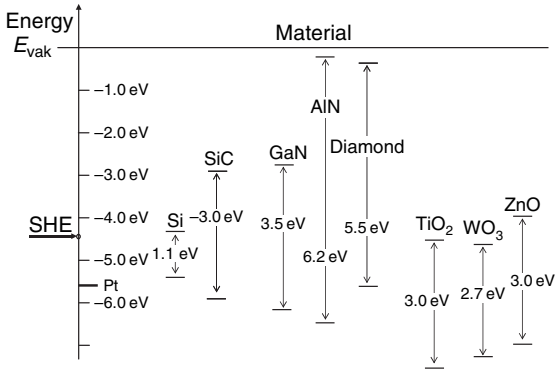

Figure 4 Approximate band structure lineup for various semiconductors, metal oxides, and Pt. The metal oxide materials are common in metal oxide semiconductor field effect transistors (MOSFETs), and are therefore not used in amperometric applications. SHE, standard hydrogen electrode.

this potential window, the electrode surface may still be active with respect to other redox reactions. At such an electrode with wide potential window, species can react at high overpotentials, which are otherwise stable in water. This is the basis of electrooxidation of hazardous organics like phenol. Typical ranges of potential windows are shown in **Figure 5**. Clearly, GaN and diamond show the highest potential windows, and also the advantage of diamond with respect to glossy carbon becomes obvious. However, the stability of GaN is less than that of diamond (discussed in Section 1.06.4.1.4).

1.06.3 Materials Synthesis and Characteristics

Depending on their use, the synthesis of bulk material and thin films is widespread from sputtering of nanocrystalline films to the growth of high-quality single layers by metal organic chemical vapor deposition (MOCVD) and the synthesis of substrates by high-temperature processes like sublimation growth.

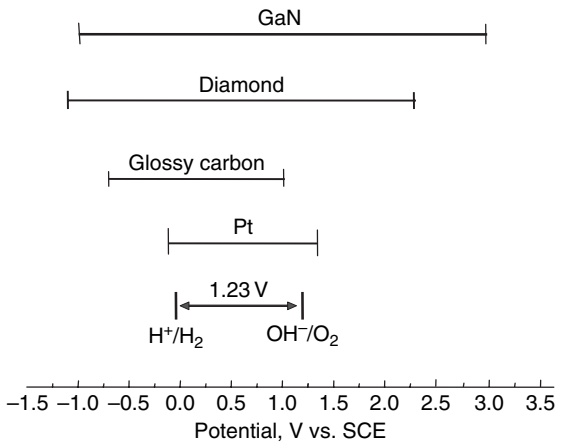

Figure 5 Potential window of water dissociation in H_2SO_4 (pH 1) for various electrode materials and the water reaction itself. The bars represent average values for currents in the microampere per square centimeter range. SCE: standard calomel electrode.

1.06.3.1 Silicon Carbide

SiC has been deposited as single crystalline, polycrystalline, and amorphous material. It has many possibilities of a stacking order of the SiC tetrahedrons and thus a high number of polytypes. The most commonly used are the cubic 3C–SiC phase and the H4 and H6 hexagonal phases. This variety is mainly reflected in the energy bandgap and the free carrier transport properties but not so much in the mechanical, thermal, and electrochemical properties. The material sublimes at around 1800°C and would (if capped) melt at 3800°C.

As amorphous material, it can be deposited at a low temperature by sputtering or ion beam deposition from a SiC target. These films are often Si rich. Films deposited by plasma-enhanced CVD (PECVD), electron cyclotron resonance CVD (ECR-CVD), atmospheric pressure CVD (APCVD), low-pressure CVD (LPCVD), and CVD under ultrahigh vacuum conditions (gas source molecular beam epitaxy (MBE)) mostly using CH_4 or C_3H_8 and SiH_4 as precursors, are amorphous, nanocrystalline, or polycrystalline, depending on the growth temperature, the grain size increasing with increasing growth temperature. On SiO_2 or Si_3N_4, the crystallites are randomly oriented but may develop some texture. The growth temperature is usually between 1100°C and 1300°C, but may be as low as 200°C (Colder *et al.* 2005). Such films are used for freestanding structures on sacrificial layers like poly-Si, SiO_2, and Si_3N_4 and are rarely compatible with CMOS postprocessing technologies (Cheng *et al.* 2002). Thin buried SiC films can be generated by high-dose ion implantation ($D \sim 10^{17}$ cm^{-2}) into the Si substrate (Serre *et al.* 1997).

Single-crystal hexagonal SiC wafers are used for bulk devices, as high-quality 4H, and 6H substrates are available for electronic and optoelectronic device fabrication (Powell and Rowland 2002). Etching is restricted to dry etching (see Section 1.06.5.2).

SiC grown on Si develops in the 3C–SiC polytype. It is therefore used in surface machined devices on Si. It is also available freestanding in wafer size, however, with some texture (available from Hoya Advanced Semiconductor Technologies). On Si it is grown by APCVD, LPCVD, and MOCVD when metal organic precursors are used at a temperature above 1300°C. The heteroepitaxial deposition on Si starts with the carboration of the Si surface and growth of a thin nucleation layer (Morales *et al.* 2003). Nevertheless, due to the high temperatures employed, it is difficult to maintain a smooth interface to the Si substrate, which becomes pitted. Due to the high mismatch, nucleation on the carbonized layer results in mosaic growth and oriented texture after outgrowth as illustrated in **Figure 6**.

In addition, the high deposition temperature causes high thermal stresses, leading to the formation of a high density of crystal defects. Migration of those defects into the Si substrate will affect its electronic, mechanical, and chemical stability. It can, for

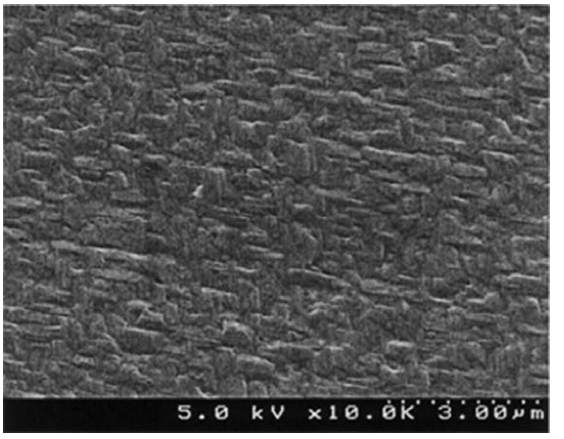

Figure 6 Surface topography of 3C–SiC layer grown by metal organic chemical vapor deposition (MOCVD) on (100)-oriented Si. (Source: Young D J, Du J, Zorman C A, Ko W H 2004 High-temperature single-crystal 3C–SiC capacitive pressure sensor. *IEEE Sens. J.* **4**, 464–70.)

example, affect the anisotropic Si wet etching characteristics essential for membrane etching. These effects are attenuated, when the film is grown on a silicon on insulator (SOI) substrate, where the top Si layer serves as a seed layer and the buried SiO_2 layer as a stress relaxation layer. The buried SiO_2 layer will also serve as a thermal barrier between the surface structure and the substrate, which is important for electrothermal actuators, and where heat loss into the substrate should be avoided. It is also generating electrical isolation between the SiC layer and the Si substrate. This is important for high-temperature application, where the Si substrate will become metallic in conduction. Layers grown on amorphous films like SiO_2 are nanocrystalline or polycrystalline. Thick films are therefore often polished.

The films can be n-type doped with N, P, and O, and p-type doped with Al or B. Nitrogen exhibits an activation energy of 50–58 meV, reduced to zero by miniband formation at approximately $3.6 \times 10^{19}\,\mathrm{cm}^{-3}$ (Eickhoff *et al.* 2004). The incorporation seems not to be influenced significantly by the crystalline quality. Oxygen is thought to be incorporated with an activation energy of approximately 200 meV. Both nitrogen and oxygen may be present, when films are grown on Si_3N_4 or SiO_2 and outdiffused into the SiC, causing residual conduction. Oxygen is thought to decorate defects and grain boundaries preferentially (Eickhoff *et al.* 2004). Thus, high residual conductivities are often observed in nanocrystalline layers.

The deposition by LPCVD is very similar to MOCVD or MBE. In the case of MBE, the deposition is mainly driven by the kinetics and deposition temperatures are lower, mainly in the range of 500–1000°C (Lee *et al.* 1997, Lim *et al.* 2004).

In contrast, most bulk single-crystal substrates have been developed for use in optoelectronics and high-power electronics, and are synthesized in hexagonal configuration (mostly 4H–SiC and 6H-SiC). Due to the high crystalline quality and low defect density (mainly micropipes and screw dislocations), films grown on these substrates can be semi-insulating with high thermal stability. They can be doped n-type and p-type as already mentioned above. However, SiC substrates are not easily etched (except with deep reactive ion etching (DRIE)) and they have, therefore, often been used in bulk devices like heater platforms, high-temperature gas sensors, and stress gauges including the entire wafer thickness as cantilever or membrane.

1.06.3.2 Gallium Nitride

Wurzite GaN grown with *a*-plane orientation contains a strong vertical charge dipole generated by the vertical N–Ga bond, which is not compensated by symmetry (**Figure 7**). This leads to a high bonded spontaneous polarization charge density at the surfaces of $\sigma_p = 3 \times 10^{13}\,\mathrm{cm}^{-2}$, and the direction of the field depending on the growth orientation. Normally obtained in MOCVD growth is the Ga face orientation, with a Ga-oxide terminated surface, when exposed to the atmosphere. Under specific conditions, the N face orientation can be obtained (Georgakilas *et al.* 2001). However, this surface is chemically less stable and therefore not frequently used.

It does not possess a natural substrate and bulk GaN is only used in proof-of-concept experiments. It is therefore mostly grown as film on foreign hexagonal substrates like Al_2O_3 and 6H–SiC. Several hundreds of micrometer thick quasi-substrates are grown by hydride vapor phase epitaxy (HVPE).

GaN is the most commonly used wide bandgap semiconductor material in optoelectronics and RF power electronics, and the materials synthesis technology has mainly been driven by these applications. The key has been a high concentration of (atomic) N radicals. Two CVD techniques are common, MOCVD and radiofrequency molecular beam epitaxy (RF-MBE). In the first case, metal organic precursors are used as a Ga source and NH_3 as a precursor for N^*, in the second case, N_2 is split in a low-energy RF plasma source. MOCVD is therefore performed mostly at around 1000°C close to the dissociation temperature of NH_3. Due to the high mismatch to

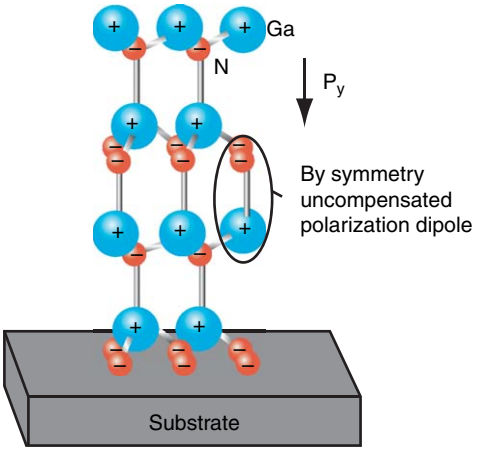

Figure 7 Origin of the spontaneous polarization in wurzite GaN.

the foreign substrate, direct epitaxial growth is not possible. Instead, a nucleation layer of low-temperature-deposited AlN (LT-AlN) with high amorphous content is used. Therefore, the first nanometers close to this nucleation layer are very defective and defects need to be outgrown subsequently.

In electronics and microsystems, the wurzite material phase can combine pyroelectric and semiconducting properties. Thus, diode and transistor piezoelectric sensor devices based on n-type as well as p-type GaN and AlGaN/GaN heterostructures have been investigated. In this case, three effects may contribute to the overall piezoresponse. First, this is the electroceramic effect, which is the variation of the surface charge dipole induced by the bonded polarization charge dipole. Second, the piezobulk effect caused by the band structure realignment and related charge redistribution in the bulk, and, third, in the presence of a stress gradient across the film the generation of free charge carrier in the bulk. The later effect has been called polarization doping and is observed in heterostructure FETs (Jena *et al.* 2002), but not well identified in piezo-MEMS structures yet.

Because this is an unusual effect, it may shortly be illustrated in **Figures 8** and **9**, showing the case of a doped GaN cantilever, which is bent by a force, acting on the tip. In **Figure 8**, the distribution of the bonded polarization charges is shown under stress, and in **Figure 9** the corresponding effect on the induced mobile charge distribution. The bending will induce a vertical stress gradient across the beam, generating a polarization gradient, which in turn will generate a distribution of free carriers (holes or electrons) across the beam. The corresponding donors or acceptors are represented by the stress-induced change in the bonded polarization charge distribution. Thus, a constant stress gradient will result in a constant free carrier profile. The effect has been first identified using a graded $Al_{(x)}Ga_{(1-x)}N$ layer with a vertical stress profile incorporated by growth. Thus, free carriers are generated without external doping. For a Ga face materials orientation, which is usually the case for MOCVD-grown layers on a LT-AlN buffer, upward bending of the cantilever will show p-type polarization doping in the bulk. Correspondingly, downward bending will result in n-type polarization doping, both generating bulk conduction paths in parallel to a piezoresistive channel on the surface.

Single-crystalline GaN films have been deposited onto a variety of substrates (Miskys and Kelly 2003), especially Al_2O_3, α-SiC, (111) and (100) Si, (111) GaAs (Kumagai *et al.* 2002), $LiNbO_3$ (Wu *et al.* 2002), and γ-$LiAlO_2$ (Takagaki *et al.* 2004a). Deposition on Al_2O_3 and SiC are common for optoelectronic and electronic applications. However, it is difficult to etch membrane structures to obtain freestanding cantilevers. Deposition on GaAs, $LiNbO_3$, and γ-$LiAlO_2$ shows rather poor quality and device grade material has not been obtained up to now. Nevertheless, it has been attempted to fabricate freestanding structures from these films. High-quality GaN layers can however be grown on (111)-oriented Si wafers. However, the large mismatch limits the thickness of the GaN layer to approximately 1 µm, before cracks appear. To circumvent this problem, graded AlGaN buffers (Kim *et al.* 2001) and AlN/GaN superlattices have been introduced (Feltin *et al.* 2001). Most successful was the incorporation of low-temperature-grown LT-AlN stress release layers into the GaN film, enabling the growth of thick GaN layers in excess of 6 µm (Krost and Dadgar 2002). Because AlN

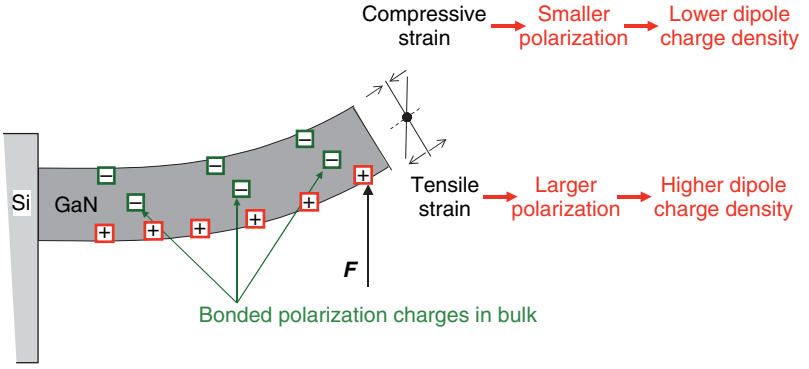

Figure 8 Change in bonded charge distribution (squares) while bending a cantilever upward, assuming that compressive strain will reduce the polarization. (Source: Neuburger M, Zimmermann T, Benkart P, Kunze M, Daumiller I, Dadgar A, Krost A, Kohn E 2004. GaN based piezo sesnsor. *62nd Device Research Conference (DRC)*, South Bend, IN, USA, Abstracts 45–6, June 2004.)

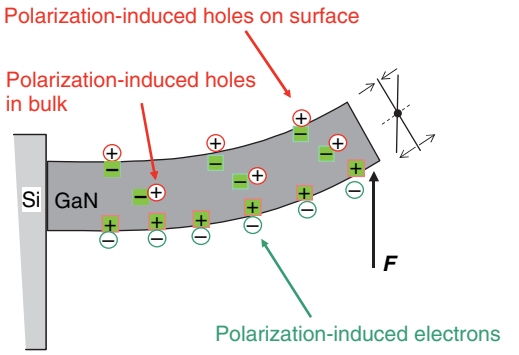

Figure 9 Compensation of bonded charge by the generation of a hole charge density (circles) in the bulk of the cantilever. This bulk effect has been named polarization doping.

contains a larger polarization field than GaN, polarization dipoles are introduced by this procedure. This is illustrated in **Figure 10**, which shows an atomic force microscope (AFM) potential scan across a GaN buffer on Si with two AlN stress release layers. It shows the growth sequence with the LT-AlN nucleation layer on the Si substrate and the strong dipoles of the AlN stress relief layer and an AIGaN/GaN FET channel, the dipole charge of which is compensated by the surface.

Most GaN structures are designed with strained AlGaN/GaN heterojunctions, making use of the piezopolarization at the interface, generating a 2D electron gas (2DEG) channel of high mobility. The various polarization charge contributions are illustrated in **Figure 11**.

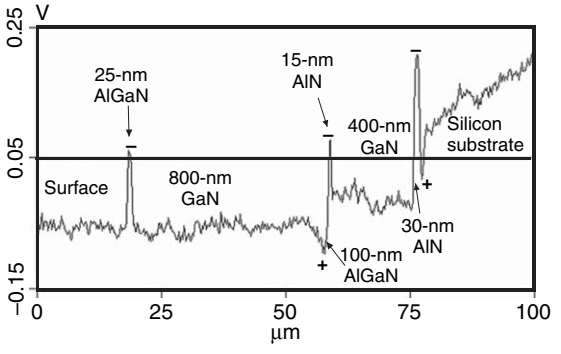

Figure 10 Measurement of polarization dipoles across a GaN heterostructure grown on Si, containing two AlN stress relief layers and an AlGaN/GaN high electron mobility transistor (HEMT) heterostructure. The measurement was performed with a potential contrast atomic force microscope (AFM) tip on a beveled cut. (Source: Dadgar A *et al.* 2003 Gallium-nitride-based devices on silicon. *Phys. Stat. Sol. (c)* **0**, 1940–9 with permission.)

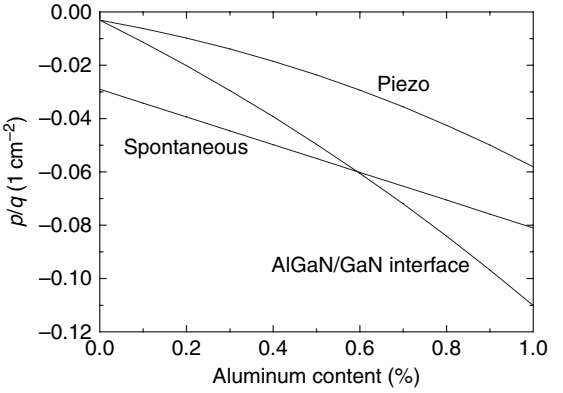

Figure 11 Contributions to the polarization discontinuity at the AlGaN/GaN interface, namely piezopolarization caused by the strained AlGaN layer and the spontaneous polarization of GaN.

This heterojunction is also the basis for FETs. Depletion mode as well as enhancement mode N channel FET structures have been realized using the interfacial 2DEG as channel, P channel devices are not attractive up to now, because of their low hole sheet charge density and mobility (Zimmermann *et al.* 2004). Nevertheless, front end signal processing circuits as well as driver circuits can be realized on-chip.

1.06.3.3 Aluminum Nitride

Amorphous and nanocrystalline AlN (mostly prepared from powder) is a traditional electroceramic with a high spontaneous polarization of $\sigma = 6.2 \times 10^{13}\,\mathrm{cm}^{-2}$. It has been used widely as a transducer material in piezoresistive sensors and in surface acoustic wave (SAW) devices on Si (Caliendo *et al.* 2003), SiC (Takagaki *et al.* 2004b), $LiNbO_3$ (Wu *et al.* 2002), GaN (Chen *et al.* 2003), diamond (Shikata and Nakahata 2004), and GaAs (Liaw and Hickernell 1994) among other substrates, and a large number of studies have been published in this field. Recently, it has also been proposed for piezoelectric actuation (Olivares *et al.* 2005). For applications in a harsh environment, the AlN film is deposited on SiC and (nano/polycrystalline) diamond. The high internal polarization field and piezostriction is used, in conjunction with its highly insulating characteristics. The semiconducting properties are not used. On the contrary, bulk conduction is considered detrimental, as it will short circuit the internal field and shield the surface. Therefore, the residual conduction may be compensated by oxygen addition. It is

deposited by a variety of techniques like powder sintering, DC or RF sputtering, ion beam deposition, and as crystalline film by MOCVD.

Bulk single-crystal AlN has become available recently, but has been designed as insulating substrate material for GaN-based power FETs (Hu *et al.* 2003) and light-emitting diodes (LEDs) (Gaska *et al.* 2002). It is highly resistive and temperature stable. **Figure 12** shows a temperature measurement of a sample grown by induction heated vapor phase transport (VPT) from an AlN powder source at 2300°C (Zhuang *et al.* 2006). In the experiment, the temperature was ramped up in steps of 100°C and the resitivity measured with probes at each temperature in vacuum. The AlN single crystals remained stable up to 1100°C. No change of the RT conductivity was observed after several cycles. At RT, the resistance through the sample is very high reaching into the teraohm range. It acts therefore as perfect dielectric. From the geometry as shown in the inset, it may be estimated to $8 \times 10^{10}\,\Omega\,\text{cm}$ at RT. The conductance changes by three orders of magnitude with temperature when heated to high temperatures. However, even at a temperature of 750°C the estimated specific resistivity of the samples is in the order of $1\,\Omega\,\text{cm}$ and comparable to the RT resistivity of semi-insulating GaAs. The increase of conductivity may be linked to impurities within the material, but may in part be counterbalanced by a decrease in mobility. Impurities commonly detected by secondary ion mass spectrometry (SIMS) in bulk AlN crystals grown by the VPT technique are oxygen and carbon (Slack and McNelly 1976).

Thin single-crystalline AlN films are commonly grown on GaN by MOCVD or RF-MBE. Because of the high mismatch, the critical thickness for the growth of a strained layer is only a few nanometers and such layers are only used for capping of the surface or intermediate smoothing and stress release layers. Thicker layers are therefore relaxed and contain a high density of defects. Nevertheless, the first LED structures could be fabricated, also indicating that n-type doping (by Si) as well as p-type doping (by Mg) are possible (Taniyasu *et al.* 2002, 2006).

The application in SAW devices is one of the few, where membrane etching or cantilever fabrication are not required. Cantilevers and membranes with AlN ceramic-like thin films (not yet containing active layers) have thus mainly been realized using Si substrates and conventional Si-MEMS processing technologies. Growth as single crystal semiconductor thin film is mainly performed on GaN buffer layers, the buffer being mostly deposited onto Al_2O_3 or hexagonal SiC. Both substrate materials are etched mainly using a DRIE process.

1.06.3.4 CVD Diamond

Diamond is the metastable cubic form of carbon with exceptional stability. The phase has been reported to survive in H_2 at 2200°C (Kumar *et al.* 1996). However, in an inert atmosphere, graphitization is observed in the range of 1500°C (Chen *et al.* 1999). In atmosphere, it starts to be etched by oxygen above approximately 750°C (Adamschik *et al.* 2000a). For high-temperature operation, it needs therefore passivation or operation in vacuum, and all high-temperature measurements above 500°C are therefore generally performed in vacuum. It does not possess a natural substrate of

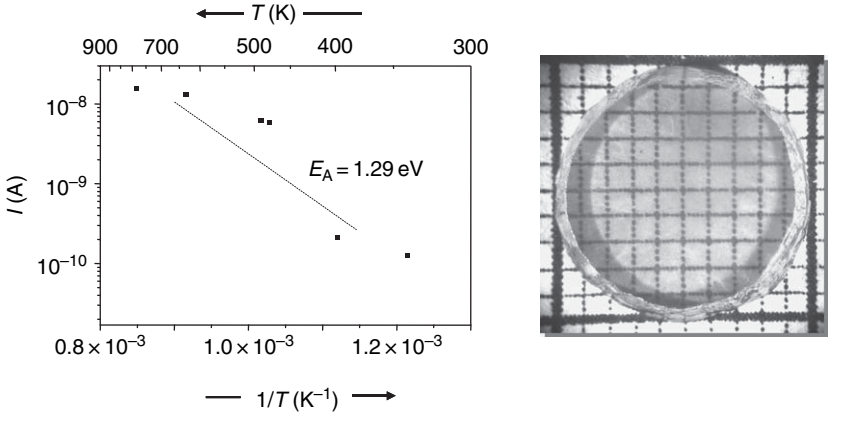

Figure 12 High-temperature conductivity measurement of single-crystal AlN up to 800°C. The data may be fitted with an average activation energy of 1.29 eV. The diameter of the sample was approximately 3 mm. (Source: Neuberger M, Aleksov A, Schlesser R, Kohn E 2007 *Electronics Lett.* **43**, 592–4 with permission.)

relevant size for a microsystems technology and is therefore generally deposited onto foreign substrates. With respect to microsystems, this is nearly exclusively (100)-oriented Si. Due to the high mismatch, the films are polycrystalline or heteroepitaxial. The exception is diamond on Ir (the Ir being deposited either on $SrTO_3$ or Si), which results in fully (100)-oriented epitaxial growth after a few nanometer thickness (Bauer *et al.* 2005). Unfortunately, this technique is still confined to small surface areas of approximately 1 cm^2.

The diamond phase can only be deposited by CVD. Two techniques are commonly employed, microwave plasma-enhanced CVD (MPCVD) and hot filament CVD (HFCVD), both techniques being used in the examples discussed below. An introduction to this subject may be found in Sevillano (1998) and Klages and Schäfer (1998). Both use a high concentration of H radicals by splitting H_2 in a high energetic microwave plasma (usually at 2.4 GHz) or by temperature while passing an array of hot wires (at approximately 2500°C). The precursor for diamond growth is usually CH_4, the growth conditions are chosen so that any graphitic phase is etched with a high rate. Thus, the H_2/CH_4 ratio is high (usually a H_2 concentration above 98% is used). The growth temperature is normally between approximately 600°C and 900°C. Deposition at high methane concentration or low plasma energy (like at 13.5 MHz) results in the deposition of amorphous carbon (a-C) or diamond-like carbon (DLC) with high graphitic content.

The deposition on Si can be separated into two phases: the seeding and nucleation phase and the outgrowth phase. Concerning seeding or nucleation, two directions are pursued: first, the seeding with nanocrystalline particles (Avigal and Hoffman 1999), sometimes embedded into an a-C film (Rotter 1999) and second the *in situ* formation of diamond nuclei at the Si surface (mostly also involving and interfacial SiC phase) by an electrical bias treatment (bias-enhanced nucleation (BEN)) (Janischowsky *et al.* 2003, Sheldon *et al.* 1994). While the deposited seed crystallites are randomly oriented, the nuclei formed by BEN can be oriented accordingly to the (100) orientation of the Si substrate. With both techniques a high density of nuclei or seeds ($>10^{11}$ cm^{-2}) can be generated, resulting in continuous films after a thickness of a few tens of nanometers.

Accordingly, two outgrowth techniques have been developed during the last decade: first, this has been the growth of highly oriented films (HOD) with a surface texture oriented with the Si substrate (Jiang *et al.* 1996, Kawarda 1998). The key was BEN of (100)-oriented crystallites with continuous outgrowth of large terraces, which start to coalesce into large single-crystalline areas. This seemed to be the near perfect case. However, during orientation-controlled outgrowth by α-parameter engineering (Wild *et al.* 1994), many smaller disoriented nuclei are overgrown and a vertical stress profile is developed, especially within the initial nucleation layer (von Kaenel *et al.* 1997). It has not been possible to eliminate this stress profile without the addition of chemical doping, which however influences the mechanical properties. Thus, HOD-coated Si wafers and freestanding cantilevers are generally bent upward (Kohn *et al.* 2001). **Figure 13** shows such a film. The second outgrowth mode is that of randomly oriented crystallites. Therefore the size of the individual crystallites is increased with film thickness, but can be limited, if growth conditions for a high nucleation rate are chosen. This is the basis for nanocrystalline films (NCD) and ultrananocrystalline films (UNCD).

For films in microsystems technologies, the surface needs to be smooth enough to allow high-resolution lithography and stress in the film needs to be controlled. Both points toward a nanocrystalline materials configuration. An overview is given in Sharda and Bhattacharyya (2004). With a grain size of 2–10 nm, this configuration is called ultra-nanocrystalline diamond (UNCD). It is realized with

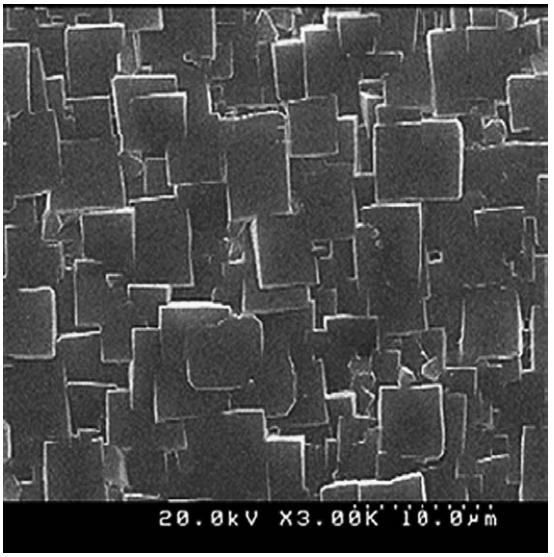

Figure 13 Scanning electron microscope (SEM) view of the surface of a highly oriented diamond surface, grown by microwave plasma-enhanced chemical vapor deposition (MPCVD) and bias-enhanced nucleation (BEN). The layer thickness is approximately 12 µm and the surface roughness is approximately 200 nm.

MPCVD with high Ar content of the plasma (Sekaric *et al.* 2002, Zhou *et al.* 1998). With a grain size between 10 and 100 nm, the material is labeled nanocrystalline diamond (NCD). It can contain individual nanosized grains or can contain thin vertical columns with a small visible grain size at the surface and nanometer smoothness (sometimes labeled 2D-NCD). Although these films contain already a continuous grain boundary network of graphitic bonds, these grain boundaries are still tight (generally less than 2 nm wide) and the films exhibit therefore many properties close to those of single-crystal material. Major differences may be observed with respect to the thermal conductivity (**Figure 14**) and electrochemical stability.

Undoped single-crystal and nanocrystalline films are generally highly resistive by deep level compensation with an RT resistivity up to the teraohm-centimeter range. Films can be doped p-type with boron during growth. Ion implantation is difficult to use, because the risk of graphite formation which is not removed during damage annealing. At concentrations below $10^{19}\,cm^{-3}$, carriers are not fully activated at RT due to a boron acceptor activation energy of 0.37 eV (Borst and Weis 1996). At high concentrations above $10^{20}\,cm^{-3}$, the activation energy vanishes and the acceptor fully activated at RT due to miniband formation with a resistivity in the milliohm-centimeter range (Werner *et al.* 1997b). These characteristics are well controlled for single-crystal material as shown in **Figure 15**. However, at high concentrations, the films become highly stressed as illustrated in **Figure 16**. The window for full activation and low stress is indeed quite small. On the other hand, highly boron-doped layers on undoped films will introduce a vertical stress profile in the stack, which can be used in stress engineering of the materials structure. Tunneling contacts to metals become possible for ohmic contact formation.

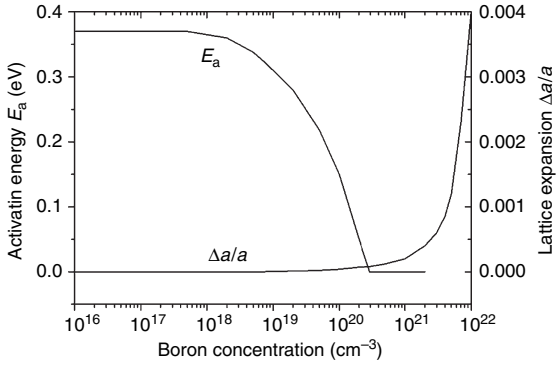

Figure 16 Mismatch induced by high concentration of boron.

Very similar data are obtained with polycrystalline and nanocrystalline material. **Figure 17** shows the incorporation of boron from the gas phase into the film with an indication of its activation. The Fermi level is not well defined for boron concentrations below $10^{18}\,\mathrm{cm}^{-3}$ and the layers may be fully compensated by donor-like defects mainly generated by the grain boundary network. Also, very high resistivity close to teraohm-centimeter can be obtained for undoped films as inferred from the characteristics of gigaohm seals in a patch clamp MEMS device (Kusterer *et al.* 2005). Complications are also expected at high doping levels ($N_A > 10^{21}\,\mathrm{cm}^{-3}$) with an inhomogeneous incorporation in the individual crystallites and the grain boundaries, and are indeed seen in electrochemistry (Becker and Jüttner 2003). At high concentrations above $10^{21}\,\mathrm{cm}^{-3}$, the film becomes highly stressed and increasingly brittle.

Donor doping is possible with nitrogen ($E_D = 1.7\,\mathrm{eV}$) (Collins 1989) and phosphorous ($E_D = 0.6\,\mathrm{eV}$), both deep impurities with negligible activation at RT (Kuizumi 2003). In nanocrystalline material, a high nitrogen concentration in the gas phase during growth leads to n-type conductivity with high RT activation (Bhattacharyya *et al.* 2001). This is mainly associated with grain boundary incorporation and grain boundary conductivity (Bhattacharyya 2004). Both p-type doping with boron and n-type doping with nitrogen have been used in NCD and UNCD films as active layers in MEMS structures.

Growth of UNCD layers has been performed at temperatures low enough to incorporate them into fully processed CMOS circuits (Xiao 2004). However, at temperatures below 400°C, the influence of graphitic bonds cannot be neglected anymore and the thermal conductivity, elasticity, and chemical properties need to be considered carefully. It may therefore be more feasible to consider the integration possibility with β-SiC FETs (Nagasawa *et al.* 2006) once the surface morphology of β-SiC is improved sufficiently. Growth of diamond on 100-oriented 3C–SiC has indeed lead to highly oriented diamond films with low spread in rotational angle (Kawarada 1998).

Stress engineering is an important aspect in the thin-film deposition technology for microsystems and relatively new to CVD diamond. In the past, most films have shown a vertical stress profile originating from the seeding and outgrowth techniques employed. Stress is especially developed during the first seeding phase, when the film coalesces and small crystallites are overgrown. Stress-free films are therefore obtained if growth starts on a high density of nucleation points, the grain size is limited to nanometer and the initial nucleation layer is only a few nanometers thick (Hernandez-Guillen *et al.* 2005). Due to the dissimilar thermal expansion of the diamond film and the Si substrate and the nonlinear behavior of this parameter, both tensile and compressive stress could be obtained by varying the deposition temperature. By specifically adjusting the growth parameter and adding chemical impurities a vertical stress profile can be artificially built in. Such a vertical stress profile has been deliberately used in bistable membrane and double anchored cantilever structures mentioned in Section 1.06.7.3 and discussed in Kusterer *et al.* (2006).

1.06.4 Transducer Elements

As already listed in the first section, the materials are used in various fields of application like electromechanical, the electrothermal, and electrochemical fields. All rely on electrically active elements and thus doped layers.

1.06.4.1 Sensor Elements

A doped layer may serve in a number of sensor functions, the main ones being discussed in the following. To some extent, the parameters needed for high sensitivity may be conflicting, like a high gauge factor (GF) for a piezoresistor and a high-temperature coefficient of resistivity for a thermistor, when a piezosensor should be operated through a large temperature range.

1.06.4.1.1 Piezoresistors

Piezoresistors are mostly realized in conjunction with membranes, cantilevers, or double anchored beams. Therefore, undercut etching or substrate etching are an important part of the piezosensor technology. The etching properties are discussed in Section 1.06.5.3.

Piezoresistors make use of several effects. First, the geometrical effect found in all conductive materials leading to change in resistance due to a change in shape, when applying an external force. Second, the change in band structure of a semiconductor, when the lattice is deformed. The lattice deformation leads to change in carrier distribution in the longitudinal and transverse valleys and thereby to a change in average effective mass. Third, the piezopolarization effect needs to be added for polar materials like discussed in the case of GaN. In the diamond lattice (3C–SiC and diamond), large highly orientation-dependent piezoresistive coefficients are found both for n-type and p-type doping, translating into highly directional sensitivities at low concentrations.

One of the important figures of merit is the GF (or K-factor), which is defined as follows:

$$\mathrm{GF} = \frac{\Delta R/R}{\Delta L/L}$$

where $\Delta R/R$ is the change is resistance and $\Delta L/L$ is the strain ε.

1.06.4.1.1.(i) Silicon carbide Freestanding 3C–SiC structure are realized on sacrificial layers, by undercut etching of the Si substrate, by DRIE or wet etching of a Si substrate. The corresponding MEMS processes are discussed in Section 1.06.5.2.

In the case of 3C–SiC, the texture and accociated defects and grain boundaries limit the GF to approximately 32 (Okojie *et al.* 1998a, Ziermann *et al.* 1997). The doping active in the resistor is only in part shallow and fully activated at RT. In addition, active areas may be isolated from the substrate by pn junctions and leakage across the pn junction can generate bypass conduction at high temperature. Therefore, the GF is not constant for high-temperature applications. The most stable temperature performance is obtained with degenerate doping levels but also a reduced GF (Okojie *et al.* 1998b). Such piezoresistors have been used in pressure sensors up to 500°C (Okojie 2006).

Pressure sensors have also been realized on 6H–SiC substrates using piezoresistors. They have been developed and evaluated for high-temperature operation (Okojie *et al.* 1998a). To realize the membrane structures, a specific DRIE process for SiC substrates had been developed (Beheim and Evans 2006).

1.06.4.1.1.(ii) GaN, GaN heterostructures, and AlN GaN piezoresistive sensors are thought to exhibit high sensitivity due to the added polarization affect. However, their technology is still difficult, and sensor structures have been investigated in various configurations, mostly with their sapphire substrate still attached. N-type (Bykhovski *et al.* 1996) and P-type GaN (Gaska *et al.* 2000) have been used as well as Schottky diodes (Strittmatter *et al.* 2003a) and metal–insulator semiconductor (MIS) diodes (Strittmatter *et al.* 2003b). Careful analysis of the materials stack as well as the various piezocontributions lead to the conclusion that Schottky diodes on P-doped GaN films should exhibit the highest GF. Indeed a GF of 250 had been identified (Gaska *et al.* 2000). In an attempt to employ the high spontaneous polarization of AlN an n-GaN/i-AlN/n-GaN sandwich structure was investigated, where the 50-nm-thick AlN interlayer acts as piezoelectric insulator (Gaska *et al.* 1997). The response was measured laterally between ohmic contacts, thus, for the current flow all three layers have been in parallel and the response also included the formation of interfacial polarization induces 2DEG and 2D hole gas (2DHG) channels. The GF(=50) measured was

in between that measured for n-type Schottky diodes and p-type Schottky diodes.

With respect to membranes and cantilever structures realized on Si substrates, only proof-of-concept experiments have been reported up to now (Brueckner *et al.* 2005, Davies *et al.* 2004). An example for the undercut etching of AlN nanobeams is given in Kang *et al.* (2005). Since this reflects an early stage of technology, a cantilever experiment shall be described here shortly. The GaN active layer had been deposited by MOCVD onto a (111)-oriented of Si substrate. This process includes also the deposition of a thin low-temperature AlN nucleation layer. The rear side was masked by a metal mask and a window etched into the Si by DRIE, the GaN serving as selective etch stop. The cantilevers are often bent downward due to the residual built-in stress in the GaN buffer layer, although containing the stress relief layers as described in Section 1.06.3.2. **Figure 18** shows the top side of a cantilever with a mesa-etched piezoresistor at the anchor point. In this case, the cantilever was realized by dry undercut etching (Zimmermann *et al.* 2006). The results are discussed in Section 1.06.4.1.6.

1.06.4.1.1.(iii) Diamond In diamond, a resistor realized with boron doping ($E_A = 0.37$ eV) will show a strong temperature activation (see **Figure 15**). Diamond piezoresistors used in the temperature regime will therefore show a mixed response (Adamschik *et al.* 2001). At RT the GF is mostly below 20, due to the effect of the incomplete acceptor activation, the grain boundaries, and the built-in stress profile within the grains. At high temperature, the doping concentration becomes fully activated but the mobility is reduced. The GF starts to drop to close of that of metals. An application in an acceleration sensor is discussed in Section 1.06.6.1.

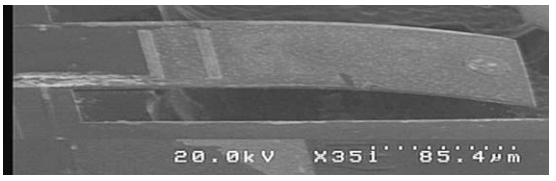

Figure 18 GaN cantilever with piezoresistor on Si substrate realized by undercut etching. (Source: Neuberger M, Zimmermann T, Berkhart P, Kunz M, Daumiller I, Dadgar A, Krost A, Kohn E 2004 GaN based piezo sensor. 62nd Device Research Conference (DRC), South Bend, IN, USA, Abstracts 45–6, June, with permission.)

Single-crystal diamond stones are used in high-pressure, high-temperature experiments performed in high-pressure cells (Boehler 2005). Diamond anvils withstand high pressures and high temperatures simultaneously without plastic deformation or cracking. However, it is difficult to control the environment at the working surface of the anvil. Typically, the temperature is determined by Raman spectroscopy with limited resolution. It has, therefore, been attempted to deposit a resistive pressure sensor structure on the working surface of the diamond stone by means of an epitaxial boron-doped resistor structure or boron-doped P-I-P diode (Zaitsev *et al.* 2001). The sensor had been tested up to 70 kbar and 850°C and was concluded, that it may work even at 1 Mbar and 1200°C. However, the piezoresistive effect is counterbalanced by the thermal activation of the deep boron acceptor and a temperature-stable high sensitivity can only be expected for temperatures, where the deep boron acceptor is fully activated and the activation of other deep centers does not interfere.

1.06.4.1.2 Thermistors

In thermistor structures, a large change of resistivity with temperature is preferable. In single-crystal material, this can be obtained through activation of a deep impurity, in a polycrystalline film carrier transport across grain boundary barriers may also lead to a high-temperature dependence.

In SiC, thermistors have been realized with RF-sputtered films with ceramic-like characteristics and applied up to 300°C (Nagai *et al.* 1982).

In diamond, the activation of the deep boron acceptor ($E_A = 0.37$ eV) has been employed. As can be seen from **Figure 15**, the temperature dependence of the carrier activation can be exponential across more than six orders of magnitude. This is also seen for the resistance, as the change in mobility is comparably small. The temperature dependence may therefore be expressed by a characteristic temperature β:

$$\beta = \frac{\ln(RT/R_N)}{(1/T) - (1/T_N)}$$

where R_N and T_N are the resistance and temperature values for the normalized conditions.

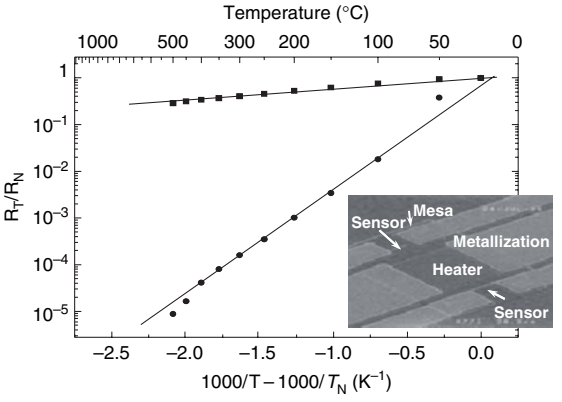

Figure 19 Diamond heater element and temperature sensor using boron-doped layers. High doping case: $\beta = 700$ K, $E_A = 61$ meV, $R_N = 230$ kΩ. Low doping case: $\beta = 4200$ K, $E_A = 360$ meV, $R_N = 6.6 \times 10^{10}$ Ω, $T_N = 300$ K. (Source: Gluche P, Leuner R, Vescan A, Ebert W, Kohn E, Rembe C, aus der Wiesche S, Hofer E P 1998 Actuator–sensor technology on electronic grade diamond films. *Microsyst. Technol.* **5**, 38–43 with permission.)

Figure 19 (inset) shows an application of such a diamond thermistor in an ink-jet spot heater for temperature control (Gluche *et al.* 1998). Two doping levels were used for the heater and the thermistor with two activation energies and two characteristic temperatures. The thermistor with low doping displays a characteristic temperature of $\beta = 4200$ K, which means that between RT and 500°C, its impedance changes by more than five orders of magnitude, well in agreement with Figure 15 (in case of a single-crystal substrate). Such thermistors have been found extremely temperature stable during operation at 500°C (Windheim *et al.* 1995).

1.06.4.1.3 Radiation detectors

All three materials: SiC, GaN, and diamond are investigated for application in DUV sensing, X-ray radiology, nuclear reactor monitoring, and high-energy physics experiments (Bruzzi *et al.* 2002). The GaN domain is however in essence the UV and DUV regime. Both SiC and diamond have been extensively investigated with respect to particle detection reaching from neutrons and α, β, γ particles to vacuum ultraviolet (VUV) and DUV. The penetration depth of these particles is in the range of 5 µm to full penetration in the case of neutrons. Detectors are therefore commonly vertical bulk devices with an active layer thickness up to several hundreds of micrometers and with contacts on both sides.

1.06.4.1.3.(i) Silicon carbide

To achieve detector grade properties, SiC active layers are generally realized epitaxially on single-crystal hexagonal (H4 or H6) polytypes. Substrates are still plagued by defects like micropipes and insulating characteristics need mostly vanadium doping to compensate for residual deep levels. Nevertheless, due to a continuously reduced defect density in epitaxial films, SiC detectors can be an alternative to Si devices in particle tracking in very high radiation environment (Sellin *et al.* 2006). Schottky diodes on 4H N^+-doped substrates and high resistive epitaxial material show very low leakage even at elevated temperature (<1.0 nA cm^{-2} at 100°C), allowing X-ray spectroscopy with high-energy resolution at elevated temperature (Bertuccio *et al.* 2004). The high materials quality is also indicated by the fact that no priming was needed to fill deep trap levels (Bruzzi *et al.* 2002). In another experiment, the resolution at 100°C was limited by the noise of the Si-JFET (junction field effect transistor) preamplifier also attached to the board (Bertuccio *et al.* 2004, Lee *et al.* 2006). Similarly, Schottky diodes have been tested as radiation detectors for 22 MeV electrons and 6 MeV photons (Bruzzi *et al.* 2003a). Beta particles (from a 0.1 mCi ^{90}Sr source) could be detected with 100% charge collection efficiency at 400 V (Bruzzi *et al.* 2003b). Neutrons have been detected with a LiF conversion layer (Dulloo *et al.* 1999).

Due to the large substrate size available the SiC, Schottky diode detector technology has already been extended to pixel detector arrays (Stevenson 2006). However, the high number of polytypes indicates already that under high fluences, carrier recombination can induce migration of defects, especially related to stacking faults.

1.06.4.1.3.(ii) Diamond

The advantage of diamond for particle detection over other materials is its radiation hardness, its high electrical breakdown strength, its high atomic density, its tissue equivalence to organic tissue, and its robustness in hostile environment. Using commercial simulation packages, the radiation damage of high doses of neutrons, electrons, protons, and α-particles have been studied and the results compared to those of Si (Mainwood 1998). It was concluded that, vacancies in Si migrate to form complex defects with dopants, whereas in diamond, the vacancies are immobile and the detector material remains usually undoped. Thus, despite the fact that diamond single-crystal material is not yet available in wafer size, a number of highly specific applications

have emerged, which may be referenced shortly in the following:

Diamond detectors in space missions:

Diamond CVD single-crystal metal–semiconductor–metal (MSM) detectors and PIN diodes (using boron acceptor and phosphorus donor doping) have been investigated for the large yield radiometer (LYRA) instrument, a solar VUV radiometer on board of the Solar Orbiter (Hochedez *et al.* 2002), and the ESA PROBA-2 mission (BenMoussa *et al.* 2006). LYRA will monitor the solar irradiance in four selected UV bandpasses from 220 to 1 nm.

C13-enriched diamond detectors have been developed to identify the isotopic composition of the solar wind (especially oxygen) in NASA's Genesis Discovery Mission (Baker *et al.* 2000).

X-ray and synchrotron beam metrology:

Quadrant structures have been fabricated on CVD diamond films as beam positioners to monitor drift in X-ray beams (Bergonzo *et al.* 1999, Marczewska *et al.* 2003, Shu *et al.* 2001). They allow permanent *in situ* monitoring of beam instabilities during experiments.

Diamond in radiology:

Single-crystal diamond has been used as solid state ionization chamber with high linearity, no memory effects, and no priming has been needed (Balducci *et al.* 2006a).

CVD diamond has been investigated for heavy ion beam tracking with energies ranging from 80 to 400 MeV u^{-1}, counting the number of impinging particles (Rebisz *et al.* 2006). The 100 MeV u^{-1} particles from a ^{76}Ge source have been counted with rates of up to 10^6 particles s^{-1} (Stolz *et al.* 2006). In this experiment, the single-crystal film had been grown epitaxially on Ir.

A 2″ diamond-on-Si wafer has been used to measure special beam distributions (Marczewska *et al.* 2003).

Diamond in nuclear physics:

CVD diamond has been investigated by several laboratories to replace existing detector materials and substitute for selected natural stones for high-dose particle detection, especially high-energy neutrons. Tests have been performed at high-energy physics and nuclear reactor facilities like at CEA, TRINITI (Bergonzo *et al.* 2001), in the Superconducting Super Collider (SSC), and the Large Hadron Collider (LHC) facilities (Allers *et al.* 1997). Using several hundreds of micrometers thick polycrystalline free-standing large area CVD substrates microstrip sensors and pixel detector arrays have been developed for the Large Hadron Collider Project (Adam *et al.* 1999, 2000).

CVD diamond has been investigated for neutron detection in several configurations:

Neutrons passing through ^{235}U will produce a number of fission products (charged particles with several tens of mega electron volt energy), which have been monitored by high-grade polycrystalline CVD diamond films (Lardon *et al.* 2006).

A ^{239}Pu radiation source diluted in nitric acid has been monitored by a diamond detector immersed into the solution (Bergonzo *et al.* 2000). Here, the high corrosion resistance of diamond has been important.

Boron deposited onto diamond has been used as conversion material, with transmutation to ^{7}Li and emission of α-particles (Mer *et al.* 2004). Alpha particles are then detected in diamond, on the other hand, the interaction with background γ-rays is less likely. This has resulted in a high neutron to γ selectivity.

The sensitivity to α-particle detection, has for example, been tested with irradiation from an Am and Cm source as well as triple ^{239}Pu, ^{241}Am, ^{244}Cm source, emitting 5.16, 5.48, and 5.8 MeV α-particles (Balducci *et al.* 2006b).

As may have become apparent, particle detectors are with few exceptions discrete devices wire connected to a low noise amplifier tailored to the bandpass characteristics of the radiation. This amplifier is generally located at some distance outside the harsh environment and the sensitivity and signal-to-noise ratio of the detector may be crucial.

1.06.4.1.4 Electrochemical electrodes

As already discussed, electrodes in electrochemistry are the electronic interfaces to liquids. Quasi-metallically doped inert electrodes are discussed here, which can be operated with high overpotentials without corrosion or fouling. SiC will form CO, CO_2, and SiO_2 at its surface under anodic polarization (Lauermann *et al.* 1997) and the electrochemical stability will in essence be similar to that of Si. GaN and AlN will form Ga and Al oxides and hydroxides on the surface (Huygens *et al.* 2000). The most inert semiconductor material is diamond.

1.06.4.1.4.(i) Gallium nitride In a similar experiment, as described below, for the case of diamond, a quasi-metallically n-type-doped GaN electrode has been bias cycled six times (**Figure 20**). The first scan indicated a potential window of nearly 4 V. However, the following scans indicate that the activity of the electrode is increasingly decreased. The electrode becomes unstable at high anodic potentials. There are several possibilities for this behavior. Most likely the surface becomes oxidized and shielded by an adsorbate layer. The detailed mechanisms are however not clear at present. Similar behavior is seen for n-type AlN (Kohn *et al.* 2005).

1.06.4.1.4.(ii) Diamond Diamond can be highly doped with boron and is therefore an ideal electrode material for applications in harsh and hazardous liquid environments. The inertness and durability of diamond is highlighted with the experiment shown in **Figure 21**. Here a single-crystal diamond electrode has been cycled many times in a wide potential window-detectible corrosion. The graph shows the surface after a 28 500 current voltage scans at 1 V s^{-1} scan speed from −3 V to +7 V DC. A total charge density of 17.85 A h cm^{-2} had been transferred. During this time the electrochemical window had been reduced from −2/+3.2 to −1/+2.7 V DC. The surface roughness has changed from 2.6 to 2.8 nm, and has thus been essentially maintained.

This high stability in the anodic regime is the basis for the application of diamond electrodes in electrooxidation and electroanalysis (Haenni *et al.* 2004, Swain 2004). This is illustrated for the three cases shown in **Figure 22**.

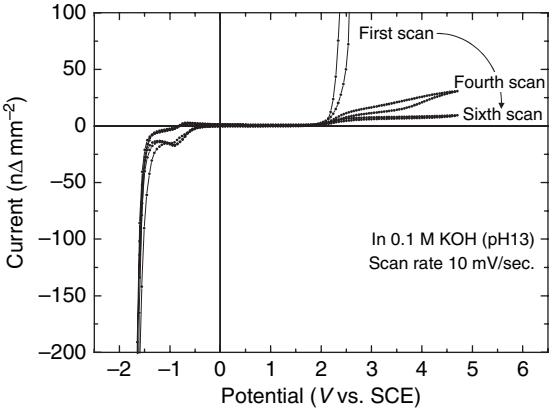

Figure 20 Voltammogram of metallically doped (n-type) GaN electrode during various number of scans as indicated, solution used 1 M KOH (pH 13); scan speed: 10 mV s^{-1} (Courtesy: Denisenko A, University of Ulm with permission.) SCE: standard calomel electrode

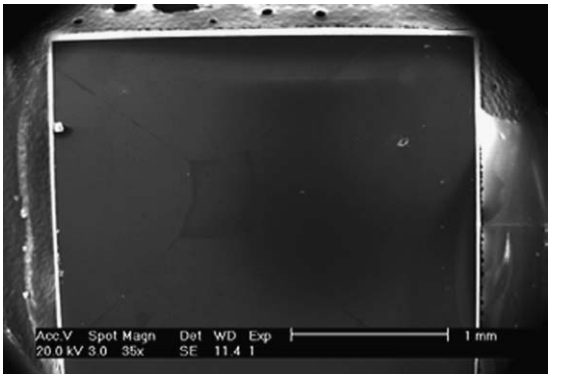

Figure 21 Single-crystal diamond electrode after 28 500 scans as described in the text; SHE, standard hydrogen electrode; SCE, saturated calomel electrode. (Source: Kohn E, Denisenko A, Ive T, Brand O, Dadgar A, Krost A, Haenni W 2005 Liquid junctions to wide bandgap semiconductors. *13th Int. Workshop Physics of Semiconductor Devices (IWPSD-2005)*, New Delhi, India, The Physics of Semiconductor Devices 2005, December 2005, pp. 750–9.)

Here, the oxidation of histamine (a biomolecule), phenol, and sulfate are shown among a large number of substances (Haenni *et al.* 2004, Rao 2000). It may be added that the oxidation of organic molecules goes through several steps and the ones shown here do not represent full oxidation. These oxidation potentials are compared with the potential window for water dissociation, the energetic location of which is dependent on the pH of the solution. A typical potential window of a diamond electrode is also shown. The correlation of the electrochemical potential scales with the physics-based energy levels is added (compare also with **Figure 5**). It can be seen that all the three reactions would not be possible with a Pt electrode.

Further improvement in sensitivity and selectivity can be obtained with microelectrode arrays. Here, the micron size of the active areas leads to a field enhancement and local modification of the Helmholz layer, again leading to an enhanced reaction rate, but also an increased influence of the grain boundary network (Colley *et al.* 2006, Soh *et al.* 2004). Such an electrode array is shown in **Figure 23**, which has been developed by CSEM (Haenni *et al.* 2004).

1.06.4.1.5 Diodes for high-temperature gas sensing

The control of gases in a high-temperature environment is a fundamental requirement for high-temperature reactions like in combustion and jet

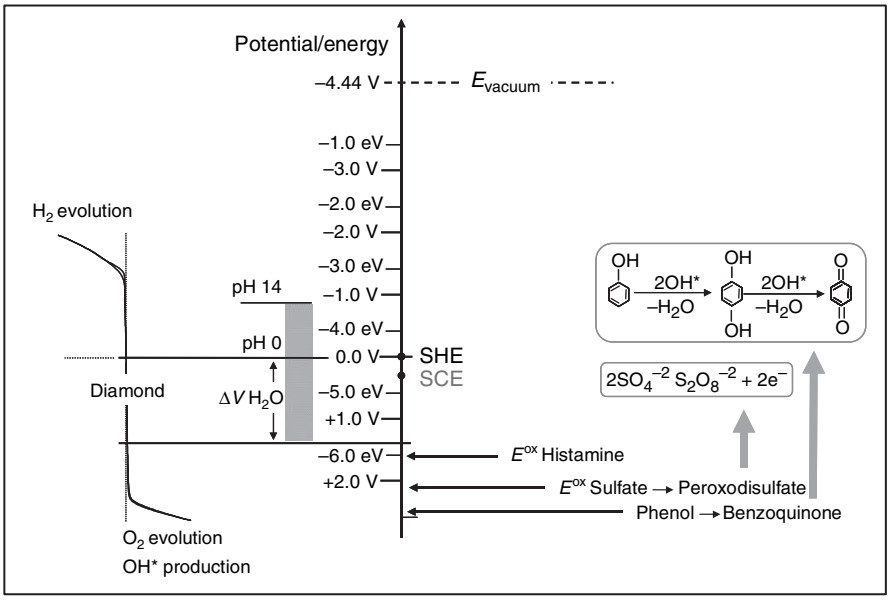

Figure 22 Redox potentials for various reactions in the semiconductor energy scale and potential window of water dissociation depending on pH. Also shown is the voltammamogram of a typical quasi-metallic-doped diamond electrode in 1 M H_2SO_4.

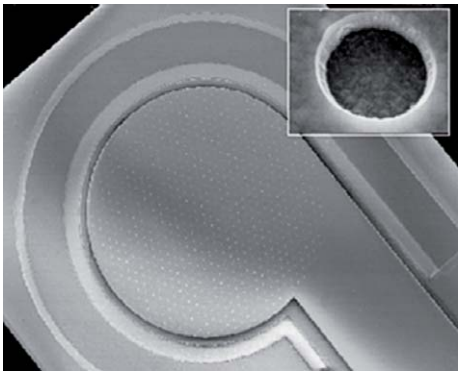

Figure 23 Diamond microelectrode array; pixel diameter 23 μm. (Source: Haenni W, Rychen P, Fryda M, Comninellis C 2004 Industrial applications of diamond electrodes. *Thin Film Diamond II (Semiconductor and Semimetals)*. Elsevier, Chap. 5.)

engines. The identification of polluting exhaust fumes is highly desirable. Gases may be NO_x, NH_3, HCl, CO, CO_2, and volatile hydrocarbons. Typical operation conditions are high temperature, chemically reactive environments, and varying oxygen and hydrogen concentrations.

Semiconductor detectors are typically based on high-temperature stable nanocrystalline metal oxides with wide bandgap like IrO_2, TiO_2, or SnO_2, which can be operated at temperatures in excess of 1000°C. Gases are detected by adsorption at the surface of the nanocrystals, causing changes in the residual electronic conduction across the grain boundaries and at very high-temperature ionic transport through the dielectric. However, single-crystal semiconductors like SiC, GaN, and diamond can also be used in combination with catalytic metals, which dissociate gas molecules into radicals at their surface like Pt, Pd, or Ir. In many cases the diffusion of protons through a thin metal film toward the semiconductor surface at high temperature is also an important contribution. The adsorbed radicals form a dipole layer on the semiconductor surface and modify its surface potential. In the case of a Schottky diode, the change in surface potential is detected by changes in the IV characteristics. In the case of a MOS diode, the change in surface potential is detected as shift in threshold voltage. The MIS diode has two drawbacks: first, the thermal activation of oxide leakage currents should not degrade the quality factor of the MOS diode in the temperature range of application and second, for the capacitive readout an RF circuit is needed. To be able to operate at elevated temperature, the semiconductor bulk and surface have to be highly stable and corrosion resistant. Both SiC and AlGaN/GaN diodes have been used successfully in this configuration. The exposure to oxygen is critical. Both materials form an oxide at the surface at high

temperature and diffusion of oxygen through this surface layer will eventually cause drift. Unlike diamond, they are stable against etching by oxygen exposure. Diamond is therefore limited to a temperature range below 500°C.

1.06.4.1.5.(i) Silicon carbide Dielectric-assisted SiC Schottky diodes have been used at temperature as high as 1000°C with Pt as catalytic Schottky metal (Spetz *et al.* 1997). Reducing gases like H_2, C_xH_y, and NH_3 are dissociated into radicals and the adsorption of protons used for detection. The sensitivity to non-hydrogen containing oxidizing molecules like NO_x or CO_2 has been linked to the porosity of the Pt Schottky metal layer and reactions of dissociated molecules with residual H radicals. High sensitivities have been obtained, when the catalytic metal is in contact with a thin interfacial layer of SiO_2 (Spetz *et al.* 2001), WO_3 (Kandaswamy *et al.* 2005), Ga_2O_3 (Trinchi and Wlodarski 2004), or mixed oxide $TaSi_xO_y$ (Tobias *et al.* 2000), indicating that the adsorption/desorption site at the interface is surface oxygen related. SiC Schottky diodes contain therefore a thin (approximately 1 nm) SiO_2 interfacial layer and may be considered a dielectric-assisted Schottky contact (MIS SiC-Schottky diode (Uneus *et al.* 1999). **Figure 24** shows a basic design and the shift in barrier potential (with Pt as a catalytic metal) by exposure to O_2 and H_2. The response time is in the millisecond range. The devices have been realized on bulk SiC crystals mainly in the 6 H polytype.

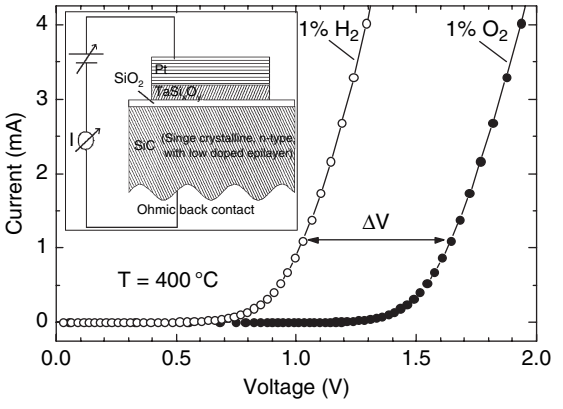

Figure 24 SiC gas sensor diode with catalytic layers as indicated in the figure with shift of threshold voltage as function of hydrogen and oxygen content. (Source: Tobias P, Rask P, Göras I, Lundström A, Solomonsson P, Spetz A L 2000 Platinum-insulator-silicon carbide structures as small and fast sensors for exhaust gases. *Proc. Sensoren und Messysteme 2000*, VDI Berichte 1530, pp. 179–87 with permission.)

Again, in the MOS diode sensor, the gases are dissociated by a catalytic metal, protons diffuse through the metal and form a dipole layer at the SiO_2 interface. This changes the field distribution across the dielectric and leads to a flatband voltage shift. In the case of gases, which do not contain hydrogen like CO and NO_x, the formation of the dipole layer is difficult, as diffusion of other radicals than protons through the catalytic metal is suppressed. Either detection is indirect by reaction with residual hydrogen, or the metal has to be porous. At triple points, where the gas phase, the insulator, and the catalytic metal meet within the diffusion length of the split molecules, radicals can be adsorbed on the insulator surface. Such points are used in the dissociation of NH_3 followed by proton adsorption. To retard diffusion of oxygen through the dielectric, with related continued SiC oxidation, the oxide layer had been modified to a $SiO_2/Si_3N_4/SiO_2$ layer stack (Spetz *et al.* 2001). The capacitance is read out under weak depletion conditions (near flatband) to avoid complications with the deep depletion/inversion behavior, depending on thermal minority carrier generation at high temperature. The device has been operated as MISiCFET (SiC metal oxide semiconductor field effect transistors (MOSFETs)) (**Figure 27**) at 800°C (Spetz *et al.* 2001).

1.06.4.1.5.(ii) Gallium nitride The same detection principles as discussed above have also been applied to GaN Schottky diodes covered with Pt and Pd. Here also a shift in barrier potential has been observed depending on the exposure to H_2, HC1, CO, and NO_x. A maximum response to H_2 has been observed between 450°C and 500°C with a shift in barrier potential from 1.15 eV by approximately 0.5 eV (Schalwig *et al.* 2001). Overall, the results indicate that gas detection in these diodes follows essentially the same fundamental principles as in the case of the corresponding SiC devices. The response is mostly nonlinear and saturates at high concentrations. This can be explained by the balance between reactivity and diffusion-limited processes and a kinetic phase transition of the adsorbate layer similar to the Pt/SiC case (Kim *et al.* 2003).

In a recent experiment, an epitaxial GaN resistor has been used for H sensing (Yun *et al.* 2005). Here the change in surface potential of the free surface and thus the change in channel resistance due to changes in surface depletion have been employed. However, the active surface states have not yet been identified.

It should be noted that the stable surface condition of Ga face GaN will be an oxygen-terminated surface. However, Ga_2O_3 will become instable in reducing the atmosphere above 700°C (Fleischner and Meixner 1992). In the atmosphere, GaN will decompose at approximately 650°C (Pisch *et al.* 1998).

A higher stability is therefore expected for an AlGaN Schottky contact, still grown on GaN. Such Pt–AlGaN/GaN diodes have indeed been operated up to 800°C in H_2/N_2 atmospheres (Song *et al.* 2005). A cross section is shown in **Figure 25**. The barrier potential increased monotonically (reaching 120 meV at 800°C). The temperature limit is thought to be reached by alloy formation between the Pt Schottky metal and AlGaN semiconductor, rendering the junction ohmic.

1.06.4.1.5.(iii) Diamond On polycrystalline diamond structures for CO gas sensing have been realized, where SnO_2 is the catalytic layer deposited onto a (nominally) undoped diamond layer on a highly P-doped substrate (Gurbuz *et al.* 1998). Thus, the IV characteristic is that of a glossy heterojunction diode (**Figure 26**). The oxygen detection mechanism has been found to be due to the modification of the oxygen vacancy density in the SnO_2 film generated by the dissociation of the oxygen-containing gas. These oxygen vacancies act as donors, donating electrons to the conduction band. This leads to a potential redistribution across the SiO_2/i-diamond junction and modification of its IV characteristics. An activation energy of vacancy generation of 1.1 kcal mol^{-1} has been found and a stable response increasing with temperature. The applied temperature range was up to 300°C, which means well below the oxygen temperature stability limit of diamond.

Using Pd instead of SnO_2, the structure has recently also been tested for the detection of benzene (C_2H_4) and toluene (C_6H_8) proposed for use in the soil as an indicator for oil contamination (Gurbuz *et al.* 2004).

1.06.4.1.6 Field effect transistors

The technology and harsh operating conditions of the ceramic-like wide bandgap semiconductors is rarely compatible with Si-CMOS technologies despite the fact that Si is the substrate in most cases. In sensing, transistor structures may directly amplify or convert signals without interconnect and matching losses, thus they are realized in the sensor material itself. Most commonly considered are FETs, as here unipolar charge transport is modulated and injection phenomena, which are in competition with deep level activation, are not dominating. Such FET structures have emerged in three areas:

gas sensing at high temperature
chemical sensing in liquids
in electromechanical sensing as extension of the piezo-resistor

1.06.4.1.6.(i) SiC MOSFETs SiC MOSFETs (MISiCFETs) have been developed primarily for high-temperature gas sensing. They are based on the MOS sensors as discussed in the previous section and the catalytic diode structures are implemented into the MOS gate. Usually Si-based MOSFETs are operated with inversion channels. In SiC-based devices, the channel is in general created by doping and has thus been buried to avoid complications with surface states and minority carrier generation at high temperature (up to 1000°C) (Spetz *et al.* 2001). Thus, the device can operate in the depletion/accumulation mode, depending on the channel doping level. The channel may be prebiased by a backgate to adjust for a high sensitivity bias point near pinch-off or may be used for drift compensation (Gurbuz *et al.* 1998) (**Figure 27**).

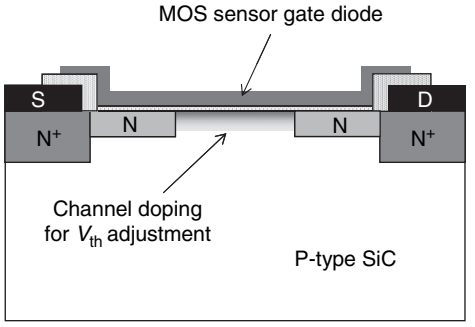

Figure 27 Schematic view of SiC metal oxide semiconductor field effect transistor (MOSFET) for high-temperature gas sensing.

1.06.4.1.6.(ii) AlGaN/GaN HEMTs Because the hexagonal GaN-based materials system is highly polar, the advantage of GaN-based HEMTs is seen in the highly efficient modulation of the channel polarization charges and the FETs may be labeled piezo-HEMTs. The piezoresistive effect has several contributions as discussed in Section 1.06.4.1.1. The example mostly employed is the AlGaN/GaN heterostructure, where an interfacial 2DEG channel of high density (with a sheet charge density in the order of 10^{13} cm^{-2}) is formed entirely by the polarization discontinuity between the AlGaN barrier layer and GaN substrate. This interfacial 2DEG is used in the FET (which is a HEMT structure) as channel. Here, the AlGaN barrier layer is strained on GaN and the polarization discontinuity is determined by the piezopolarization induced by the stress and the difference in spontaneous polarization between the two materials. The various contributions to the polarization charges are given in **Figure 11**. A general cross section of the AlGaN/GaN piezo-HEMT is shown in **Figure 28**, and a band structure diagram in **Figure 29**. The 2DEG channel is generated at the AlGaN/GaN interface by the polarization fields with

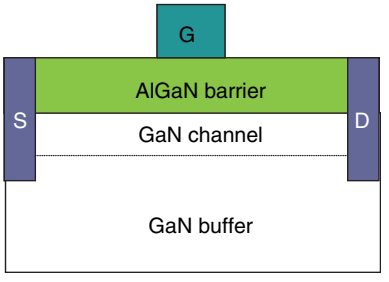

Figure 28 Cross section of AlGaN/GaN piezo-HEMT (high electron mobility transistor).

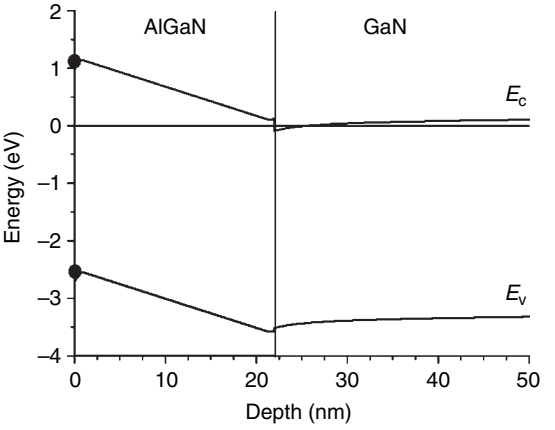

Figure 29 Associated bandstructure of the heterojunction of **Figure 28**; AlGaN with 30% Al content.

a countercharge at the surface (mostly in surface states often called surface donors) (Ibbetson *et al.* 2000).

Therefore, this structure is sensitive to stress as well as to changes in the charge state of the surface due to the absorption of polar molecules. Thus, they have been used in all three applications: as high-temperature gas sensors employing the heterostructure diode as discussed in Section 1.06.4.1.4; as ChemFET in biochemical applications based on the electrode characteristics as discussed in Section 1.06.4.1.3; and as a membrane pressure sensor and as a force sensor on a cantilever as a bias-controlled piezoresistor.

As with HEMT gas sensors, they are based on the gate electrode with catalytic metal coverage. The signal is then capacitively coupled to the 2DEG channel of the FET. The operation with Pt gate has been demonstrated up to 300°C for H_2, C_2H_4, and CO detection with high sensitivity, but also a low level of saturation (Schalwig *et al.* 2001).

For biochemical applications, the ChemFET structures have usually been realized on sapphire as the thermal properties of SiC are not important. In this case, the surface of the AlGaN barrier layer is the electrochemical electrode, capacitively coupled to the channel. The surface in contact with the solution is in general an Al, Ga oxide or Al, Ga oxynitride, naturally formed by the contact with the water-based solution with an associated redox potential most likely generated by hydroxyl active sites (Steinhoff *et al.* 2003). The stability of this oxide surface will determine the stability of the ChemFET, especially under high anodic overpotentials. The stability of a strongly

oxygen terminated GaN electrode surface is shown in **Figure 20** and reflects in essence the characteristics of an AlGaN surface with 30% Al content. Thus, the area of safe operation is limited by the onset of anodic current transfer at approximately +2.5 V (against SHE). This potential appears in the FET operation between gate and drain and limits the region of safe operation in the output characteristics. This is illustrated in **Figure 30** for operation of the ChemFET in dilute HC1 with pH 3.8. However, it should be noted that the gate bias range covered by a solution of pH 1 and 13 is only approximately 1 V. Therefore, for high sensitivity, enhancement mode devices with short gatelength operating in a small gate and drain bias window are needed, which are however difficult to realize. Nevertheless, such AIGaN/GaN HEMT structures have been used in biochemical investigations (Steinhoff *et al.* 2005). Studies on reliability and degradation are not available yet.

With respect to AlGaN/GaN piezo-HEMTs they have initially been realized on sapphire and tested with the substrate still attached (Kang *et al.* 2003). Therefore, the response had been moderate. Fabricated on Si substrates as discussed in Section 1.06.4.1.1, FETs could be realized on membranes and cantilevers (Kang *et al.* 2004). On GaN, cantilevers have been investigated as bias-controlled piezoresistors (Zimmermann *et al.* 2006). Approximately half of the channel current could be modulated, when bending the 120-μm-long cantilever 30 μm upwards. The beam had been approximately 2.3 μm thick and contained one stress relief layer and a 20-nm-thick strained AlGaN HEMT barrier layer. The YM of cantilever extracted from mechanical bending measurements was 190 GPa. This may be compared with a value of 250, obtained by nanoindentation (Jian *et al.* 2003). The highest relative change in output current of 50% has been obtained for operation with a gate voltage ($V_{gs} = -3.0$ V) near pinch-off (**Figure 31**). However, the experiment did not allow to separate the individual contributions of the overall piezoresponse and the thermal stability of the device. The operation of AlGaN/GaN polarization-based HEMTs up to 750°C (Daumiller *et al.* 1999) may however indicate that operation at high temperature is possible without loosing the piezopolarization.

1.06.4.1.6.(iii) Diamond FETS Diamond FET technologies are still rather immature and just emerging. Two fields of application drive this development. First, these are high-power, high-temperature electronics and second, electrochemistry and biochemistry. FETs have been realized based on two channel concepts. As a first concept, electrolyte–solution–gate FETs have been realized using the hydrogen-terminated surface, which induces a near-surface 2DHG (Kawarada *et al.* 2001). This structure does not contain extrinsic channel doping. The surface chemistry

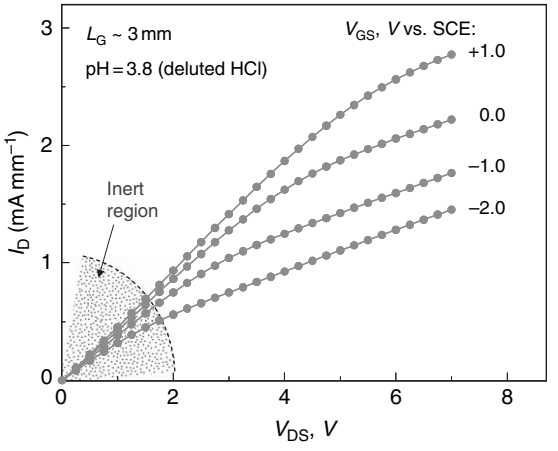

Figure 30 GaN-based high electron mobility transistor (HEMT) with AlGaN electrode and area of safe operation as described in the text. SCE: saturated calomel electrode

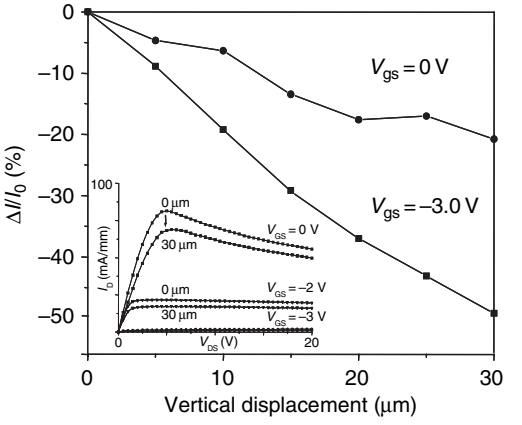

Figure 31 Response of AlGaN/GaN piezo-HEMT (high electron mobility transistor) for two different gate potentials. The structure is similar to the one shown in **Figure 18**. (Source: Zimmermann T, Neuburger M, Benkart P, Hernandez-Guillen F J, Pietzka C, Kunze M, Daumiller I, Dadgar A, Krost A, Kohn E 2006 Piezoelectric GaN sensor structures. *IEEE Electron Devices Lett.* **27**, 309–12.)

leading to this configuration is still in debate, but commonly transfer doping from surface adsorbates to form the 2DHG is made responsible (Strobel *et al.* 2004). Thus, this surface should be extremely sensitive to liquid environments. However, the hydrogen-terminated surface is chemically not active, active sites have to be added, for example, by oxidized spots or electrochemically active defects. Second, the hydrogen termination is not stable at anodic potentials (Kondo *et al.* 2005). Therefore, the response of such FETs in the liquid environment is in general only conditional stable or may even be subject to degradation (Müller *et al.* 2003).

In a second approach, the channel is created by a thin boron doping spike with a peak concentration high enough for full activation. Because the sheet charge that can fully be modulated by the gate without breakdown, is limited, the thickness of the spike needs to be in the nanometer range, which is difficult to realize. This configuration has been called delta doping (Kunze *et al.* 1999). However, in this case, the surface can be oxygen terminated in the same way as used for electrochemical electrodes. It is, therefore, an extremely reliable system, which can operate in the entire range of pH and under high overpotentials. A first result is shown with **Figure 32**, also indicating the measurement arrangement, where the shift in transfer characteristic is shown between pH 1 (1 M H_2SO_4) and pH 13 (1 M KOH). The experiment has been repeated several times and slight changes are observed, which had been associated with degradation of the passivation surrounding the active gate electrode area (Denisenko *et al.* 2006).

1.06.4.2 Actuator Elements

Many microsystems contain moving parts, which have to be actuated. Concerning a basic cantilever, the actuation dynamics is basically reflected in the mechanical resonance frequency of the beam as seen from eqn [1], where E is the YM, ρ is the density of the material, t is the thickness of the cantilever beam, and l is the cantilever length.

$$f_{\text{res}} \cong 0.16\sqrt{\frac{E}{\rho}}\frac{t}{l^2} \qquad [1]$$

Two groups of parameters influence the dynamics: the materials properties with the ratio of E/ρ and the geometry with the ratio t/l^2. For fast response thick short cantilevers are desired, pointing toward an activation mechanism, which can generate high forces. Because the materials discussed here possess a high YM, again a high actuation force is required. Common actuation principles are the electrostatic, piezoelectric, and the electrothermal actuation.

On the other hand, devices may be operated in aggressive liquids and a different type of actuator is needed. The best-known device in this respect is

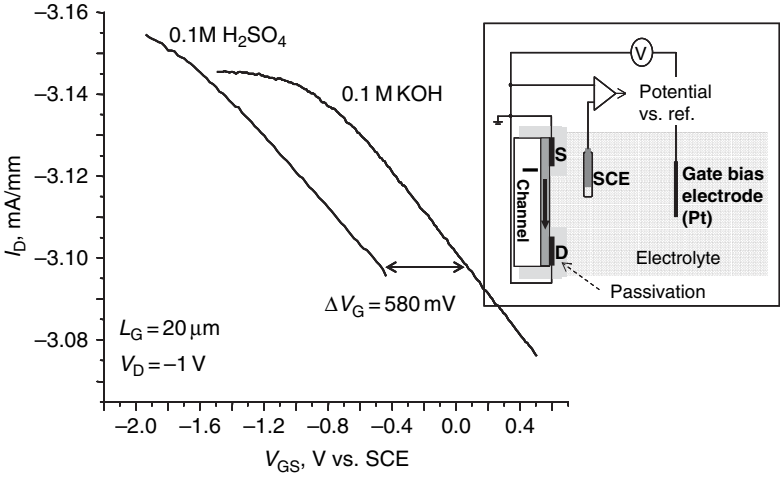

Figure 32 Diamond ion-sensitive field effect transistor (ISFET) transfer characteristics for two different solutions with pH 1 and 13 and measurement arrangement. The structure was realized with boron-doped delta channel and oxygen-terminated surface. (Source: Denisenko A, Jamornmarn G, El-Hajj H, Kohn E 2006. pH Sensor on O-terminated diamond using boron doped channel. *Diamond 2006*, Estoril, Portugal, Abstract 16.5, September 3–8, 2006; private communication, with permission.) SCE: saturated calomel electrode.

probably the ink-jet and the actuator either a piezo-element or a microheater. Microheaters are discussed first.

1.06.4.2.1 Microheaters

Microheaters have been commonly realized with high melting materials like graphite or BN and HfB_2 films (Solzbacher *et al.* 2000) and used in a temperature range of up to and above 1000°C. At this high temperature, oxidation and corrosion are critical and only doped oxides like SnO_2:Sb can withstand these conditions reliably (Spannhake *et al.* 2006). Substrates are often alumina or SiC ceramics. N-type-doped single-crystal epitaxial SiC itself has been used up to 1000°C in air, although it is not totally oxidation resistant, and above 1200°C in an inert and reducing atmosphere (Mlcak *et al.* 2004). Thus, SiC allows use of doped layers as heaters and to realize the entire stack, which is thermally stressed, in monolithic form. SiC is therefore the mostly used material for heater platforms.

Diamond can also substitute all elements needed in a microheater structure (Yang and Aslam 1996). Although attacked by oxygen above approximately 750°C, heaters are still extremely durable during heat cycling even without external passivation. This is shown in **Figure 33**. Here a heater element of 1 mm^2 surface area is covered with a thin water film and operated in the open mode of an ink-jet without cavity (Kaiser *et al.* 2002). The graph illustrates water ejection from the heater surface with a pulse repetition rate of 2 kHz and a pulse power density of approximately 1 MW cm^{-2}. When the power is applied, the surface is heated up to the spinodalian temperature (of 324°C for water), igniting spontaneously the phase transition. A thin vapor layer develops across the heater, ejecting a bubble from the water film, thermally isolating the heater surface immediately. Thus, the heater temperature will be essentially higher than the spinodalian temperature. When the vapor layer collapses, high mechanical cavitation forces act on the heater surface. Obviously, it is advantageous, to employ a monolithic system with intrinsically balanced thermal stresses. Additionally, in the case of diamond, the grain size of the film can be used to tailor the thermal properties. When grown with low grain size like in the case of UNCD, the film will act as a thermal barrier toward the substrate. When outgrown with larger grain size (or in a 2D-NCD configuration), the heater itself and its connection to the metallic contacts will be an efficient heat spreader.

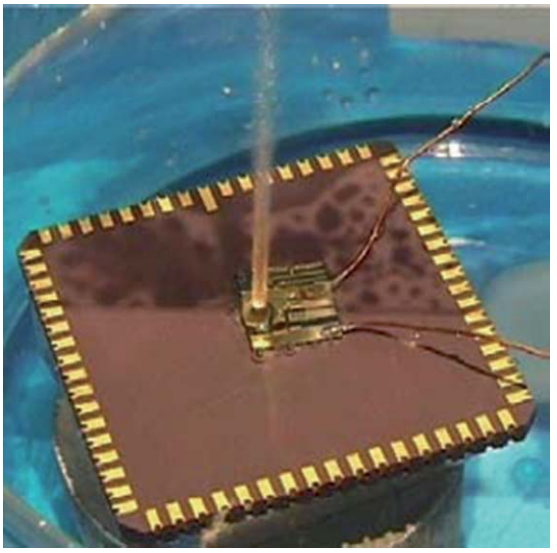

Figure 33 Diamond heater with 1-mm^2 surface area in water driven by a 10 μs pulse train of 200 V at 50 Ω and with 2 kHz repetition rate, resulting in microfountain action. Height of the water column is approximately 20 cm.

1.06.4.2.2 Electrostatic actuator

In the electrostatic case, the two opposite plates of an air gap capacitor are attracted by an applied field, the limit being the breakdown field either across the air gap or the anchor isolation. For a constant driving voltage, the force is a hyperbolical function with displacement, whereby the displacement changes along the beam. If the cantilever is curved, as it is often the case for a vertically gradually stressed films, additional to the deflecting force a bending moment M_z needs to be taken into account (Schmid 2006). Because the beam is increasingly accelerated toward the counterplate, this results in small forces in the beginning, and in snapping, when the separation becomes small. Therefore, it is difficult to hold the beam in an intermediate position. Thus, this driving principle is predestined for switching across small gaps but not the adjustment of a displacement. An overview for the material selection of electrostatic actuators can be found in (Srikar and Spearing 2003).

Figure 34 shows the switching speed for an identical geometry of a cantilever fabricated of diamond, AlN, SiC, and Si, respectively. It can be seen that the stiffer material needs a higher voltage for the displacement to close the switch. However, applying high driving voltages (approximately five times the threshold voltage) all cantilevers can be driven with comparable speed. Therefore, the high YM is only a minor disadvantage, when high driving forces can be

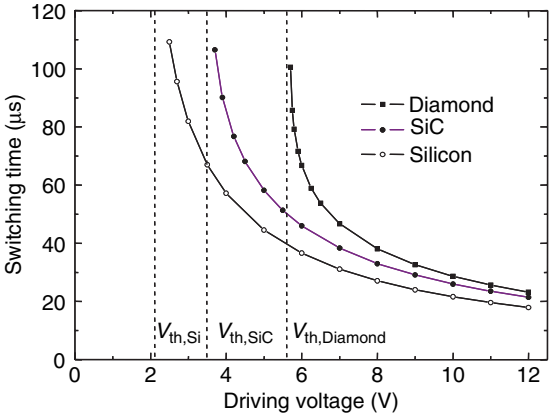

Figure 34 Switching time versus switching voltage of single-ended cantilevers of identical geometry for Si, SiC, and diamond.

generated. However, this means also high driving voltages. It holds especially for curved beams, with high tip displacement. High driving voltages may interfere with the signal voltage. This is especially true when operated at high temperature, where the isolation of the anchor is reduced due to temperature-activated leakage. Otherwise, this actuation principle is not temperature sensitive. The switch stays closed as long as the voltage is applied, however, no DC loss occurs.

1.06.4.2.3 Piezoactuator

In the case of piezoactivation, the driving force is the induced strain in a piezoelectric crystal due to an external electrical field. In a certain range, the interaction between the vector of the electrical field $\mathbf{E}_{el}$ and the vector of induced strain $\mathbf{S}$ can be described by a linear relationship and a matrix of piezoelectric coefficients.

Perovskites like $BaTiO_3$, $KNbO_3$, $KTaO_3$, $SrTiO_3$, and $PbTiO_3$ are typical piezoelectrics with large piezoelectric coefficients. They are deposited by techniques like MOCVD (Zhao *et al.* 2004), sol–gel spin-on (Zeng *et al.* 1999), pulsed laser deposition (Wan *et al.* 2002), or ECR-PECVD (Chung *et al.* 2000). After deposition, they generally need to be poled by an annealing step under bias, where the individual dipoles are oriented. They are then operated in a regime of temperature and field, where this orientation is maintained. A commonly used compound of $SrTiO_3$, and $PbTiO_3$ is PZT (lead zirconate titanate) (which can however have various composition ratios). It can show high piezoelectricity up to a Curie temperature of approximately 450°C and a linear elastic regime up to approximately $10\,kV\,cm^{-1}$, where depolarization effects become apparent (Klaasse *et al.* 2004). Thus, the range of application is rather limited. Nevertheless, high driving forces can be developed.

A material with high polarization and high-temperature stability is wurzite AlN. It is deposited with a preferred orientation of the polarization, which is usually perpendicular of the surface (*c*-axis). To avoid random orientation in sputtering processes, orientation is obtained by the self-bias developed during deposition or an external DC bias and bombardment of Ar ions, providing the energy for the surface ion reorientation (Elmazria *et al.* 2004, Olivares *et al.* 2005).

For use in MEMS structures, these materials are deposited as thin films and for narrow thin-film cantilevers two common modes are exploited, namely the d_{31} mode and d_{33} mode (see, for example, APC 2002) (**Figure 35**).

In a thin-film arrangement, the d_{31} mode is used with vertical polarization (*z*-direction in **Figure 35**), and the dipoles of the ferroelectric have to be poled

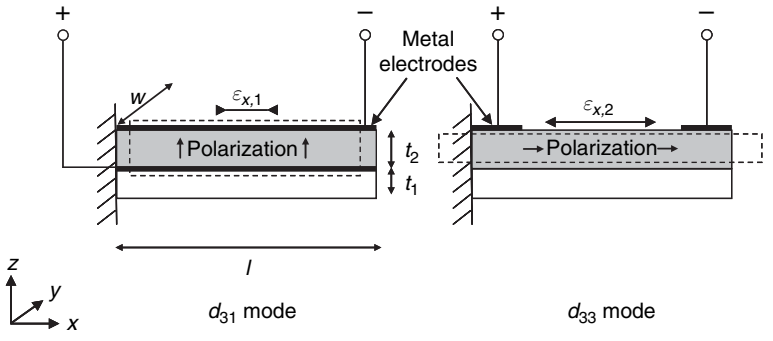

Figure 35 Schematics of common modes used in piezoelectric unimorph cantilever actuators.

Table 5 Materials parameters of piezoelectrics

	d_{31} (pm V^{-1})	d_{33} (pm V^{-1})	Curie temperature (°C)	Depolarization field (V cm^{-1})
PZT	−180	360	~350	2×10^4
AlN	−2	4	>1000	5×10^6
$BaTiO_3$	−78	190	118	3×10^4
$LiNbO_3$	−0.85	6	1150	–

in this direction. In this mode, the metal electrodes are arranged on top and bottom of the film, and the mechanical response perpendicular to the electrical field acts with $\varepsilon_{x,1}$ in direction of the cantilever beam length (**Table 5**).

The approach has recently also been applied to PZT/diamond unimorph. The cantilever used had been a 40-μm-long UNCD beam of 1.0-μm thickness with a top PZT layer of 0.1-μm thickness deposited by MOCVD (Srinivasan *et al.* 2006). A tip deflection of approximately 2 μm for a driving voltage of 5 V was demonstrated. With its high piezocoefficients, the PZT/diamond pair will generate high contact forces and high resonance frequencies, it will however only operate in a limited temperature range. The other alternative would be AlN/diamond with smaller piezocoefficients of AlN, but with the ability to operate at high temperature. **Figure 36** shows a calculation of the contact force, which can be generated with an AlN/diamond cantilever of different length operating in the d_{31} mode. In this calculation, a deflection of 2 μm has been assumed. The maximum field applied to AlN was 1 MV cm^{-1}, which is approximately two orders of magnitude higher than possible for the case of PZT. To achieve the full potential, high voltages need to be applied or a multiplayer stack with intermediate contact plains would be needed. The graph illustrates that high contact forces can be obtained, but also that the structural design is critical.

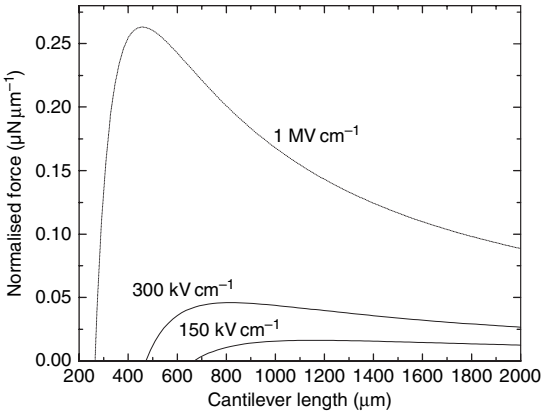

Figure 36 Simulated contact force (normalized on the cantilever width) of an AlN/diamond unimorph actuator in the d_{31} mode as a function of cantilever length (layer thicknesses: $t_{AlN} = 3.2$ μm, $t_{dia} = 2.0$ μm). The cantilever had a separation of 2 μm with the substrate. There is no contact force before the cantilever touches the substrate.

The second possibility is the exploitation of the d_{33} mode. Here, the piezoelectric film needs to be poled horizontally and thus parallel to the surface. For single-crystal wurzite AlN films this means that they need to be grown laterally in M face direction, which is difficult to obtain. In the d_{33} mode, case contacts are deposited at the ends of the structure and an electrical field applied in x-direction (**Figure 36**). Usually the arrangement is an interdigitated finger structure and large forces can also be obtained for long beams with low driving voltages. With d_{33} being normally larger than d_{31}, larger deflections can be obtained. Taking the case of diamond, which possess the highest YM, a PZT film on a diamond cantilever poled for d_{33} mode can expand by more than 500 ppm and can generate compressive stresses of more than 350 MPa (for a YM of PZT of 70 GPa). This value is larger than the stress, which can be generated by the electrostatic actuation and is in the same order of stresses, which can be generated by thermoelectric actuation (bimetal effect, see below). The static power consumption is determined by the electrical loss of the piezoelectric and can be extremely low for highly insulating films.

1.06.4.2.4 Bimetal actuator

The thermoelectric actuation is based on the thermally induced strain in a material in its elastic regime. As bimetal actuator, consisting of a two-layer stack it makes use of the thermally induced strain differences between the two layers. The vertical stress $\sigma_x(z)$ developed across bimetal pair is

$$\sigma_x(z) = E_i(\varepsilon_x - \alpha_i \Delta T) \qquad [2]$$

where α_i is the difference in the coefficient of thermal expansion of the two layers and ε_x is the strain induced by a nonthermal intrinsic stress and external loads.

Both SiC and diamond possess low coefficients of thermal expension, show no plastic range before fracture, and are elastic over a wide range in temperature. They are therefore ideal in combination with metals of high coefficient of thermal expansion (**Table 4**). With high temperatures, high bending moments can be generated, the limit imposed by the interfacial adhesion of the films and high-temperature softening of the metal. Thus, such metals are usually hard metals like Ni and Cu.

High bending moments can be obtained using a materials combination with a high YM for the beam structure and large coefficient of thermal expansion for the bimetal. A proper figure-of-merit is the product $E_{\text{beam}} \times \sigma_{\text{bimetal}}$ (**Table 2**). Diamond possesses the highest figure of merit and **Figure 37** shows the tip deflection achieved by a bimetal pair of nickel/diamond. The actuation is largely linear and no snap-in effect is expected. Such cantilevers can therefore also be used for a defined tip placement.

This quasi-static relationship is obtained after the heat flow is balanced. Thus, fast switching requires a fast heat flow, which on the other hand means a high heating power level for standby. To circumvent this problem, bistable or monostable bridge configurations are needed. They require tight geometrical control and stress engineering of the films. A diamond-based bistable bridge actuator is discussed in Section 1.06.6.2.

1.06.5 Technologies

Microsystems technologies are very heterogeneous, depending on the application. Nevertheless, most technologies are aimed to be compatible with CMOS technologies. If the sensor technology is not CMOS compatible, discrete device structures are hybrid integrated with a systems carrier. The materials discussed here, are aimed at applications in extreme conditions, beyond the capability of Si. Therefore, the development is still largely on the basis of discrete devices. Elements are bulk machining for membrane structures, surface machining for 3D structures including a sacrificial layer technology. These will be discussed in the following sections.

1.06.5.1 Bulk Machining

Bulk machining describes processing technologies based on substrate etching. It had originally been developed for the etching of Si for membrane fabrication and the preparation of molds.

Hexagonal SiC single-crystal wafers (4H and 6H) are available and can be used as substrate for all-SiC MEMS. The SiC substrate can be dry etched using a high-density fluorine-based plasma by DRIE or inductively coupled plasma-reactive ion etching (ICP-RIE) (Beheim and Evans 2006), mostly containing digital etch/passivation cycling (Bosch process, Lämmer and Schlip). Such a process has been used to obtain freestanding SiC cantilevers (Hossain *et al.* 2006).

Single-crystal diamond is not available in wafer size and polycrystalline diamond wafers, which are several hundreds of micrometers thick and polished, are mainly used as quasi-substrates for optical windows or heat sinks (Wild 1998, Wörner 1998). They are also etched in oxygen containing plasma of high etch rate by ICP-RIE.

The majority of MEMS processes in SiC and diamond therefore make use of an Si substrate. Thus, to a large extent the Si bulk machining processes have been copied onto the case considered here, where the ceramic-like semiconductor is the membrane material or the active pattern realized by the mold. The Si dry etching follows the normal routine used in Si-MEMS and is either by wet etching in hot KOH or dry in a high-density plasma.

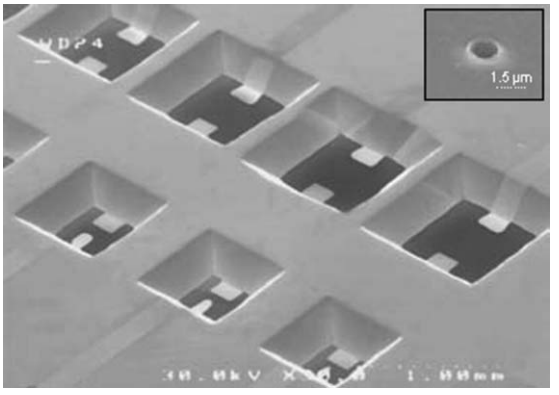

Figure 38 Planar cell patch clamp array with nanocrystalline diamond (NCD) membrane and Pt electrodes on front and rear side (the diamond film is transparent to the e-beam exposure). In the inset, the clamp hole located in the center of each compartment is shown. (Source: Kusterer J, Alekov A, Pasquarelli A, Müller R, Ebert W, Lehmann-Horn F, Kohn E 2005 A diamond-on-Si patch-clamp-system. *Diamond Relat. Mater.* **14**, 2139–42, with permission.)

Vertical sidewalls of high aspect ratio are again obtained by DRIE. Wet etching by KOH results in (111)-oriented slopes.

Figure 38 illustrates an example of a Si bulk machining process for diamond membrane fabrication, showing an array for a planar patch clamp system (Kusterer *et al.* 2005). In the SEM micrograph, the diamond compartments with the membrane are transparent to the e-beam exposure. In the center of the membrane, a clamp hole of approximately 1-µm diameter has been etched. In this application, the compartments are filled with liquid and sloped walls as obtained by Si wet etching in hot KOH are advantageous. The top and bottom Pt electrode metallizations are clearly visible.

1.06.5.2 Surface Machining

Surface machining is the extension of the microelectronics technology into the third dimension to obtain freestanding beams for cantilevers, bridges, hinges, and gears and for enclosed structures like capillaries and cavities.

The desired relief structure may be obtained by metal plating of a prestructured pattern, undercut etching, or conformal deposition onto a prefabricated pattern with subsequent etching of the sacrificial support material (molding). The sacrificial layer technology is especially a key aspect in the fabrication of closed structures like capillaries and cavities. Sacrificial layer materials used are SiO_2, metals and polyimides deposited by evaporation, plating, plasma CVD, or spin-on. Top layers are usually poly-Si, poly-SiC, and metals like Ni. The sacrificial layer is etched selectively, generally by a liquid solution, with respect to the deposited film. Such a technology has been developed for SiC and diamond structures, however, not as yet for GaN- and AlN-based devices.

In the case of SiC, such patterns are usually not grown by selective epitaxy or back etching, but by overgrowth of the relief structure of a sacrificial SiO_2, SiN_4, or poly-Si layer (Cheng *et al.* 2002). This step is then followed by polishing the surface until the isolated SiC pattern is left. Finally, the mold is etched completely to obtain freestanding structures, or the SiC structure processed further (Mehregany and Zorman 1999). After conformal overgrowth of the mold by the SiC film, its surface is in general not planar and strongly textured and needs to be polished (using diamond powders). In full MEMS processes like the MUSiC foundry process originating from Case Western Reserve University (CWRU, Ohio) (Trade mark, used by FLX Micro, Ohio) the realization of a SiC mold can be realized three times for the stacking of three layers in total.

With respect to diamond, molding has been used to realize field emitter arrays (Davidson *et al.* 2003), microchannels (Ralchenko and Givargizo 2003), and AFM tips (Beuret *et al.* 2000, Kulisch *et al.* 1997). In all cases, the molding material was Si. A flow chart for the realization of a micro emitter array and individual field emitter elements are shown in **Figure 39(a)** and **39(b)**. As can be seen, tip ends can be very sharp depending on the Si mold preparation.

In diamond, back polishing is difficult because of its hardness. Instead, selective growth and dry etching (in an oxygen plasma) have been used extensively (Auciello *et al.* 2004, Kohn *et al.* 1999, Rangsten *et al.* 1999, Yang *et al.* 1999). This is illustrated in **Figure 40**, where the process flow for an electrostatically driven cantilever switch is shown (Adamschik *et al.* 2000).

The main sacrificial layer material is SiO_2. However, it is difficult to deposit with a thickness of several micrometers without stress and cracking. Here, plated metal structures are an alternative. Such a process with plated Cu as sacrificial layer material has been developed for diamond (Müller *et al.* 2004). The process is sketched in **Figure 41** for the case of the fabrication of an all-diamond capillary, where the liquid will only be in contact with a diamond surface.

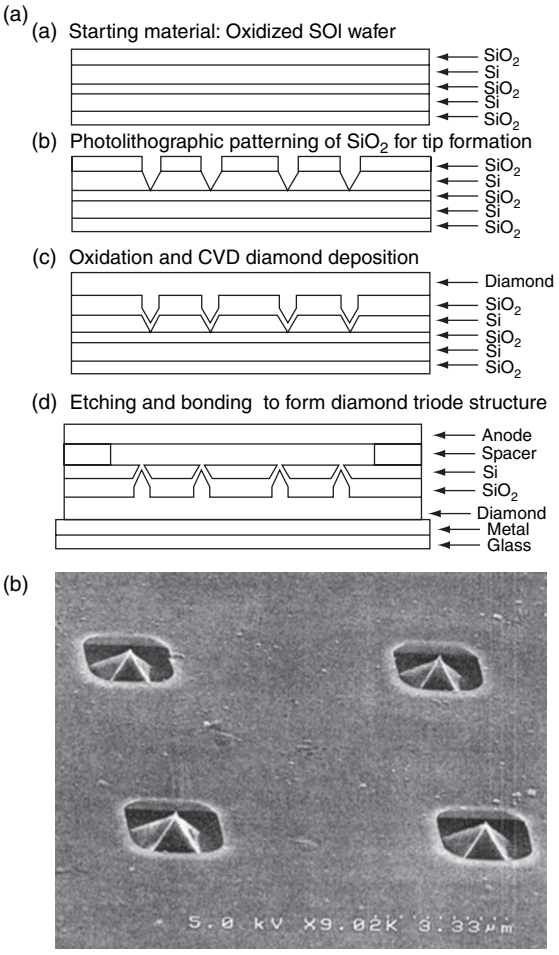

Figure 39 (a) Flow chart of the fabrication routine of a diamond field emitter array. (Source: Davidson D, Kang W P, Wisitsora At 2003 Diamond field emission devices. *Diamond Relat. Mater.* **12**, 429–33 with permission.) (b) Individual field emitter elements realized by the process as sketched in (a).

It was designed for applications in aggressive media like the all-diamond ink-jet, which is discussed below.

1.06.5.3 Surface Processing

During processing, surfaces have been in contact with many materials like metals, hard dielectrics, and polymers. They have to withstand high temperatures, aggressive liquids, and thermal stresses. Although being inert, they need to provide high chemical activity in the liquid and good adhesion and controlled interdiffusion in contact with solid films.

1.06.5.3.1 Ohmic contacts

Contact metallization schemes have been developed mainly in connection with electronic and optoelectronic device structures, and there exists extensive literature on this field. They are in general based on silicide-, nitride-, or carbide-forming conducting alloys with refractory metals like Ti, Ni, or W. They are therefore alloyed at high temperature, even when tunneling is provided by high doping. Nevertheless, although annealed at high temperature, in most cases, the devices are not operated at high temperature. Thus, the reliability of each contact system is still critical. In general, for devices operating in aggressive media contacts are passivated or hermetically encapsulated.

SiC, Ti, Ni, Cr, Ti:Ni, and Ti:W have been extensively used and annealed at temperatures up to 1000°C. Si diffusion barriers have been TiN and $TaSi_2$. The complete stacks used have been Ni/Cr/W, Ti/TiN/Pt, and Ti/$TaSi_2$/Pt. For high-temperature gas sensing, ohmic contacts used were $TaSi_x$ with Pt overlay (Spetz *et al.* 2001).

For GaN/AlGaN heterostructures Ti/Al/Ni/Au, annealing above 850°C has become a standard contact system, which has allowed short time operation up to 1000°C (in the case of AlInN/GaN FETs) (Ruvimov *et al.* 1996). Both Ti and Al have a small work function difference to Ga, which dominates the Ga face surface properties (Schmitz *et al.* 1998).

With respect to diamond, contacts have been developed to the hydrogen- and oxygen-terminated surfaces. The hydrogen-terminated surface is chemically unstable and contacts are not reliable under harsh conditions. On oxygen-terminated surfaces, the surface potential is pinned at approximately 1.7 eV and contacts are best provided on degenerately boron-doped layers by tunneling. Contacts have been developed around Cr/Au and Ni alloyed at a moderate temperature. For high-temperature operation, a W:Si/Pt/Au contact has been used on highly boron-doped contact layers (Vescan *et al.* 1996).

1.06.5.3.2 Schottky contacts

Schottky contacts should form a reliable (temperature stable) interface with the semiconductor. SiC, Ni, and $TaSi_2$ have been found stable up to around 600°C (Saxena *et al.* 1999). However, most contacts for gas sensing are based on Pd or Pt.

In the case of GaN, the surface potential should not be pinned as seen from the dependence of the barrier height on the work function difference

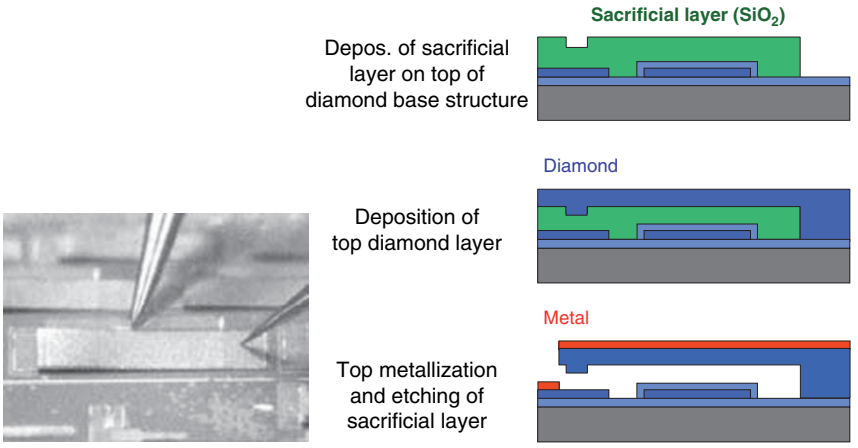

Figure 40 Sketch of SiO_2 sacrificial layer technology in diamond for realization of cantilever switch. (Source: Adamschik M, Schmid P, Ertl S, Ebert W, Käb N E Kohn 2000a CVD-Diamond for high temperature MEMS applications: First example: Diamond microswitch. *Proc. 5th International High Temperature Electronics Conference (HiTEC)*, Albuquerque, NM, USA, June 2000 with permission.)

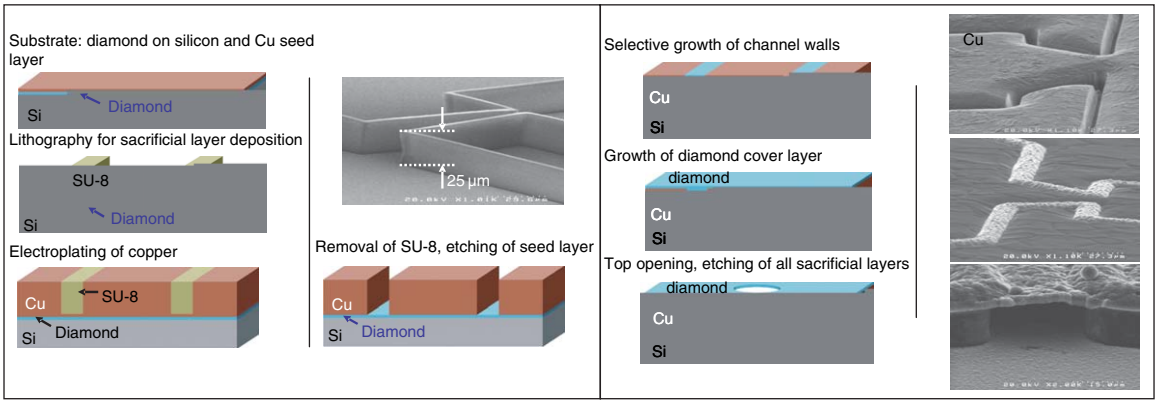

Figure 41 Sacrificial layer technology for diamond capillaries, based on Cu-plating, SU-8 patterning, and nanocrystalline diamond (NCD) overgrowth. (Source: Müller R, Schmid P, Munding A, Gronmaier R, Kohn E 2004 Elements of surface microfluidics in diamond. *Diamond Relat. Mater.* **13**, 780–4, with permission.)

(Schmitz *et al.* 1998). Therefore, Schottky barrier materials are mostly Pt and Ni. However, on the technical surface, a native oxide coverage may determine the interface and pin the surface potential. This is especially observed for AlGaN, where for an Al content of 30%, a barrier height of approximately 1.5 eV is observed (Ibbetson *et al.* 2000).

With respect to diamond, reliable Schottky barrier contacts are only possible on oxygen-terminated surfaces. Here, the barrier height is pinned at approximately 1.7 eV, with an experimental spread between 1.5 and 2.0 eV. High-temperature stable contacts have been realized with W:Si/Au, where the W:Si had been kept amorphous by addition of nitrogen during deposition (Vescan *et al.* 1998).

1.06.5.3.3 Passivation layers

Passivation layers should normally protect the active semiconductor surface from the surrounding environment. In sensors the active surface is exposed to the environment and passivation is needed to protect the peripheral areas. Depending on the environment, passivation layers need to have good adhesion, also during stressing, they are usually chemically inert, corrosion-resistant dielectrics (acting as diffusion barriers to water diffusion) and with wide bandgap

(and thus high electrical breakdown strength). They are therefore in general Al_2O_3, SiO_2, Si_3N_4, and nanocrystalline AlN in the case of diamond (McGoech *et al.* 1999). In electrochemistry, epoxies are used extensively.

1.06.5.3.4 Heteroepitaxial growth and interfaces

Most wide bandgap semiconductors are grown on foreign substrates with high mismatch, preventing direct overgrowth with low dislocation density. Therefore, in nearly all cases, a thin buffer layer is acting as nucleation layer for oriented outgrowth. Epitaxially ordered layers are formed already a few nanometers above this film. On Si, such buffers are for SiC, a carborization layer to nucleate SiC (Morales *et al.* 2003), for GaN and AlN a low-temperature AlN buffer, on Al_2O_3, SiC, or Si as discussed in Section 1.06.3.2, and for diamond a carborization step together with bias enhancement of nucleation (Yun and Dandy 2005). In the case of cubic SiC and diamond, the overlayers are textured. In the case of diamond for growth of nanocrystalline layers, seeding is often performed with nanodiamond particles deposited from a suspension or with nanoparticles attached to a plasma-generated a-C layer (Rotter 1999).

1.06.5.3.5 Etching

All ceramic-like semiconductors discussed here are highly etch resistant. Etching in wet solutions is difficult, but generally possible by photochemical reaction when illuminated with above bandgap UV illumination. In the case of SiC, Si, diamond etching of deep trenches is often performed with high density, high energetic plasmas (ICP-RIE), often with chemically assisted erosion by addition of Ar. Deep trenches with vertical walls and high aspect ratio are usually etched in by cycling between etching (e.g., using dilute SF_6) and sidewall passivation by polymerization (e.g., using dilute CHF_3) in a large number of sequences (Bosch process) (Lämmer and Schlip).

SiC can be etched in hot KOH at approximately 600°C (which will also remove Si at a higher rate). Wurzite SiC has also been etched electrochemically in HF (Chang *et al.* 2006, Mikami *et al.* 2005) or in KOH-solutions, activated by UV light (Kato *et al.* 2003). Thus, it is usually dry etched (by ICP-RIE as mentioned above) in fluorine-containing gases like SF_6 or NF_3 mixed with Ar and O_2 (Beheim and Evans 2006). Such etching processes have been used to obtain suspended microstructures in bulk 6H–SiC substrates (Hossain *et al.* 2006) and to obtain nanometer-sized double-clamped SiC beams by underetching of a SiC layer on a Si substrate (Yang *et al.* 2001).

GaN with N face polarity is etched in KOH (Li *et al.* 2001). Material with Ga face polarity is etched in KOH only when assisted by DUV light (Youtsey *et al.* 1997). However, GaN, AlGaN, and InGaN can be dry etched in plasmas mostly containing Cl for chemical activation or Ar for physical activation by chemically assisted ion beam etching (CAIBE) (Ping *et al.* 1996), ECR, RIE, or ICP (Basak *et al.* 2000, Pearton *et al.*, 1994, Shul *et al.* 1996). Controlled etching needs to be performed in a mild plasma, to prevent loss of nitrogen. High precision is obtained by digital etching, where in sequence a nanometer-thin oxide layer is formed, which is subsequently removed (Buttari et al. 2002). InGaN has been used as thin sacrificial layer grown between two GaN layers and removed by photoelectromechanical etching (Stones *et al.* 2001). Photochemical etching has also been used in conjunction with selective etching on PN structures (Stones *et al.* 2001, Strittmatter *et al.* 2001). Because the bandgap of InGaN is smaller than that of GaN, at the chosen wavelength, the GaN film is not absorbed and thus not etched. AlN has been dry etched in an Ar/C_2 and H_4/H_2 ECR plasma (Pearton *et al.* 1994).

AlN is etched by KOH solutions, depending on quality. While the N face is attacked by the etch solution, the Al face is not etched, presumably due to oxide passivation (Vartuli *et al.* 1996, Zhuang *et al.* 2002). Diamond cannot be etched in any wet solution, but is dry etched by oxygen. The process is critical, because the texture of the nanocrystalline film may result in a roughened surface or even needles. Masks that are used need to be oxygen resistant and are therefore mostly metals like Ti/Al. Perpendicular sidewalls can be obtained depending on the plasma conditions as well as by sidewall passivation by metal oxides, originating from back-sputtered mask material (Ding *et al.* 2005). Etching of nanocrystalline material in an O_2 atmosphere becomes noticeable above 750°C, starting at grain boundary sites. Microbody structures have been etched and patterned by a focused ion beam (Murakawa *et al.* 2003).

1.06.5.3.6 Chemical functionalization

Most functionalized surfaces in biochips are metal-oxide surfaces using the hydroxyl group as linker. Their reactivity is generally high, and are used

oxides with high stability. This excludes in many cases SiO_2 and therefore also the native oxide on SiC. GaN and AlN have been functionalized with organosilane (Baur *et al.* 2005).

In the case of diamond, on the other hand, the high intrinsic stability of its surface may make its functionalization difficult. But, indeed the diamond surface can provide stable bridges to biomolecules through specific reactive groups. These functional groups can then be used as a starting point for the attachment of more complex molecules such as DNA or proteins to the surface (Härtle *et al.* 2004, Wenmakers *et al.* 2005). Clean surfaces, oxygen-, and hydrogen-terminated surfaces have been modified and functionalized by electrochemical and photochemical processes to form covalent C═C links, carboxylic acid groups, N–C bonds, and C–F groups (Freedman and Stinespring 1990, Ohtani *et al.* 1998, Tsubota *et al.* 2004). To date, the photochemical method is mostly used as developed by Hamers (Nichols *et al.* 2005) with UV illumination (Hg line at 245 nm) of hydrogen-terminated diamond to produce a carboxyl (C═C) link. This process involves electron/hole pair generation and electron emission into the liquid. The main advantage seen is that the C═C linker is extremely stable, for example, in the hybridization of oligonucleotides (Yang *et al.* 2002).

Most biomolecules are charged. Therefore, detection of the covalent linkage can be via field effect. This is indeed used in ChemFET structures based on (H induced) surface channel devices (which are however only conditionally stable as already mentioned) (Garrido *et al.* 2005, Strobel *et al.* 2004). After functionalization, direct electron transfer could be observed between the redox center of an enzyme and the diamond electrode (Härtle *et al.* 2004). This means diamond can combine biofunctionalization not only with ISFET but also with electrode properties.

1.06.6 Diamond-Based Applications

Some applications have already been discussed, where the complexity and technological requirements have been limited. These have been electrochemical electrodes, radiation detectors, and GaN-based piezosensors. In the following, three examples based on CVD diamond with performances under extreme and harsh conditions are discussed to further illuminate the potential of this young material. While SiC can already be explored commercially in foundry processes, diamond microsystems are just emerging.

1.06.6.1 Acceleration Sensor

Both SiC and diamond possess high stiffness and high fracture strength. They are, therefore, especially suited for applications, where high forces are developed. The following is an example, where a diamond membrane has been structured into a bridge structure with Si seismic mass for sensing shock and fast acceleration (**Figure 42**). The thickness of the diamond film had been 15 µm, the YM 850 GPa (approximately 80% of the ideal value), and the fracture strength (bending the cantilever downward) was 4.7 GPa (approximately half of the ideal value), the data obtained by resonance frequency measurements of

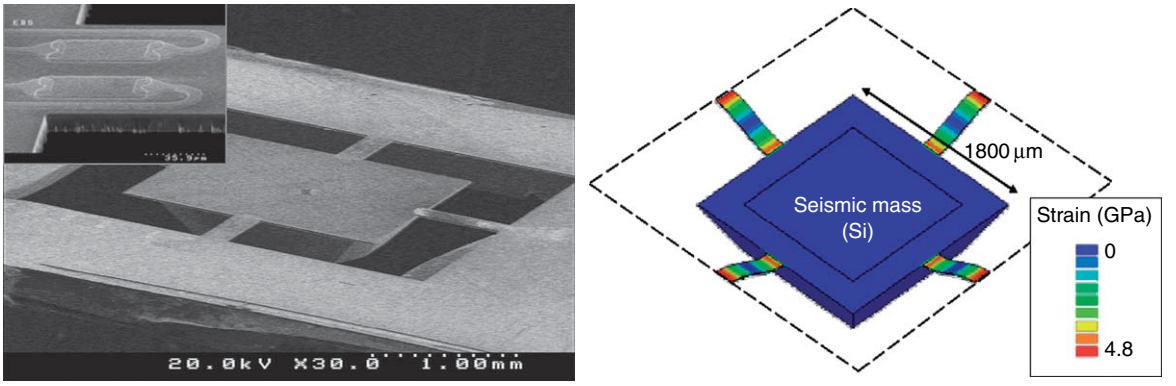

Figure 42 Bridge acceleration sensor with Si center seismic mass. Piezoresitors shown in the inset. *On the left side* simulation shows displacement at 7000 ***g*** acceleration, creating a critical stress of 4.8 GPa, leading to fracture. (Source: Kohn E, Gluche P, Adamschik M 1999 Diamond MEMS – a new emerging technology. *Diamond Relat. Mater.* **8**, 934–40 with permission.)

single anchored cantilevers and nanoindention measurements. The active elements are boron-doped piezoresistors integrated at the anchor position (see inset in **Figure 42**) realized as described in Section 1.06.4.1.1. In this case, at moderate activation of the boron doping (indicating a doping level above $10^{18}\,cm^{-3}$), the GF was 8.0. The piezoresistors were arranged in a fourfold bridge. Two resistors were located at the end of the beams, two outside the suspended structure for reference. The signal was read out by a Wheatstone bridge circuit on a circuit board. The accelerator was tested in shock experiments up to 40 GPa. However, it was realized that this had been earlier than the fracture of bridges could be expected. The fracture limit of the sensor was simulated using the measured materials data assuming the experimental fracture strength. This is shown in **Figure 42** (right). As can be seen, the critical stress appears at the outside anchor position of the bridges. At this condition, the acceleration was 7000 $\boldsymbol{g}$ (Kohn *et al.* 1999).

1.06.6.2 High-Temperature/High-Power Electrostatic Switch

Microswitches are a basic component of RF MEMS because of their low insertion losses and high current switching capability. They are either discrete devices or part of integrated circuits (ICs). In most cases, they are cantilevers or bridges and either DC or RF coupled and electrostatically actuated. Materials used are poly-Si or metals like Ni. Interstructural insulation is often provided by oxides or nitrides with their mechanical and thermal properties essentially deviating from those of the conductor materials. Both SiC and diamond are attractive as cantilever materials because of their high stiffness translating into high switching speeds, but also high switching voltages as discussed in Section 1.06.4.2.2. Both materials also open up the possibility of high-temperature and high-power operation.

The case discussed is an all-diamond microswitch, the advantage being that diamond is used as multifunctional material to replace all the materials normally needed in the stack. The basic technology has been described in Section 1.06.5.2. Some more details are given in Ertl *et al.* (2000) and Adamschik *et al.* (2002) and may be apparent from **Figure 43**. The switch has been designed as a DC coupled switch for RF applications to switch bias level and signal simultaneously.

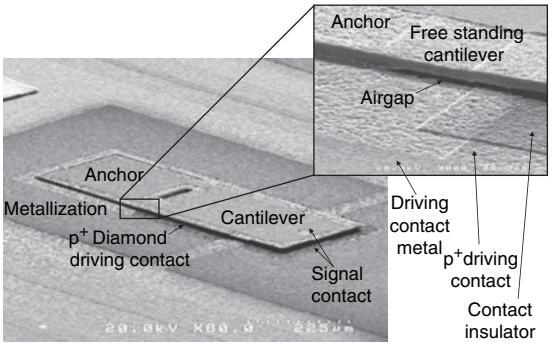

Figure 43 Basic structure of electrostatic cantilever switch. The various parts have been realized by selective growth and SiO_2 as sacrificial layer material. (Source: Adamschik M, Kusterer J, Schmid P, Schad K B, Flöter A, Kohn E 2002 Diamond microwave micro relay. *Diamond Relat. Mater.* **11**, 672–6.)

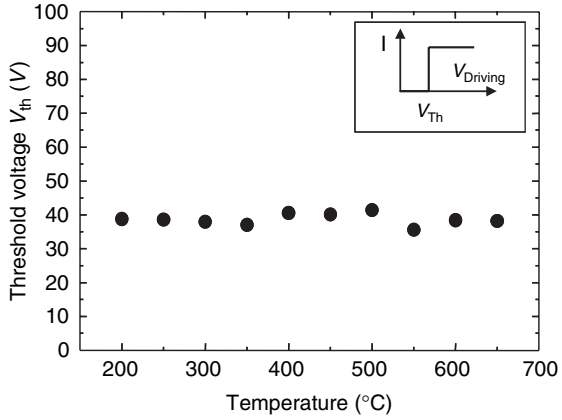

Figure 44 Threshold voltage for switching versus operating temperature. (Source: Adamschik M, Schmid P, Ertl S, Ebert W, Käb N E Kohn 2000 CVD-Diamond for high temperature MEMS applications: First example: Diamond microswitch. *Proc. 5th International High Temperature Electronics Conference (HiTEC)*, Albuquerque, NM, USA, June 2000.)

The switching properties had been evaluated up to 650°C. In essence, the threshold voltage remained constant, indicating no change in YM due to plastic deformation (**Figure 44**) (Adamschik *et al.* 2000). Mechanically, the device was switched in a vacuum of up to 800°C. In this experiment, the cantilever was deflected by a micromanipulator. No sticking or fatigue was encountered.

The DC on/off ratio of the switching resistance was $>10^9$ at RT. At high temperature, leakage across the diamond anchor, the diamond base plate, and Si

substrate became noticeable in this specific case. However, even at 800°C, the ratio was still better than 10^4 (**Figure 45**). This residual conductivity was thought to be generated by activated grain boundary conduction, activation of nitrogen, which has been used to support nanocrystalline growth and the activation of residual boron.

For an allowed temperature of the contact tip during operation at 600°C, which may be realistic for operation under vacuum, a DC current density of more than 250 kA cm^{-2} should be permissible. The simulation was based on thermal conductivity values of 25% of the ideal value for the nanodiamond cantilever and 50% of the ideal value for the base plate of the highly oriented diamond (Adamschik *et al.* 2000a). This result had stimulated overdrive experiments to determine the breakdown limit. The result of such an experiment is shown in **Figure 46** (see also Adamschik *et al.* 2000b). The thermal overload resulted in burning a hole into the cantilever due to reaction with atmospheric oxygen. Molten Au is piled up around the hole. Thus, the local temperature reached was essentially higher than 1000°C. Based on the contact resistance and contact area measured before destruction, a power density of 0.74 MW cm^{-2} was applied. Nevertheless, the cantilever did not stick and switching was possible even after the destructive event (as shown in the inset).

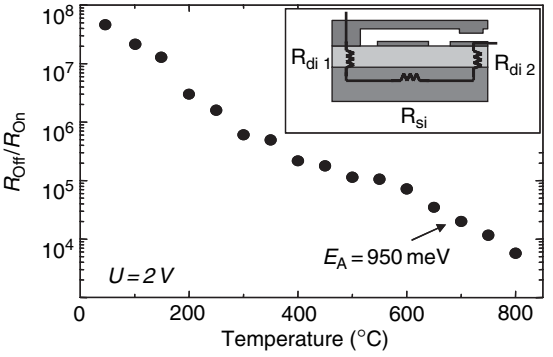

Figure 45 Ratio of the switch resistance in the off-state and on-state versus operating temperature. The reduction of R_{off} with temperature is mainly caused by activation of deep levels in the undoped nanocrystalline diamond (NCD) film, the bypass current path also being indicated. (Source: Adamschik M, Schmid P, Ertl S, Ebert W, Käb N E Kohn 2000 CVD-Diamond for high temperature MEMS applications: First example: Diamond microswitch. *Proc. 5th International High Temperature Electronics Conference (HiTEC)*, Albuquerque, NM, USA, June 2000.)

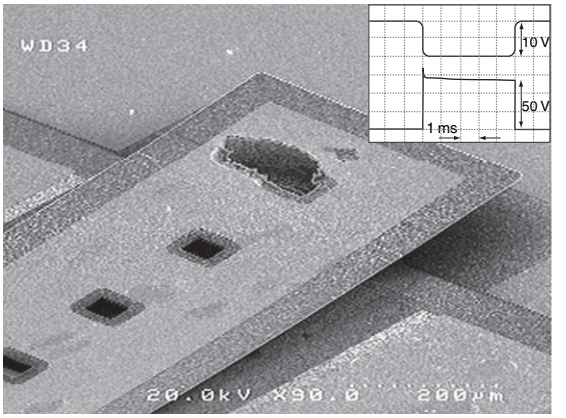

Figure 46 Cantilever switch after overdrive experiment (see text) also shown is the switching characteristics afterward. 1.06.6.3 Ink-Jet for Aggressive Media

Ink-jet devices are one of the most popular microfluidic devices, mainly used for ink printing. Many different, mostly heterogeneous, configurations with various actuation principles have been developed. Mostly they are Si-based MEMS devices, containing either a thermoelectric or a piezoelectric actuator element, a polymer capillary system, and a metal nozzle plate (Aden *et al.* 1994).

While they are very well optimized for their application, the hybrid nature of the materials stack imposes strong limits on their operating environment. The materials employed may not be compatible with aggressive chemicals and/or organic solvents because of corrosion of the metal nozzle plate or dissolution of the polymer capillary system and/or the glue used for bonding. In the case of the bubble jet with electrothermal actuation, thermal stress due to different thermal expansion coefficients of the individual layers within the stack may result in cracking or even delamination. This limits the lifetime of such devices as well as their range of operating temperature and their compatibility with aggressive fluids and organic solvents. Other actuator elements other than the spot heater are difficult to integrate and therefore rarely used in on-chip systems.

With respect to the bubble jet concept, various approaches can be found in the literature to facilitate the technology for on-chip integration. For example, to avoid a polymer capillary system, Si bulk

micromachining is used, but requires the heater integration on the nozzle plate (backshooter) (Krause *et al.* 1996, Lee *et al.* 2002). In another approach, capillaries have been realized in an SOI approach (Baek *et al.* 2004). Usually planar capillaries are realized by a high aspect ratio sacrificial layer technology, employing SiO_2, Ge, and SiN (Wang *et al.* 2004). Heater materials are refractory metals like Pt or refractory compounds like HfB_2 and need passivation.

Therefore, the replacement of the entire stack by only one material seems desirable. Both SiC and diamond are heater materials and highly corrosion resistant and seem thus to be appropriate. In the approach described here, diamond (NCD) has been used as a multifunctional material. The entire chamber including the heater and capillary structure has been realized in a diamond-on-Si technology and has thus been labeled an all-diamond ink-jet. Therefore, the entire structure is chemically inert, corrosion resistant and thermally stable and can be used to dispense any liquid like concentrated acids or hot KOH.

A key requirement for microfluidic elements is a technology for encapsulated microchannels. They have been fabricated by conformal deposition of NCD and sacrificial layer etching. High aspect ratios are needed, which are difficult to obtain with SiO_2. Therefore, a sacrificial layer technology based on electroplated Cu has been developed as described above. In this process, the Cu sacrificial layer has been deposited onto a sputter-deposited seed layer and plated in between an SU-8 pattern with steep sidewalls. The Cu pattern was overgrown with another NCD film after deposition of a diffusion barrier and nucleation layer. Despite the different thermal coefficients of expansion of diamond, the Si substrate and the Cu, no cracking was observed during overgrowth at 700°C. The heater and wire connections within the chamber have been realized by quasi-metallic p-type-doped diamond resistors, need no passivation, and are highly corrosion resistant. They were fabricated before the capillary walls were grown as already discussed in Section 1.06.4.2.1. To open the capillary, the Cu pattern was etched in 30% HNO_3. The resulting ink-jet pattern is schematically shown by the cross section in **Figure 47** and the micrograph of the realized structure is shown in **Figure 48**.

In the bubble jet, actuation is generated by superheating of the liquid. By applying short heating pulse, a thin liquid film is heated at the interface to its spinodalian temperature (324°C for water), resulting in a liquid to vapor phase transition within microseconds. The vapor bubble expands instantaneously, separating the liquid from the heater, ejecting a droplet through the nozzle hole. The droplet reaches a velocity between 5 and 17 $m\,s^{-1}$ depending on the liquid (mainly its density) and the heater pulse power and duration.

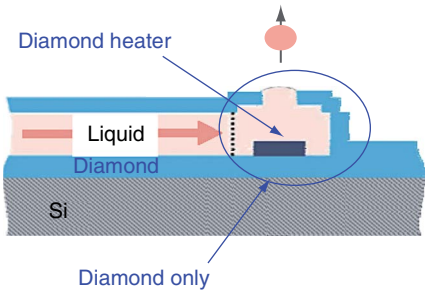

Figure 47 Schematic cross section of all diamond ink-jet. (Source: Mueller R, Gronmaier R, Janischowsky K, Khon E 2005 An 'all-diamond-inkjet' using sacrificial layer technology. *Diamond Relat. Mater.* **14**, 504–8 with permission.)

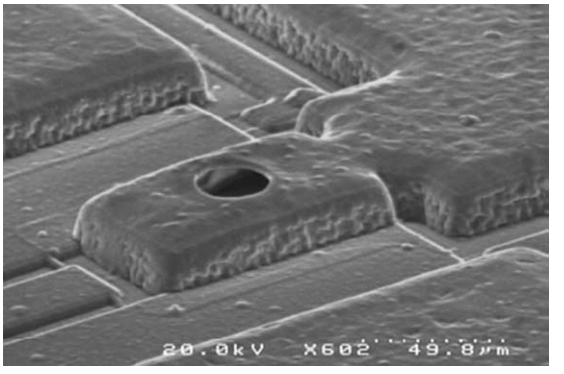

Figure 48 Scanning electron microscope (SEM) micrograph of the all-diamond ink-jet cavity and nozzle opening. (Source: Mueller R, Gronmaier R, Janischowsky K, Khon E 2005 An 'all-diamond-inkjet' using sacrificial layer technology. *Diamond Relat. Mater.* **14**, 504–8 with permission.)

The inertness and chemical stability of the system has been tested dispensing 40% concentrated sulfuric acid to etch Cu patterns into a Cu thin-film sputter deposited onto a glass slide. The glass slide was mounted 10 mm over the ink-jet nozzle plate on a motorized stage. The result can be seen in **Figure 49**, where holes were etched into the Cu film. The droplet velocity was measured to 13 $m\,s^{-1}$ using pseudocinematography, allowing operation at a frequency of 10 kHz.

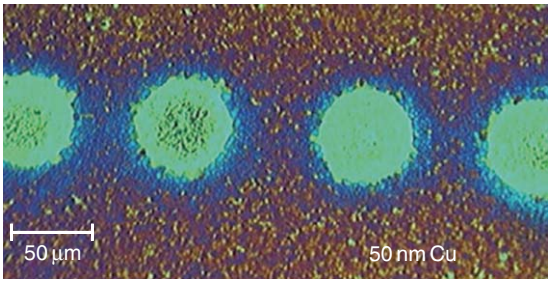

Figure 49 Micrograph of HNO_3 ink-jet drops on 50-nm Cu on glass. (Source: Müller R, Berger W, Janischowsky K, Kusterer J, Kohn E 2005 'All-diamond-inkjet' for dispension of aggressive liquids. *63rd Device Research Conference (DRC)*, Santa Barbara, CA, USA, Abstracts 229–30, June 2005.)

1.06.7 Integration Aspects

Technologically, integration means the interconnection of prefabricated parts into a complex structure or system. Thus, it could be part of the technology of the sensor element itself or part of the sensor or actuator element integration with their readout or driver circuitry. Many aspects are then also relevant for packaging.

Sensors need signal readout by low noise amplifiers, which should be closely integrated. Equally, actuators need drivers directly connected to minimize wiring losses. Candidates are MOSFETs and JFETs on α-SiC (mostly 6H, Friedrichs and Stephani 2006, Slater *et al.*) and β-SiC (Nagasawa *et al.* 2006) and also AlGaN/GaN HEMTs (Daumiller *et al.* 1999). Diamond is not an option yet. While MISiCFETs have been realized in CMOS configuration (although with low hole mobility), GaN-based HEMTs have only shown attractive characteristics for n-type channels. However, up to now, all these configurations have not been used in monolithic integration of sensor elements, despite improvements in the sensor component technology resulting in 1D and 2D arrays like in the case of SiC and diamond particle detector arrays discussed above. Thus, in general, the readout and driver electronics are hybrid integrated. Such technologies are discussed in the following section.

1.06.7.1 Wafer Bonding

Active layer transfer technologies have been developed to connect active layer structures of various materials with a variety of other substrates. It is usually performed in two steps: wafer splitting and wafer bonding. In the first step, the wafer containing the active layer structure is prepared for splitting. This may be obtained by high-dose proton implantation – the wafer is bonded top side down onto the new base substrate, and finally the active surface layer split off from the original wafer.

Implantation with a high dose of protons leads to the formation of planar defects or platelets, which develop into microcracks and microcavities along the peak implant concentration, eventually leading to blister formation at elevated temperatures. The technique has been applied to Si, SiC, GaN, and diamond (Tong *et al.* 1995, 1997). The different bond strength of the materials is reflected in different activation energies for blister formation, which is approximately 1.2 eV for Si and 4.2 eV for diamond. Therefore critical temperatures range from 200°C for Si to 850°C for diamond. In the case of GaN on sapphire, the interface has been laser irradiated with a wavelength absorbed by the GaN but not the sapphire. At high irradiation dose the GaN is dissociated forming N_2 at the interface and the GaN layer is split off (Miskys *et al.* 2003).

Wafer bonding is obtained on hydroxy-terminated surfaces, where the hydroxyl bonds act as bridges to the other surface. The best-known process is the smart-cut process (Aspar *et al.* 1997), where SiC and GaN layer structures have been bonded to silicon base substrates (Cong *et al.* 2004). A similar process has also been developed for the bonding of Si onto diamond (Aleksov *et al.* 2005). Here, the diamond had been grown highly oriented on Si. However, it had been difficult to obtain the high degree of flatness needed across a large surface area.

1.06.7.2 Device Transfer Technology

Hybrid integration will also allow the heterogeneous integration of various types of substrates. One such hybrid technology is the transfer of device structures without substrate onto a base substrate. It involves a lift-off process for the device to be removed from its substrate. Such a process for the transfer of GaN disks, involving a sacrificial layer technology is described in Stones *et al.* (2001).

1.06.7.3 Chip Soldering

In many cases, the sensor chip has to be attached to the base plate by a high-temperature stable soldering or a brazing process. Concerning high-temperature stability, alloys with refractory metals are used, mostly centering around the alloys also used for contact

formation. However, they may be rather brittle, introducing high local stresses. In addition, if small patterns of micrometer size need to be joined together, the kinetics of the formation of the liquid phases is difficult to control, resulting in the formation of rough surfaces and squeeze out. An alternative is solid liquid interdiffusion processes based on isothermal solidification also called SOLID (Hübner *et al.* 2002). In solid–liquid interdiffusion, a low melting metal (i.e., Sn) is placed in between two contacts of a high melting metal (i.e., Cu, Au, and Ni) and heated until the contacts are wetted by the liquid phase of the low melting component. During annealing at a constant temperature, alloying reactions transform the liquid phase into solid intermetallics from both sides. In the Cu/Sn system the bond can be formed slightly above the melting point of tin (232°C), with a solid fast growing η-Cu_6Sn_5 intermetallic phase being transformed into ε-Cu_3Sn, which is stable up to 640°C. If all tin is consumed in the reaction and transformed into the high-temperature stable alloy from both interfaces, the final joint is also stable up to 640°C. The concept is illustrated in **Figure 50**, also showing the phase transformations.

The high-temperature stability of the final joint allows stacking of several chips onto each other without softening the previous joints. In this way, up to six 10 µm thin Si chips have been stacked (Benkart *et al.* 2005). The technology has also been applied to solder a diamond DUV array onto a Si substrate, which could also be an array in SiC or GaN (**Figure 51**). Despite the formation of the joint at approximately 300°C, a high thermal stability of the final joint of approximately 500°C is obtained.

The same technology has also been applied to a bistable diamond switch based on a bistable bridge configuration (**Figure 52**). The actuator is based on the bimetallic concept using a diamond/nickel pair (see Section 1.06.4.2.4) and switched by cycling the temperature. Here, the device is assembled from two parts, the base plate and the actuator. They are also soldered together by the Sn/Cu SOLID process.

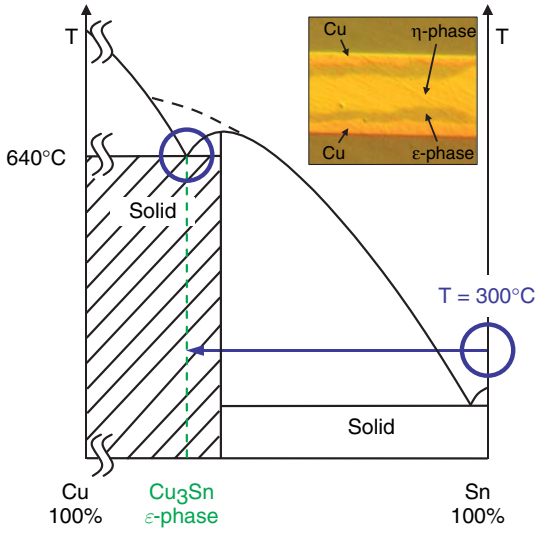

Figure 50 Schematic phase diagram of Cu:Su alloy and indication of liquid solid soldering process (SOLID), see also text. The inset shows schematically the formation of the various phases during alloying. The final ε phase is stable up to 640°C. (Source: Hübner H, Ehrmann O, Eigner M, Gruber W, Klumpp A, Merkel R, Ramm P, Roth M, Weber J, Wieland R 2002 Face-to-face chip integration with full metal interface. *Proc. Advanced Metallization Conference*, *AMC 2002*, Vol. 69, pp. 53–8.)

1.06.7.4 Hermetic Sealing

Devices sensing in a harsh environment have their surface exposed to this environment, however their peripheral structures may need to be hermetically sealed in many cases. Such sealed cavities have been traditionally realized by capping with ceramics (SiC, Al_2O_3, and AlN) or glass–ceramic sandwiches. In a smaller scale this technology has borrowed from the traditional flip-chip bump packaging, where the chip is directly attached to another level of metallization, eliminating wire bond connections. In such a direct chip attach technology, an SiC membrane pressure sensor for an operation at 600°C has been packaged and sealed using dielectrics like AlN, high-temperature melting glass, and Kovar (Okojie *et al.* 2001). In this case, it has been especially important to balance the thermal stress components to eliminate fatigue. Increasingly, micron-sized structures are however sealed with approaches based on 3D thin-film structures with materials like SiO_2, Si_3N_4, and poly-Si (Gogoi and Mastrangelo 2001, Lin *et al.* 1998). The connection between the lid and the substrate may also be a soft metal like thick Au, which can absorb thermal stress (Savrun 2002). Recently, approaches using diamond have also emerged (Zhu and Aslam 2006, Zhu *et al.* 2004) using a molding technique.

1.06.8 Conclusions

In this chapter MEMS materials and devices have been discussed as they have emerged within the last decade. In many cases, the application had been very

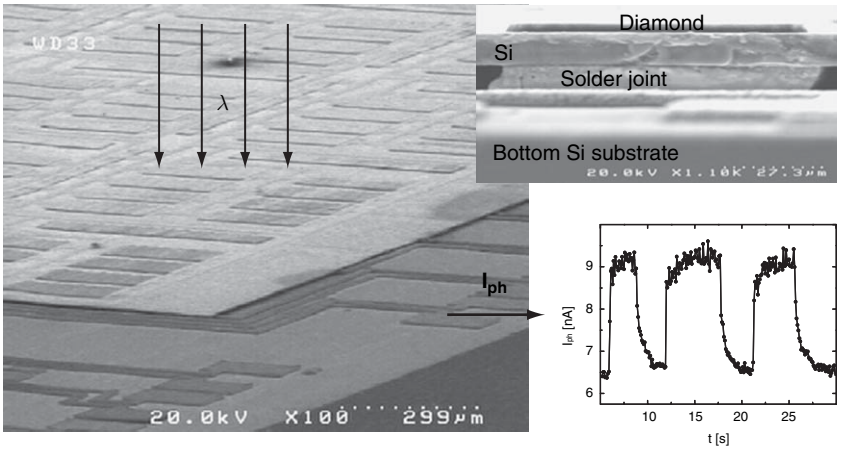

Figure 51 Micrograph of vertically integrated diamond deep ultraviolet (DUV) detector array with Cu:Sn solder joint (soldered as described in **Figure 50**) shown in the inset. Also shown is the photocurrent response. (Source: Kaiser A, Kueck D, Benkart P, Munding A, Prinz G M, Haittmann A, Huebner H, Sauer R, Kohn E 2006 Concept for 3-D intergrated UV sensor. Mater.* **15**, 773–6 with permission.)

specific and the driving force had been conditions outside the materials capability of Si. Three materials have emerged: SiC, GaN, and diamond, where GaN represents a materials matrix including InAIN, AlGaN, and InGaN and thus heterostructures. Each of the materials has its own specific advantage and disadvantage and it seems that they can complement each other.

SiC is certainly the most mature material within this group. Most of its ideal properties are second best to ideal diamond. It can be cubic, when grown on Si, and also hexagonal, where it develops a large number of polytypes. Here it is available with a large substrate area, but the stability may be limited by polytype transformation at defects. It sublimes at around 1800°C, and SiC heaters have been operated at 1200°C, the highest temperature of operation of all three materials candidates. It can be doped n-type and p-type and CMOS devices are in essence available for a smart sensor integration in 4H or 6H polytype. The main fields at present are high-temperature piezo-MEMS and high-temperature gas sensors, both oriented toward combustion engine and jet engine control and space applications. It is

the most widely used material for many fields and first MEMS components are already available commercially.

GaN is still a young material and basically confined to optoelectronics and high-power electronics. However, it is the first highly polar semiconductor material. AlN is a traditional electroceramic with a high polarization and high thermal stability, surpassing the depolarization temperature of other piezoelectric materials like PZT essentially. However, single-crystal semiconducting AlN is just emerging and not yet available in large size and high crystalline quality. The high-temperature stability of single-crystal AlN and the AlGaN/GaN and InAlN heterojunctions is very promising despite of their high defect density. If GaN is capped, like in the case of a heterostructure, its thermal stability has been found essentially higher than the GaN decomposition temperature in the atmosphere. Thus, it is one of the few piezoelectric materials with very high depolarizing and decomposition temperatures, but used in MEMS only in proof-of-concept experiments up to now.

Diamond is a material with extreme properties, but burns in oxygen at a high temperature and starts to graphitize at defect sites above approximately 1500°C. In an inert H atmosphere the diamond phase itself has been found stable at 2200°C. However, to obtain large surface areas, deposition onto a foreign substrate is still polycrystalline or nanocrystalline. Certain properties are then determined by the grain boundary characteristics rather than those of diamond. Diamond electronics is not yet available for integration and the film growth conditions are not yet compatible with CMOS processes on Si and SiC. It is therefore still confined to discrete device applications. However, high quality (mostly thick freestanding) films are very attractive for use under extreme conditions like for the detection of high-energy particles in the nuclear environment, in high energy physics, or space. It is also the only inert, highly corrosion-resistant nonmetallic electrode in electrochemistry and therefore increasingly used in poisonous and hazardous environments for analysis as well as for wastewater treatment. In both of the above-mentioned fields, detectors (particles and UV) and electrochemical microprobes, the first diamond arrays have emerged in a first step toward integrated systems.

With respect to electromechanical structures, a similar performance can be obtained in diamond, SiC and Si by scaling the geometry. At present Si-MEMS device structures are scaled down into the nanometer range using single-crystal high-quality material. However, with improved quality of SiC and nanodiamond substrates, the geometries will shrink. A rather important step will be taken, when single crystal large area diamond wafer becomes available. Several groups are investigating single-crystal growth on Ir, upscaling the present substrate size of $1\,cm^2$ to 4″-diameter wafers. This would enable nanometer-sized MEMS in single-crystal diamond, which are presently only investigated by proof-of-concept experiments (Prawer *et al.* 2006).

Acknowledgments

This work contains many contributions of our diamond and GaN-based technology groups over several generations of Ph.D. students. Here I would like to thank in particular Joachim Kusterer for his contribution to the MEMS technology and intensive help with the preparation of the manuscript. A special mention is the contribution of Andrej Denisenko with respect to many fundamental aspects of diamond electrochemistry. With respect to the advanced materials configurations investigated and implemented into device structures, the cooperation with Zlatko Sitar's group at NCSU (AlN) and of Alois Krost at the University of Magdeburg (GaN-on-Si) and Dieter Gruen at Argonne Laboratories (ultra-nanocrystalline-diamond) has to be acknowledged readily. Many thanks also to Werner Haenni (CSEM, Switzerland) for joint experiments and stimulating discussions concerning diamond electrochemistry. Last but not the least, many stimulating discussion within the community should not be left unmentioned. The work cited has been supported financially in part by the European Union, the German Ministry of Education and Research and the German Research Society (DFG).

Biography

Dr. Kohn earned his Ph.D. at the Technical University of Aachen (Germany) in 1975. After many years in industry in Germany, France and the U.S. he joined the University of Ulm as professor and director of the Department of Electron Devices and Circuits in 1989. His research activities include design and technology of advanced electronic device structures, especially field effect transistors, in a number of semiconductors, recently III-Nitride heterostructures and diamond for high temperature and high power applications. This is accompanied by work on advanced packaging technologies and MEMS sensor and actuator devices, especially based on CVD diamond, mainly for RF applications and applications in electrochemistry and life science. He is a member of the IEEE and Electrochemical Society and has served as IEEE distinguished lecturer. Currently he is serving as conference organizer of the 'Diamond' conference series. Dr. Kohn has coordinated joint German and European project groups and has been a partner to US programs. He has been a visiting fellow to the University of Wales, the Norwegian Institute of Technology, Cornell University and the Air Force Research Laboratories in Dayton (Ohio) and has been an Adjunct Professor of Physics at the New Jersey Inst. of Technology, Newark (NJ, USA). He is the director of the Steinbeis Technology Transfer Centre 'Semiconductor Devices'. His activities have led to two spin-off companies, GFD (Gesellschaft für Diamantprodukte) and MicroGaN. He has contributed with more than 300 scientific publications to the field.

1.07 Wet Etching

Kazuo Sato and Mitsuhiro Shikida, Department of Micro-Nano Systems Engineering, Nagoya University, Aichi, Japan

Glossary

Anisotropic etching Etching system where etching front does not advance omni-directionally. There are two types of anisotropic etching by the origin of directionality. One is the directionality caused by the incident angle of etching media, i.e. ions, atoms, and solid particles. Another is the directionality caused by the etched material that has an anisotropic nature like single-crystals. Antonym: **isotropic etching**.

Anodic etching Etching system that provides a positive electric potential to the wafer during etching. When silicon is etched in highly concentrated HF solution under positively biased potential and illumination, the silicon surface shows a variety of morphologies from porous to smooth ones depending on the electric potential and the strength of the illumination.

Anodization When anodic etching is applied to silicon wafer using HF solution as an etchant, silicon surface is etched porously, maintaining the single crystal structure in the remaining material. Such etching system is used for making porous silicon for applications such as photo- and electroluminescent devices, sacrificial layer of microstructures, and so on.

Buffered HF (BHF) Buffered HF is a HF solution diluted with water or NH_4F water solution. When oxide film on a silicon surface is needed to be removed, buffered HF solution is useful, because it selectively dissolves the oxide film at a moderate etch rate.

Diffusion-limited process Chemical etching is a series of process as follows; diffusion of a reactant in the environment, absorption of the reactant to the substrate surface, reaction between the absorbed reactant and substrate material, detachment of the

reaction product, and diffusion of the product to the environment. When the diffusion time is dominant over the total process, i.e. the reaction time is negligible compared to diffusion, the total process is called as diffusion-limited process. In case of diffusion limited process, stirring the solution is effective to enhance the etch rate. Antonym: **Reaction-limited process**.

EDP Mixture of ethylenediamine and pyrocatecol water solution. This is an anisotropic etching solution for single crystal silicon. It has excellent selectivity to oxide mask and also to p^{++} etch stop layer. Disadvantages of EDP solution is that it is highly toxic, and it can easily react with oxygen and quickly ages.

Electropolishing For the purpose of smoothing a silicon surface, photoelectrochemical etching using highly concentrated HF solution is used. Depending on the applied potential, the etched surface morphologies changes from porous to smooth ones. Higher potential is recommended to obtain a bright surface.

Etch stop technique For the purpose of controlling the height of microstructure or membrane thickness in the etching process, etch stop techniques have been developed. In case of anisotropic etching of silicon where uniform thickness reduction is available, p^{++} layer, p-n junction, and SOI wafers are utilized for the etch stop purposes.

HF, HNO_3, CH_3COOH water solution HF, HNO_3, CH_3COOH water solution is an isotropic etching solution for silicon. The system is diffusion-limited process, and thus it is isotropic.

Isopropyl alcohol (IPA) For the purpose of suppressing mask corner undercut during KOH etching of Si(100) wafer, isopropyl alcohol is dissolved to KOH water solution to the saturation level. The corner undercut decreases because that the etch rate ratio of Si (110) to (100) decreases by the addition of IPA to KOH solution. Such solution is also used to get a better smoothness on Si(100), though large hillocks can sometimes grow on Si(100) as a drawback.

Isotropic etching Etching system where etching front advances omni-directionally. Mask undercut advances laterally from the mask edge with the same distance to the etch depth. When the etch depth becomes large, a small sized island mask pattern will disappear from the surface. Antonym: **Anisotropic etching**

KOH Potassium hydroxide (KOH) water solution is an alkaline solution, showing strong anisotropy in etch rate of single crystal silicon. It is easy to handle compared to EDP, showing stronger anisotropy compared to TMAH solution.

Laser beam processing When a laser, typically YAG laser, is irradiated to the wafer before or during etching, one can get a different type of etch profiles than without laser irradiation. This is because of the thermal effects, one is destroying crystalline structure of the substrate material prior to etching, and other is local enhancement of etching at the laser irradiated surface during etching. Laser-enhanced etching is sometimes applied to anisotropic etching of silicon.

Mask corner compensation When fabricating thick micromechanical structures on a wafer by utilizing etching, the mask periphery is severely attacked by side etching. Even when anisotropic chemical etching is applied, mask corners of an island pattern are heavily undercut. One of the methods protecting the mask corner from the undercut is to add an additional masked area to the corner of the island. This additional masking area is called mask corner compensation.

Mechanical dicing Dicing is a process using a rotating grinding wheel to make grooves on a silicon wafer. It is usually used to cut silicon devices into pieces from a wafer. Dicing can be also utilized to make grooves followed by chemical anisotropic etching for making microstructures on a silicon wafer. Laser dicing is an alternative to the mechanical dicing for such purposes.

Open-circuit-potential (OCP) When a silicon substrate is etched in an alkaline solution in an equilibrium state, the substrate stays at a negative potential assuming that the solution is at zero potential. There is no electrical current flowing between the substrate and the solution. The substrate potential under such a condition is called as the open-circuit-potential.

p^{++} layer When silicon is heavily doped by boron at the concentration higher than $1 \times 10^{-19}\,cm^{-3}$, the etch rate of silicon in alkaline solution decreases two orders of magnitude compared to lightly-doped silicon. Because that the boron-doped silicon is p-type, heavily doped silicon region is called p^{++} layer. By utilizing this phenomena, the p^{++} layer is used as an etch stop layer for fabricating membrane structures on a silicon wafer. It is reported that a p^{++} layer doped with Ge or P does not show such a drastic decrease in etch rate observed with B.

Passivation potential When a silicon substrate is etched in an alkaline solution, the electrical potential of the substrate is at negative potential in equilibrium against the solution which is at zero potential. When applying a potential to the silicon towards positive direction, the silicon surface started to be oxidized and etching stops. The critical potential at which the etching stops is called as passivation potential.

p-n Junction A silicon p-n junction is useful for the etch stop technique during alkaline etching. The applied etch-stop system is set such that the n-silicon layer is biased in positive potential, while the p-substrate is exposed to the etchant. Because of the existence of p-n junction, no current flows through the junction even the n-layer is positively biased. Thus the etching advances in the p-substrate as long as the etching front does not meet the junction. However, once the etching front reaches the n-layer, current flows from the silicon to the solution. Thus the etching stops leaving a precisely controlled thickness of n-layer on the wafer.

Porous silicon Photoelectrochemical etching of single crystal silicon using highly concentrated HF solution results in a variety of surface morphologies. When the applied potential is low, porous silicon layer is obtained. Porous surface remain a single crystal. Such a layer is utilized for photo and electroluminescent devices, sacrificial layer of microstructures, and so on.

Reaction-limited process Chemical etching is a series of process as follows; diffusion of a reactant in the environment, absorption of the reactant to the substrate surface, reaction between the absorbed reactant and substrate material, detachment of the reacted product, and diffusion of the product to the environment. When the reaction time is dominant over the total process, i.e. the diffusion time is negligible compared to reaction, the total process is called as reaction-limited process. In the case of reaction limited process, crystalline materials often show anisotropy in the etch rate. Antonym: **Diffusion-limited process**.

Selectiveness Etching utilizes selectiveness in many ways. The etch rate selectivity between the work and etching mask materials is essential for etching process. The other example is the etch-stop techniques described in the text. Anisotropic etching is another case of selectiveness in the process.

Silicon-on-insulator (SOI) The wafer having a single crystalline silicon layer at the top of a wafer electrically insulated from the wafer substrate. Insulator can be a silicon oxide film separating the surface from the substrate. In such a case, the buried oxide film works as an etch stop layer for alkaline etching system.

Step flow model Etching model assuming that the crystal surface is composed of terrace and atomic steps. Terrace surface is chemically stable, while the atomic steps are easy to etch. Etching proceeds mainly as a removal of atoms at the step edges, consequently rows of the atomic step move in lateral direction during etching. This model is developed and established in the field of crystal growth, the reverse process of etching.

Surface micromachining One of the micromachining methods to create movable mechanical structures on a wafer. It is composed of a multilayered film deposition processes each followed by the patterning the film by etching. After completing the layers of deposition process, a certain layer is selectively etched off. As a result, remaining film layer becomes a movable structure partly supported by the substrate, or even fully released from the substrate. This type of machining is in contrast to the bulk micromachining that utilize the substrate material as a structure.

Surfactant During silicon anisotropic etching using alkaline solution, bubbles are generated as an etching product on the silicon surface. It is believed that bubble detachment from the silicon surface is enhanced by the addition of surfactant to the solution, thus results in a smooth surface finish.

TMAH Tetra-methyl-ammonium-hydroxide water solution. It is an alkaline solution, and used as an anisotropic etching solution for silicon. It has high selectivity in etch rate to the silicon oxide film as a mask material. It does not contain alkaline metal ions such as potassium and sodium which are harmful to ICs on the chip. It is also used as a developer for the photo-resist materials in the lithography process.

Wulff–Jaccodine's construction A graphical method predicting an anisotropically etched profile on a single crystal surface.

1.07.1 Introduction

Wet etching characteristics are classified into two groups, i.e., isotropic and anisotropic systems. The etching mechanism is analyzed as a series of materials transfer and chemical reaction processes. The variation in etching characteristics like isotropy and anisotropy is explained by the difference in the dominant process among series of materials transfer and chemical reaction processes.

Isotropic etching systems and its applications are introduced for silicon, silicon dioxide, and silicon nitride.

Anisotropic etching systems for single-crystal silicon are introduced. Selections of etching solutions and etching mask materials are discussed. Variation in etching shapes obtained by anisotropic etching is described in relation to the etching solution, the wafer orientation, and the etch-mask design. The etch rates are given in detail as a function of crystallographic orientations of silicon. A wide range of practical technologies for controlling etching shapes are introduced and summarized. Finally, advantages and disadvantages of wet and dry etching systems are compared from the engineering point of view.

Origin of etching anisotropy is discussed on the atomistic level. It is shown that the number of dangling bonds of the surface atom is not an appropriate index representing anisotropy in etching.

Etching profile simulation systems supporting process design of single-crystal materials are introduced. Simulation results are demonstrated for silicon and quartz etching.

Anodic etching system that allows electropolishing or porous silicon layers on a silicon wafer is introduced. Applications such as selective removal of microstructures, micro and macroporous silicon are described.

1.07.2 Etching Characteristics – Isotropy and Anisotropy in Etching

Etching is a micromachining process that removes solid material from a substrate surface. Wide ranges of etching media such as liquid, gas, plasma, and ion are utilized. This chapter focuses on wet etching processes that use liquids, i.e., etchants, as the etching media. When the work surface is partially coated with a protective film, etching advances selectively in an area without film coating. The protective films, i.e., etching masks, are made of polymers (photoresist materials), metals, and silicon compounds, which can be selected depending on the resistivity against the etchant.

The aim of an etching process is to selectively remove materials. The key word of etching is selectiveness. The following are examples of how selectiveness plays a key role in etching processes.

The first example is selective removal of material from a work surface only in the area of the mask aperture that is patterned in an arbitrary 2D shape. This is a normal method known as photoetching. Due to the advancement of photolithography technologies, photoresist films as protective films can be well shaped in fine patterns on the order of submicrometers in size. Such fineness of the material removal pattern is the major advantage of the etching process over other material removal processes such as mechanical machining.

The second example is selective removal of a material from other materials. The simplest application is removing an SiO_2 film from the Si surface. Fluoric acid attacks the oxide, but attacks silicon only slightly. An advanced application is to remove a single layer of a material among layered materials that coexist on the same substrate. Even when different materials are layered on the substrate, a single material layer can be selectively removed, as long as an opening is connected to the etchant from the material to be removed. This type of removal is further applied to surface micromachining to release a structural film material partly from the substrate. This allows fabricating freestanding micromechanical structures that move or mechanically oscillate on the substrate.

Thus, selectiveness is the key issue that makes etching processes successful. **Table 1** summarizes liquid-phase etchants for silicon and silicon compounds. An etched recess shows different shapes depending on the difference in etching systems.

The cross sections of typical etched recesses are shown schematically in **Figures 1** and **2**. Etching systems are categorized into two classes depending on the characteristics of the etching profiles. One is isotropic and the other is anisotropic etching. When etching advances normal to solid surfaces during the etching process at any place on the substrate except the masked surface, the etched cross section becomes like the one shown in **Figure 1**. Etching advances under the mask material and results in a round profile at the mask periphery. The etching advancing under

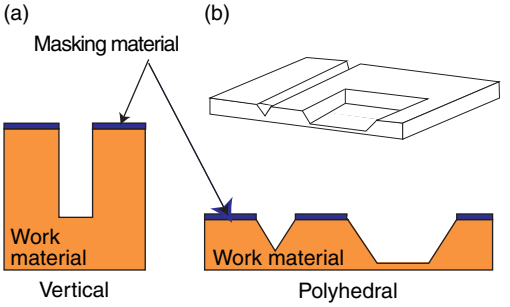

Figure 2 Anisotropically etched profiles. (a) Vertical, (b) polyhedral.

the mask is called mask undercut, or side etching. When a deep isotropic etching is applied to a narrow-patterned mask area, side etching from both sides meet at the center of the masked area, and the mask is finally lost. This type of etching is called isotropic etching.

On the contrary, when material removal takes place selectively in certain directions, the cross sections of the etched recess become like the one shown in **Figure 2**. Such etching is called anisotropic etching. When etching advances only in a single direction perpendicular to the substrate, the etched profile becomes like the one shown in **Figure 2(a)**. When the work material has an anisotropic nature, for instance, being a single crystal, the etched cavity often becomes polyhedral as shown in **Figure 2(b)**.

Unlike electronics circuit fabrication, microelectromechanical systems (MEMS) require that highly 3D structures be fabricated, and the etching depth sometimes reaches tens or hundreds of micrometers. For such fabrication purposes, anisotropic etching is useful, because it can transfer 2D mask pattern deep into the substrate. On the other hand, in isotropic etching, fine pattern of the masking material is easily lost after some depth of etching because of heavy undercut etching that advances beneath the masking material.

Anisotropic etching is further categorized into two depending on the anisotropy. One type utilizes directionality of the etching species physically hitting the surface of the substrate. This can be achieved by dry etching processes that utilize ions accelerated by external electromagnetic or electrostatic forces. Typical processes are reactive ion etching (RIE) and ion beam etching. The etched profile looks like that shown in **Figure 2(a)**. Another type of anisotropic etching utilizes the anisotropy of the substrate material, e.g., single crystals. Both silicon and quartz are available as single-crystal wafers. Etch rates are strongly dependent on the crystallographic orientations; thus the etched cross section shows variations as given in **Figure 2(a)** and **2(b)**, by combinations of wafer orientations and mask designs. The process is dominated by the chemical activeness of the orientations of single crystals. This is further explained in the next two sections.

Single-crystal silicon is wet etched both isotropically and anisotropically depending on the etching systems (**Table 1**). This is explained below.

Chemical wet etching results from a series of processes. The processes are:

(1) Diffusion of etching species in solution approaching the solid surface.
(2) Absorption of the species onto the solid surface.
(3) Reaction of the etching species and the solid atom.
(4) Release of the etched product from the solid surface.
(5) Diffusion of the product into the solution.

These processes are schematically shown in **Figure 3**. Although processes (2), (3), and (4) are not easily detectable as separate, diffusions (1) and (5) are definitely different processes from the rest. The time duration necessary for etching is schematically shown in **Figure 4** for two cases: one for fast reaction cases and another for slow reaction cases.

In the case of fast reactions, the etching species always becomes limited near the solid surface. Materials transfer in the solution is a key to accelerate the etching process. The process is dominated by diffusion. Such a process is called diffusion-limited process as shown in **Figure 4**. The silicon etching process uses a mixture of HF, HNO_3, and CH_3COOH, as given in **Table 1**. Because the chemical reaction is so fast, the surface always suffers from the lack of an etching species. Due to the isotropic nature of diffusion in liquid, the etching profile change becomes isotropic for the diffusion-limited etching process. When one wants to enhance the etching, it is effective to stir the etching solution. This enhances the supply of the etching species.

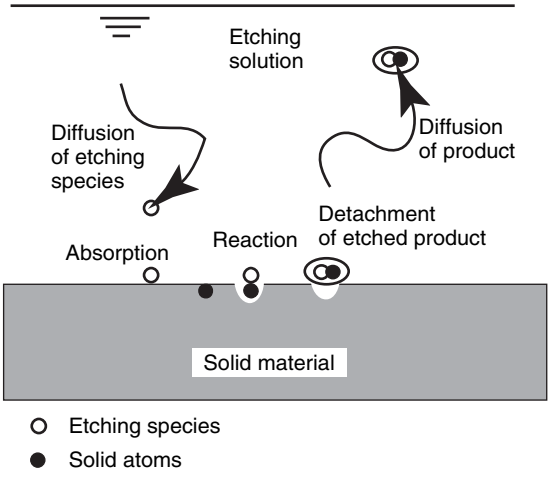

Figure 3 Series of processes that take place during wet etching.

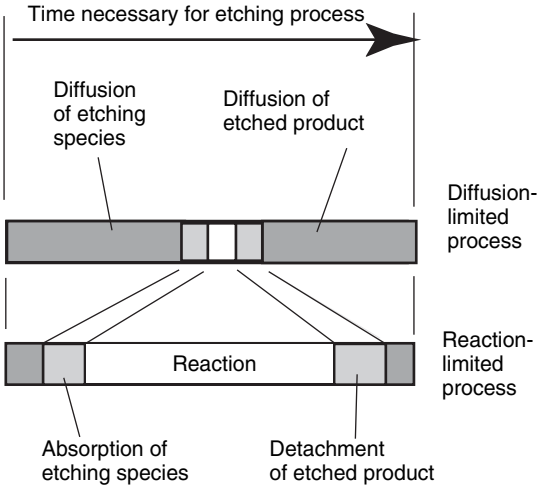

Figure 4 Comparison of diffusion-limited and reaction-limited processes in time domain.

However, it is difficult to achieve uniform flow velocity in omnidirections over the silicon wafer surface. Uniformity in etching profile usually deteriorates because of the stirring motion. An example is the silicon acoustic lens, which has a concave lens profile etched by using this method, as mentioned in Section 1.07.3. Excellent uniformity and sphericity of the lens profile were obtained by stopping the stirring agitation, i.e., by sacrificing etch rates as a trade-off.

On the other hand, in a slow reaction process, i.e., in the case of alkaline etching of silicon using KOH, tetramethylammonium hydroxide (TMAH), and ethylenediamine (EDP) (**Table 1**), the dominant process is the reaction shown in **Figure 4**. Such a system is called reaction-limited process. Now the different reactivities among different crystallographic orientations become obvious. As mentioned in the next two sections, the etch rates for (100) and (111) silicon, using a KOH water solution, differs by nearly 2 orders of magnitude. This is because of the difference in the chemical activeness of the crystal surface having different surface morphologies due to the crystal lattice structure. Even in the case of an isotropic system, such morphological difference exists for single-crystal silicon surfaces, and actually in a $HF/HNO_3/CH_3COOH$ system, a small amount of anisotropy can be observed in the geometry of the etched cavity on a single-crystal silicon, which is discussed in Section 1.07.3. It is understood from **Figure 4** that sometimes the reaction part is not negligible, even in the case of diffusion-limited processes.

1.07.3 Isotropic Etching of Silicon and Related Materials

Isotropic etching is a process in which etching advances in normal to solid surfaces with a uniform etch rate at any place on the substrate except on the masked surface, as has been discussed in Section 1.07.2. Examples of isotropic etching solutions are given in Table 1. The isotropic etching solutions are very reactive chemicals for work materials. Thus, the etching system becomes a diffusion-limited process.

Silicon is isotropically etched with a mixture of HF, HNO_3, and CH_3COOH water solution. Etching advances according to the following series of reactions:

$$HNO_2 + HNO_3 \rightarrow 2HNO_2 + 2OH^- + 2h^+$$

$$Si + 2H_2O + 4h^+ \rightarrow SiO_2 + 4H^+$$

$$SiO_2 + 6HF \rightarrow H_2SiF_6 + 2H_2O$$

The first equation explains that HNO_3 generates OH^- and holes. The second equation is the oxidization of silicon by the holes. In the third equation silicon dioxide is dissolved by HF. The CH_3COOH added in the mixture is used to moderate etching reactions. Depending on the ratio of these three components, the etch rate drastically changes as shown in Figure 5.

In Figure 5, photographs of the top view of the etched cavity starting from a small circular mask aperture are shown. They are of quasi-round profiles, reflecting the isotropic nature of the etching system. The profile of the cavities is the etching fronts deeply undercutting the mask apertures.

When the profile of the cavities etched with different fractions of three components is compared, a cavity etched under the condition A has a slightly square shape representing an anisotropic nature. On the other hand, the one etched under condition C is isotropic, though the bottom of the cavity is not as smooth as the other that provides clear reflection of the illumination from the bottom. Thus, isotropy and surface smoothness are in a trade-off relationship. It is recommended that a mixture of 49 wt.% HF:69 wt.% HNO_3:CH_3COOH with a volume fraction of 2:3:3, as given in Table 1, and an etching temperature at 50°C (Hashimoto *et al.* 1993) for compromising the isotropy and surface smoothness be chosen.

Isotropic etching solution for SiO_2 is HF water solutions. A concentrated 49% HF solution rapidly etches SiO_2 with an etch rate of 1.8 μm min^{-1}. Instead of such a strong etchant, buffered HF (BHF) is usually used to etch an SiO_2 film, which is deposited on silicon wafers by thermal oxidization or CVD processes. Typical components are 49 wt.% HF + 50 wt.% NH_4F with a volume fraction of 1:6

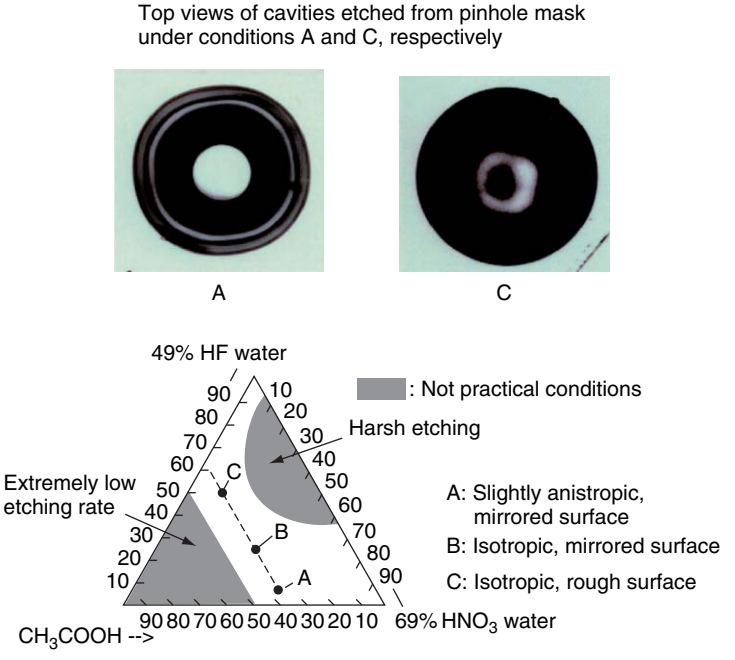

Figure 5 Etching characteristics change based on the change in relative ratio in the HF–HNO_3–CH_3COOH system.

or 49 wt.% HF + 40 wt.% NH_4F with a volume fraction of 1:7. Etch rate is about 0.1 μm min^{-1} at room temperature. This is a mild solution, in contrast to a concentrated 49 wt.% HF solution.

It is widely used for removing SiO_2 films. It is also used as an etchant for releasing polycrystalline silicon microstructures from a silicon substrate during surface micromachining. In such a case, etch rate of the sacrificial layer of SiO_2 can be enhanced by doping P, and in some cases by also doping B, to the oxide film. Phosphosilicate glass (PSG) and boron-doped PSG (BPSG) are removed by the diluted HF solutions. Addition of up to 50 vol.% HCl to the diluted HF is recommended for enhancing the etch rate ratio of the sacrificial glass layers of the structure materials such as polycrystalline silicon and silicon nitride.

Isotropic etching solution for Si_3N_4 is H_3PO_4 water solution at an elevated temperature of 160–180°C. Positive photoresist materials cannot withstand such a harsh condition. Some negative photoresists are used for patterning Si_3N_4 films and an SiO_2 film deposited on the nitride is also used as a mask material against hot H_3PO_4 solution.

Isotropic etching is not widely used in micromachining, because substrates cannot be deeply etched using this system that results in a heavy side etching that deteriorates fine mask patterns. In exceptional cases, such as when fabricating hemispherical concave cavities, an isotropic etching system is useful.

Isotropic etching is used for fabricating an acoustic lens on a silicon substrate (Hashimoto *et al.* 1993). The photographs of the silicon acoustic lens are shown in **Figure 6**. It has a concave profile at the tip whose radius is 55 μm with an excellent sphericity of 0.2 μm with a mirror-finished surface. It is mounted on a scanning acoustic microscopy system, and is used for focusing and receiving ultrasonic vibration at 1 GHz allowing an acoustic image resolution of 1.8 μm. The etchant used is a HF, HNO_3, CH_3COOH water solution. The periphery of the cavity is mechanically ground in a tapered shape using an abrasive grinding method.

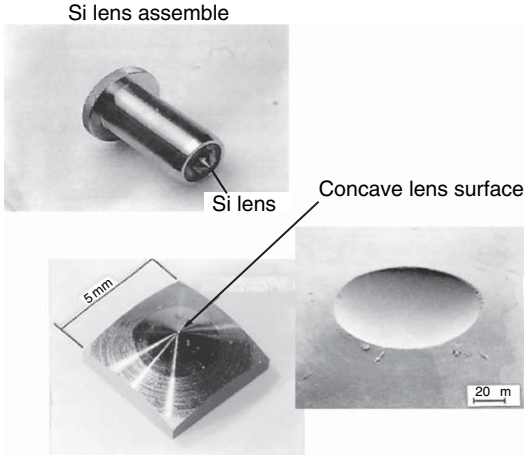

Figure 6 Isotropically etched silicon lens applied to an acoustic microscopy system.

1.07.4 Anisotropic Etching

Anisotropic chemical etching of silicon has been used for fabricating various micromechanical devices such as pressure sensors, acceleration sensors, ink-jet printing heads, and chemical analysis systems. As the (111) orientation of single-crystal silicon is chemically stable and has an extremely low etch rate when compared to other orientations, this type of etching system has been utilized to minimize undercut from a mask pattern edge during deep etching of silicon wafers. Only for such purposes, science in etching mechanism is of less importance than is developing practical technologies. Practical technologies such as etching solutions, mask materials, and etch stop techniques have been developed and widely utilized. However, depending on the increasing demands for dimensional accuracy of fabricated device, for quality of etched surface, and for fabricating various 3D structures, a deeper understanding of etching mechanisms is required.

The aim of this chapter is to give an overview of recent advances in anisotropic etching science as well as to introduce state-of-the-art technologies for MEMS microfabrication.

1.07.4.1 Anisotropic Etching of Silicon

Single-crystal silicon has a diamond lattice structure as shown in **Figure 7**. Each silicon atom has four covalent

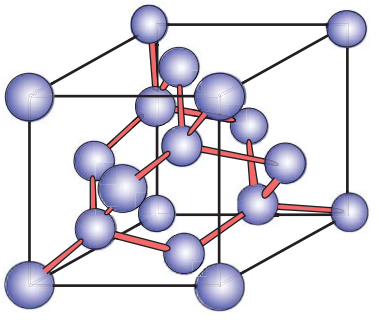

Figure 7 Diamond lattice structure of single-crystal silicon.

bonds. Each bond connects a different pair of atoms. Figure 8 compares three different surfaces cut from the same crystal. They are indicated by using the Miller index as (100), (110), and (111), respectively. When an atom is located on a surface, the bond belonging to the atom loses a neighboring atom. It is known as a dangling bond. The dangling bonds easily react with the etching agent. Though, in many cases, the dangling bonds do not remain free-ended, that is, the surface bonds are reconstructed by combining with each other in high vacuum, or the bonds are terminated with hydrogen atom in water, those bonds on the surface are still a source of surface reactions, i.e., etching.

When the number of dangling bonds on three differently oriented surfaces, (100), (110), and (111), are compared, it is apparent that the (111) surface has the smallest number of bonds (Figure 8). There is only one dangling bond per surface atom for (111), whereas there are two for (100), and one dangling bond plus two surface bonds for (110).

This is a conventional explanation for why (111) is stable against etching. It is partly true when the stability of the surface is discussed qualitatively. However, atom removal from perfectly flat (111) is a minor case that actually occurs on a crystal surface. In most of the cases, a large number of atoms are removed from atomic steps and kinks. Etch rate must be quantitatively discussed based on such dynamic models. It turned out that the conventional static model is insufficient to describe anisotropy in the etch rate for silicon. This is discussed later in this chapter.

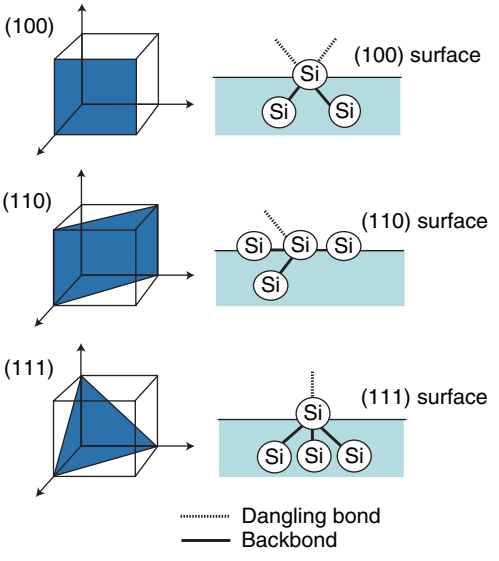

Figure 8 Number of backbonds and dangling bonds of a Si atom on a surface oriented at (100), (110), and (111).

1.07.4.1.1 Etching solutions

Solutions showing orientation dependence on the etch rate of silicon are KOH, TMAH, EDP (ethylenediamine and pyrocatecol), N_2H_4 (hydrazine), CsOH, and NaOH. All are used as water solutions. The chemical reaction for any of these etching solutions is described as follows:

$$Si + 2OH^- + 2H_2O \rightarrow SiO_2(OH)_2^{2-} + 2H_2$$

Silicon reacts with water and an OH^- ion and produces hydroxide ion and hydrogen gas bubbles.

Etching masks are usually made of either SiO_2 or Si_3N_4. The Si_3N_4 mask is excellent in terms of etching selectivity, but when compared to an SiO_2 mask it is not easy to apply on and to remove from the wafer surface. Photosensitive resist films are not durable against etching. Metals such as Ni are sometimes used as a mask material. However, one has to be careful against contamination of solutions with metallic ions, which may deteriorate etching properties such as etched surface roughness and etch rates.

Selection of the etching solutions is made by the following guidelines.

1.07.4.1.1.(i) KOH KOH shows strong anisotropy, and shows large values of etch rate ratios among orientations of about 100 as listed in Table 2 (Shikida *et al.* 2000). It means that high controllability can be expected in etched profiles, while suppressing mask undercut. KOH solutions are less toxic than other etchants. Exhaust solutions after use are easy to process. These are the main reasons why KOH is widely used for fabricating silicon microstructures in industry.

A drawback with KOH is that an SiO_2 mask is significantly etched during a long etching time. Selectivity of Si to SiO_2 mask is about 150 under normal conditions. Another drawback is that KOH etching is incompatible to IC processes because contamination with potassium ion is strictly prohibited in IC processes. Though KOH etching is possibly separated from an IC process, and potassium ion can be removed from the device surface by appropriate rinsing, care must be taken when the microstructure is integrated with electronics circuits.

1.07.4.1.1.(ii) Tetramethylammonium Hydroxide Tetramethylammonium hydroxide (TMAH) is the second major etchant, although it has only recently been introduced (Tabata *et al.* 1991). It is a counterpart of KOH. Etching rate ratios among orientations are

Table 2 Anisotropic etch rates for KOH and TMAH solutions

	Etch rate ($\mu m\,min^{-1}$)		*Etch rate normalized by that for (100)*	
Orientation	*34wt.% KOH (70.9°C)*	*20wt.% TMAH (79.8°C)*	*34wt.% KOH (70.9°C)*	*20wt.% TMAH (79.8°C)*
(100)	0.629	0.603	1.000	1.000
(110)	1.292	1.114	2.054	1.847
(210)	1.237	1.154	1.967	1.914
(211)	0.983	1.132	1.563	1.877
(221)	0.586	1.142	0.932	1.894
(310)	1.079	1.184	1.715	1.964

(331)	0.845	1.099	1.343	1.823
(530)	1.273	1.097	2.024	1.819
(540)	1.283	1.135	2.040	1.882
(111)[a]	0.009	0.017	0.014	0.027

[a]Etch rates for (111) were too small to be measured from the spherical surface. It was separately measured from groove width increments during deep groove etching on Si (110) wafer (Shikida *et al.* 2000).

less than that of KOH: about one half of KOH for (100)/(111) and (110)/(111) as listed in **Table 2**. TMAH is more expensive than KOH. When the solution is exposed to air containing CO_2 for a long period, the etching characteristics deteriorate.

In spite of the above drawbacks, TMAH has reasons for being accepted by industries. TMAH does not etch nitride mask at all. It attacks SiO_2 mask at an extremely low rate of 15 nm h^{-1} at 90°C (Tabata *et al.* 1991). It does not contain any harmful species to electronics circuits. SiO_2 mask can be easily used for deep silicon etching. One can also design fabrication processes including TMAH etching as an IC-compatible process.

1.07.4.1.1.(iii) Ethylenediamine and others In the early period of micromachining, EDP was widely used. It shows high etching ratios among orientations. A big advantage over KOH solution is that EDP is compatible with IC fabrication process. However, TMAH, EDP, which is also compatible with IC, is used in the micromachining process; this advantage became an absolute reason for selecting this etchant. It is toxic to the human body, causing cancer. Hydrazine is also toxic and inflammable.

1.07.4.1.2 Etching shapes

Etching shapes are categorized into two: one is concave-etched profiles and the other is convex-etched profiles.

Concave-etched profiles on silicon wafers have been fabricated so far for applications in pressure sensors and ink-jet printer head structures. Examples are shown in **Figure 9**. In the case of concave profiles, orientations having an etch rate that is locally minimum appear. Si (111) is the only orientation that has an etch rate of a local minimum for any etching conditions. One can find Si (111) as sidewalls of deep groove on Si (110), and tapered sidewalls on Si (100) in the figure. Depending on the etching conditions, other orientations sometimes show a locally minimum etch rate among other orientations. Si (100) often shows a local minimum for KOH and TMAH water solutions, but does not in cases of EDP, or KOH with isopropanol, or TMAH with a surfactant. In summary, examples of an etched profile obtained by anisotropic etching on an Si (100) wafer are schematically shown in **Figure 10**. The examples of an etched profile obtained on Si (110) wafer are also shown in **Figure 11**. Note that the etching profile is different for different etching solutions. This means that characterization of anisotropy

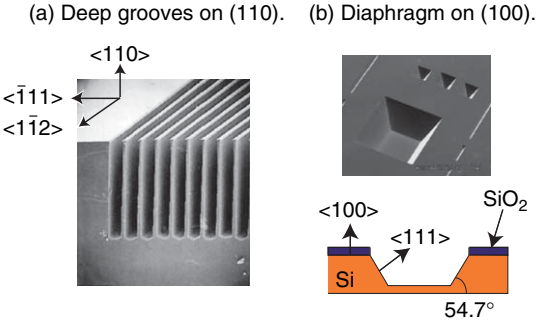

Figure 9 Examples of anisotropically etched microstructures on single-crystal silicon substrates.

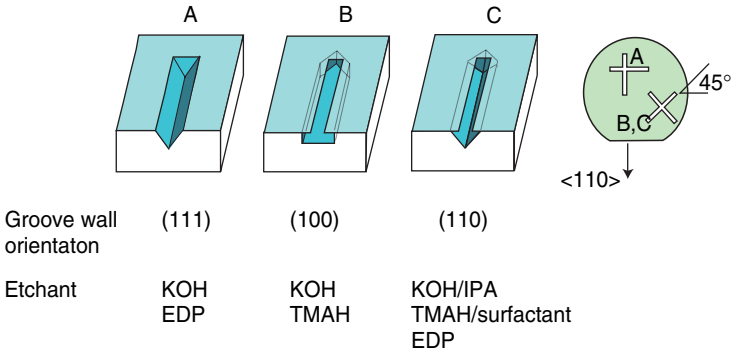

Figure 10 Emerging orientations appearing during groove etching of Si (100).

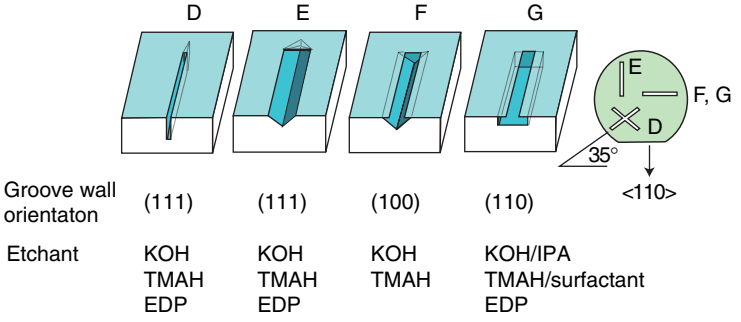

Figure 11 Emerging orientations appearing during groove etching of Si (110).

in etch rate is of importance for fabricating microstructures using wet anisotropic etching.

On the other hand, convex-etched profiles have been introduced for applications as shown in Figure 12. This is an array of silicon needles etched on a Si (100) wafer for the purpose of transdermal drug delivery. The needle profile is defined by fast etching orientations using a KOH solution, i.e., by (110) and others. In case of convex profiles, orientations having an etch rate that is locally maximum appear. It becomes far more difficult to predict and to control etch profiles having large etch rates. Again, characterization of anisotropy in etch rate is of great importance.

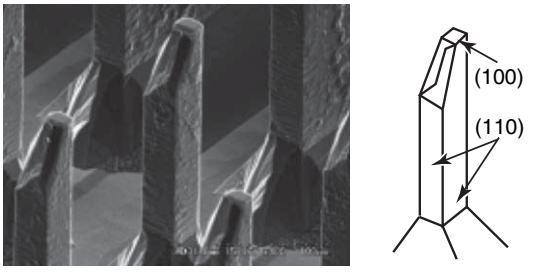

Figure 12 Fast etching orientations emerging as a convex etching profile in case of needle fabrication on Si (100). (Source: Cheng D, Gosálvez M A, Hori T, Sato K, Shikida M 2006 Improvement in smoothness of anisotropically etched silicon surfaces: Effects of surfactant and TMAH concentrations. *Sens. Actuators*, **A125**, 415–21.)

1.07.4.1.3 Masking materials

Most popular etching mask materials for alkaline solutions such as KOH and TMAH are SiO_2, Si_3N_4, and SiN. These materials are deposited on a silicon substrate by various deposition methods. It is required that the deposited films be free from pinholes. Thermal oxidation processes for SiO_2, and high-temperature CVD process for Si_3N_4, are recommended from the above requirements. Low-temperature physical vapor deposition (PVD) and plasma-enhanced chemical vapor deposition (CVD) sometimes cause trouble because the deposited film is not durable against an etchant.

In the case of KOH etching, the etch rate of SiO_2 is not negligible as shown in Figure 13, even if it is a thermally grown oxide. The etching ratio of Si to SiO_2 is about 150 at 70°C. This value is not as high as that of Si to Si_3N_4 or SiN. Deep silicon etching, such as when penetrating whole-wafer thickness about 400 μm, requires a thick layer of SiO_2 of about

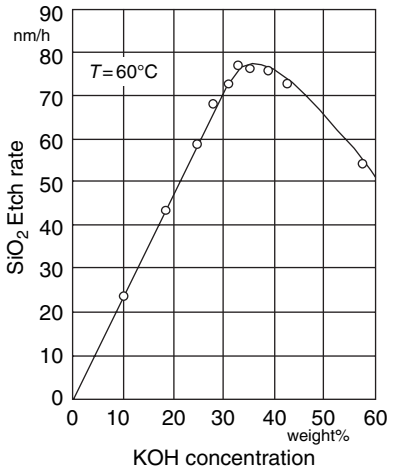

Figure 13 Etch rate of SiO_2 at 60°C as a function of KOH concentration. (Source: Seidel H, Csepregi L, Heuberger A, Baumgärtel H 1990 Anisotropic etching of crystalline silicon in alkaline solutions, I. Orientation dependence and behavior of passivation layers. *J. Electrochem. Soc.* **137-11**, 3612–26.)

2.5–3 μm. This is a disadvantage of SiO_2 – but advantages are easy to grow by thermal oxidation and easy to remove using HF-based solutions. On the other hand, Si_3N_4 is superior in terms of etching selectivity, but is not easy to remove. For the removal of Si_3N_4, a hot H_3PO_4 solution at an elevated temperature of 160–180°C is required. Silicon oxide or some negative photoresists are durable for such harsh etching conditions.

In case of TMAH etching, both SiO_2 and Si_3N_4 are excellent materials in terms of etching selectivity (Tabata *et al.* 1991). Thus, SiO_2 is recommended as a mask material for TMAH etching, because of the easiness of its deposition and removal.

Metallic films such as Ni and Pt are also durable against alkaline etching. However, it is not strongly recommended that metallic masks be used, because metallic ions in alkaline solutions often deteriorate etching qualities such as surface roughness and etch rates. Change in surface roughness as well as in etch rate caused by metallic contamination on the order of ppb level was recently reported by Tanaka *et al.* (2003).

1.07.4.1.4 Anisotropy as a function of orientations

Some work has been reported on the characterization of the orientation dependence in the etching of single-crystal materials. Ueda *et al.* (1986) measured the decrease in the thickness of quartz wafers having different surface orientations. This was the most direct method of evaluating anisotropy in etching. However, a dense net of data as a function of orientation is hard to accumulate because of the numerous experiments required for a single etching condition. Weirauch (1975) measured the undercut length distribution around a circular mask pattern made on a silicon wafer. Seidel *et al.* (1990) and Kendall *et al.* (1982) also measured the undercut length, not of a circular mask but of a sharp vertex of triangular mask pattern. Because a number of triangular mask patterns are densely located in a rotational position with respect to each other on the same wafer, this type of measurement was called the wagon-wheel method. An etched example of the wagon-wheel is shown in **Figure 14**. Though these mask undercut measurements were effective for qualitative visualization of anisotropy, the obtained data did not necessarily show correct etch rates, because the side-etched planes were not always perpendicular to the wafer surface. Measurements of the tilting angle of the wall were necessary for quantitative characterization, as shown in **Figure 15**.

The use of a hemispherical single-crystal silicon specimen, as shown in **Figure 16**, was proposed for the measurement of anisotropy in etch rate by Sato *et al.* (1998). Crystallographic orientations appear on the hemispherical surface, which is mechanically ground, lapped, and polished into a mirror. Etch rates for any orientation can be calculated from the dimensional change before and after etching of the spherical surface. The radius of the hemisphere is 22 mm, which is large enough when compared to the etch depth. This allows interference among

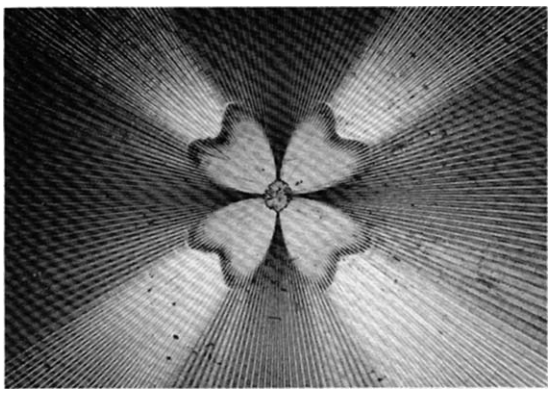

Figure 14 Enlarged top view of the wagon-wheel pattern after etching for visualizing anisotropy as a planer distribution. Figure 18 An etch rate contour map as a function of orientation for 40% KOH (34wt.% KOH) at 70°C.

orientations, i.e., the disappearance of some orientations from the surface is negligible.

A comparison of hemispherical specimen surfaces before and after etching is given in **Figure 17**. Though the maximum etching depth was about 150 µm, one can observe anisotropy with naked eyes, i.e., three-time symmetry around (111) and four-time symmetry centered by (100) are visible on the specimen. An etch rate contour map for 40% KOH (34wt.% KOH; commercially available KOH grains contain 85wt.% KOH and 15wt.% water of crystallization) at 70°C is shown in **Figure 18**. The contour map is a projection of the hemispherical specimen surface whose top is orientated to (100).

It is clear that a deep minimum in etch rate is located at (111), shallow local minimum at (100), and relatively high values at (110). There are also saddle points on the map.

However, the contour map pattern is not consistent among different etching conditions. The measured etch rates as a function of orientation are listed in **Table 2** for KOH and TMAH water solutions. The concentrations and etching temperatures are selected so that the etch rate of Si (100) becomes almost equal for KOH and TMAH.

The etch rate contour maps for KOH and TMAH are compared in **Figure 19**. It can be observed that for both etching solutions the local minima in etch rate exist at (111) and also at (100), though the valley of (111) is much deeper than that of (100). The difference is that the triangular contour patterns around (111) are rotated by 60° between KOH and TMAH. This clearly means that anisotropy is not only uniquely determined by silicon crystal lattice structure, but also by the interactions between chemicals in solution and silicon surface.

1.07.4.1.5 Technologies for controlling etching shapes

There are various recipes that can provide different etching results. When a micromechanical structure is designed, etching profiles can be controlled by introducing the following technologies.

1.07.4.1.5.(i) Etching species and concentrations Etching shape becomes different when the etching solution, i.e., the etching species, and concentrations differ. KOH and EDP showed different groove profiles from each other, as shown in **Figures 10** and **11**.

Deep groove profiles etched on a Si (110) wafer differ also between TMAH and KOH, as graphically analyzed using Wulff–Jaccodine's construction (Jaccodine 1962), as shown in **Figure 20**. The analysis is based on the principle that among a number of

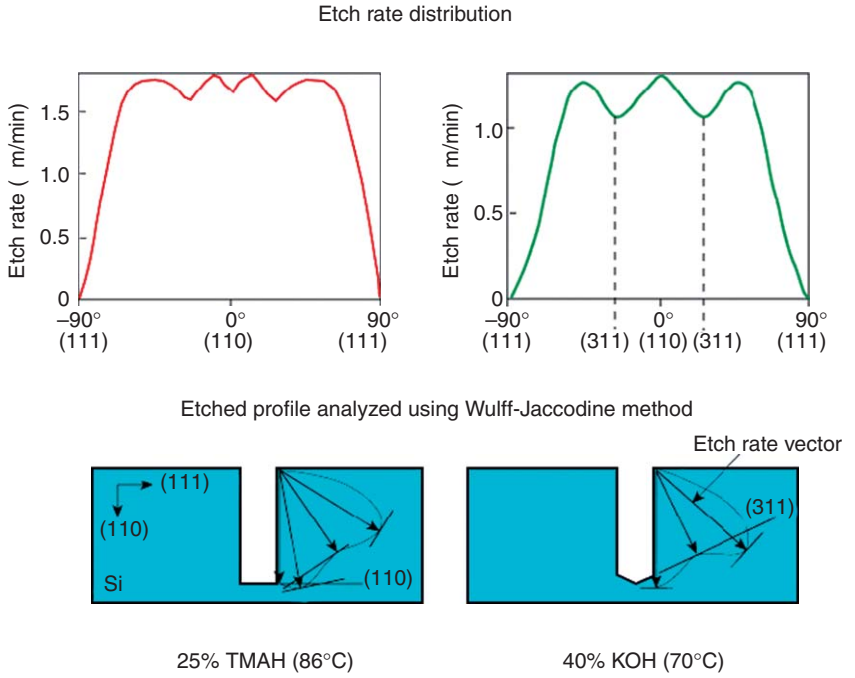

Figure 20 Comparison of etch profiles of deep grooves on (110) etched by using KOH and TMAH, respectively. (Source: Sato K, Shikida M, Matsushima Y, Yamashiro T, Asaumi K, Iriye Y, Yamamoto M 1998 Characterization of orientation dependent etching properties of single crystal silicon: Effects of KOH concentration. *Sens. Actuators A* **64–1**, 87–93.)

potential etching profiles, drawn perpendicular to the etch rate vectors, only a set of profiles that minimize the total surface energy composes a real profile. The results show that the bottom surface of the groove is flat for TMAH and wedge-shaped for KOH. This is because the etch rate vector distribution in the groove cross section differs between two etchants. In case of KOH, a local minimum in etch rate at (311) is deeper than that of TMAH. Thus the (311) orientation appears as the groove profile with KOH, whereas (110) appears with TMAH.

Similarly, a change in solution concentration also results in different etch profiles. Only by the difference in KOH concentration, the groove bottom profile becomes different, as shown in **Figure 21**. The reason is again that the etch rate contour map differs by the difference in KOH concentration (Sato *et al.* 1998). In such cases, it is important to select etching conditions to control etched profiles. An etch rate contour map is necessary for predicting etched profiles.

1.07.4.1.5.(ii) Effects of additives in etching solutions Some additives are used aimed at the following two effects.

(1) Suppressing mask corner undercut without using compensation mask patterns.
(2) Obtaining a smooth etched surface on (110).

It is known that some types of alcohol such as isopropyl alcohol (IPA) added to KOH water solution are effective in minimizing mask corner undercut on (100) silicon. It is also effective in reducing etched surface roughness of the (110) surface. As the (110) plane appears as a result of (100) wafer etching and makes an angle of 45° from the wafer surface, an addition of IPA to the KOH solution was proposed for fabricating a 45° mirror for the purpose of reflecting a light coming out from an optical fiber on the wafer in a direction perpendicular to the wafer surface (Bäcklund and Rosengren 1992).

In order to get a sufficient effect, IPA must be dissolved to a saturation level in KOH water solution. On the other hand, some surfactant added to TMAH shows similar effects, even if the concentration is as low as a few percent. Sekimura (1999) reported the striking effects of a small amount of surfactant polyoxiethylene-alkyl-phenyl-ether (commercial code name is NCW, a product of LION Ltd.) added to the TMAH solution.

Figure 22 shows the effects of surfactant added to TMAH (Sato *et al.* 2001). The rectangular mask corner has been severely undercut by pure TMAH solution, whereas the corner was little etched by TMAH with a surfactant NCW. The undercut at the mask corner depends on the relative etch rate of (110) among other orientations. As shown schematically in **Figure 22** (*top*), the ridge developing from the mask corner is the intersection of two (111) planes. The ridge is on the (110) plane, or more precisely on ($j\,j\,1$), where j is an integer. When the etch rate of (110) or ($j\,j\,1$) decreases when compared to that among other orientations, the mask corner undercut is suppressed. This happens by the addition of NCW, as shown in **Figure 23**. The advantage of surfactant/TMAH over IPA/KOH is that the amount of the additive being effective is as low as

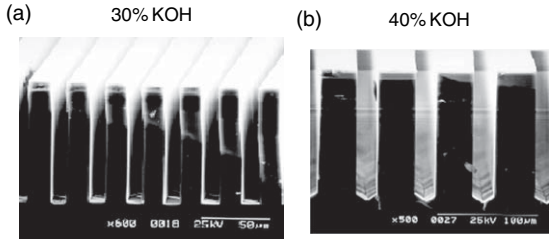

Figure 21 Influence of KOH concentration on the deep groove profile on (110). (Source: Sato K, Shikida M, Matsushima Y, Yamashiro T, Asaumi K, Iriye Y, Yamamoto M 1998 Characterization of orientation dependent etching properties of single crystal silicon: Effects of KOH concentration. *Sens. Actuators A* **64–1**, 87–93.)

Mater.* **13-5**, 285–91.)

2% volume fraction. However, the surfactant does not work as well with KOH as it does with TMAH.

1.07.4.1.5.(iii) Compensation mask patterns

Mask corner undercut during etching of mesa structure on Si (100) is often a problem as mentioned above, and efforts have been done to minimize it. One of the solutions is to use a mask having additional masked areas that can delay the corner undercut. The examples of mask corner compensation pattern are shown in **Figure 24**. One is a square pattern (**Figure 24(a)**) whose center is located at the corner of the original mask, and another is an oblique pattern (**Figure 24(b)**) whose sides are angled at 45° from the <110> directions.

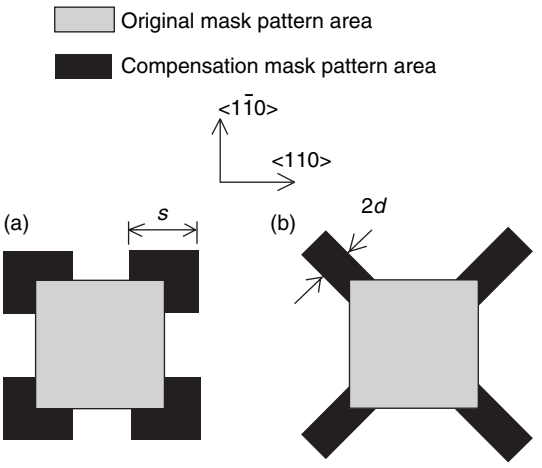

Figure 24 Examples of compensation mask patterns for minimizing mask corner undercut for Si (100) etching: (a) square and (b) 45° oblique.

With a square compensation pattern (**Figure 24(a)**), based on time increments, the underetch advances from the periphery of the small square pattern to the center. Until the etch-front reaches the center of the square, the original mask corner survives. The etch profile change under the square compensation pattern is shown in **Figure 25**. The size of the square pattern s in **Figure 24(a)** needs to be designed based on the etching simulation shown in **Figure 25**, or by experimental trials. Another disadvantage is that the bottom periphery of the etched mesa does not become rectangular, though the masked top of the mesa is perfectly rectangular as shown in **Figure 25**.

In case of 45° oblique pattern (**Figure 25(b)**), one has to use pure KOH or TMAH that has local minimum in etch rate at (100) orientation. One should not use additives that make the local minimum at (110). The reason is that the oblique pattern aims at the etched sidewall along oblique sides to become perpendicular to the wafer surface. Because the sidewalls are oriented to (001), the side etching (undercut) from the oblique sides advance with the same rate as that normal to the wafer surface. The width of the oblique bar should be designed as $2d$, where d is the

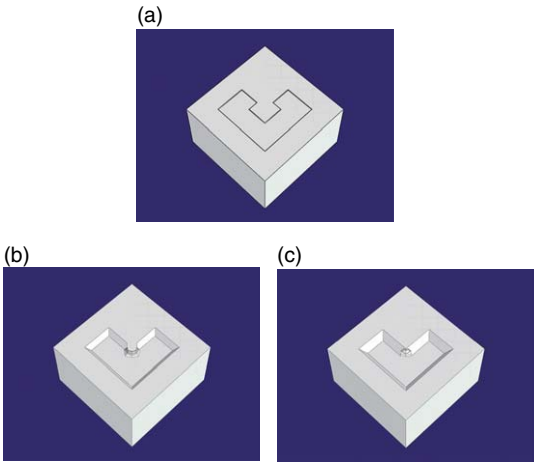

Figure 25 Effects of a square compensation mask pattern suppressing mask corner undercut. (a) Initial mask pattern, (b), (c) etched profiles as time sequence. Simulation results using MICROCAD (FabMeister-ES). (Source: Sato K, Asaumi K, Kobayashi G, Iriye Y, Shikida M 2000 Development of an orientation-dependent anisotropic etching simulation system MICROCAD. *Electron Comm. Jpn. Part 2* **83–4**, 13–22.)

etch depth. When the etch depth reaches the value d, the compensation pattern entirely disappears. An oblique pattern has advantages such as a simple design rule and an excellent finished etch profile. One disadvantage is that when the compensation pattern has to be connected to the neighboring mask pattern because of the lack of space around the island mask pattern, the compensation structure does not disappear easily from the wafer surface. One should carefully estimate the residual structure size in such a case.

1.07.4.1.5.(iv) Multisteps of etching using different mask patterns A single step of etching provides only simple etch profiles composed of (111), (100), or (110), which are orientations existing at a local minimum on a etch rate contour map. When the etching is interrupted and the masked area is replaced with a pattern different from the previous one, different etched profiles become available.

The example is a two-step etching fabricating a round profile at the base of a cantilever on a (100) wafer. The process is shown schematically in Figure 26. The first etching makes a preform of the cantilever much shorter than the final length. The second etching is applied with a mask for the final length of the cantilever structure. When a step profile made by the first etching is totally exposed to etching, the step profile changes during the second etching until it disappears. Just before the disappearance of the step, one can obtain a smooth round profile at the base. The design issues are first and second etch depth and offset length between the first and the second mask. This should be done by an etching simulation system, as described in the following section.

By applying this process, a cantilever beam having a round profile at the base was fabricated, as shown in Figure 27. The round profile was formed both at the top and at both sides of the cantilever base (Koide *et al.* 1992).

It is of course difficult to apply a photolithography process once the wafer surface becomes nonflat by the prior etching process. In order to avoid the difficulty in applying the photoprocess, in particular, the resist coating process, a layered mask process is recommended. Different mask patterns are layered by using different mask materials before silicon etching. When the first etching is finished using the first mask pattern, only the first layer is removed. Then the second mask pattern emerges on the wafer surface, and the second etching is ready to start. The process limitation is that the mask opening pattern must be larger than that of the mask used in the prior etching process to avoid interference between mask patterns. Mask materials should be preferably different from the viewpoint of etching selectivity. However, even with the same material like SiO_2, one can create a layered mask structure by varying the thickness. In the case of the cantilever in Figure 27, three layers of masks of the same material SiO_2 were used for fabricating an acceleration sensor chip (Koide *et al.* 1992).

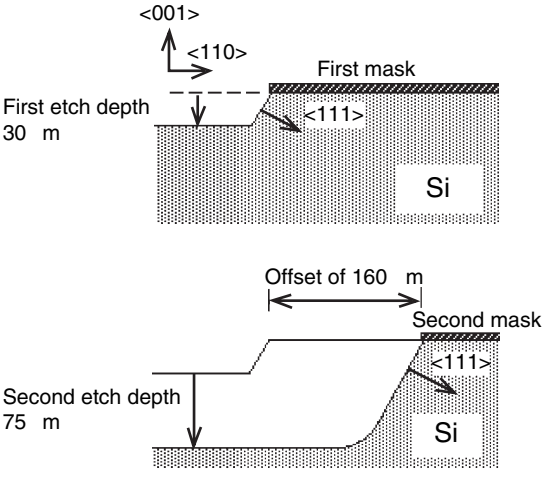

Figure 26 Two-steps etching process fabricating a round profile at the base of a structure extending to <110> direction on a Si (001) wafer.

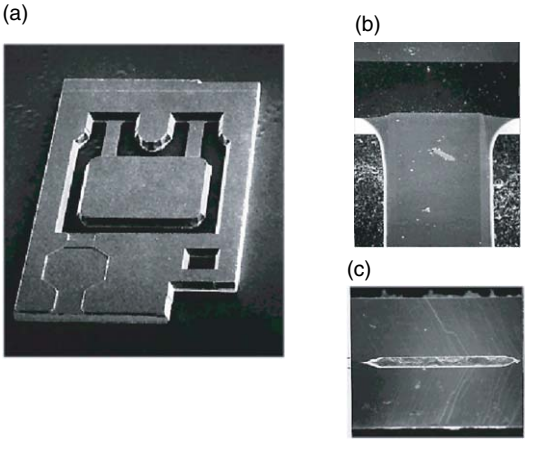

Figure 27 Acceleration sensor structure having a round profile at the base of a cantilever fabricated by using three steps of KOH etching. (a) Total view of the chip, (b) an enlarged view of the cantilever base top, (c) cross section of the beam 15 μm thick.

1.07.4.1.5.(v) Etching from both sides of the wafer Etching profiles show more variations, when the etching is applied from both sides of the wafer. In the previous section, such a process was applied for the acceleration sensor chip in **Figure 27**. Once the etching fronts meet in the middle of the wafer, etching can easily advance in lateral directions as well as in the thickness direction. Thus a 3D microstructure can be fabricated. More examples will be presented in Section 1.07.4.2.

1.07.4.1.5.(vi) Etch Stop techniques An etch stop technique is often required for controlling the thickness of etched structures. The simplest way of controlling etched thickness is by controlling the etching time. This is possible because of the high uniformity in etching depth due to the reaction-limited etching process, in particular, by using KOH solutions under good temperature control in the etching bath. Etch depth variation over the wafer is usually less than 1 μm after hundreds of microns of deep etching. This is an advantage over deep dry etching. However, because of the nonuniformity in initial wafer thickness depending on the wafer suppliers, the resulting membrane thickness may become less uniform than the etch depth.

Besides etching time control, some etch stop techniques are used for the control of the etched depth or etched membrane thickness. They are (a) p^{++} etch stop, (b) electrochemical etch stop using p–n junction, and (c) silicon-on-insulator (SOI) wafer. They are explained in the following section.

1.07.4.1.5.(vi).(a) p^{++} etch stop When silicon is heavily doped with boron to a concentration in the range of 10^{19} (cm^{-3}) or more, the etch rate decreases drastically. The etch rate as a function of doping concentration is shown in **Figure 28** (Seidel *et al.* 1990). When the front side of a wafer is heavily doped with B, and etched from the rear side of the wafer, the p^{++} layer remains as a membrane or cantilever structure, as shown in **Figure 29**. The thickness of the highly doped layer is in the range of a few micrometers. This was utilized from the early stage of silicon micromachining. However, the application was limited because of the following drawbacks.

When an impurity like B is highly doped in the range mentioned above, silicon is no more a semiconductor but becomes a conductor. Electronics circuits cannot be integrated on the same surface. This is a disadvantage for MEMS applications, where integration of mechanical and electrical functions is expected.

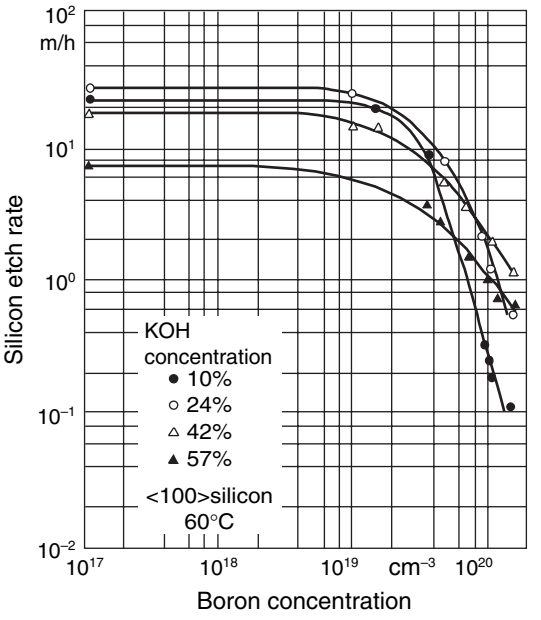

Figure 28 Influence of B-doping concentration on the etch rate of Si (100) using KOH solutions. (Source: Seidel H, Csepregi L, Heuberger A, Baumgärtel H 1990 Anisotropic etching of crystalline silicon in alkaline solutions, II. Influence of dopants. *J. Electrochem. Soc.* **137-11**, 3626–32.)

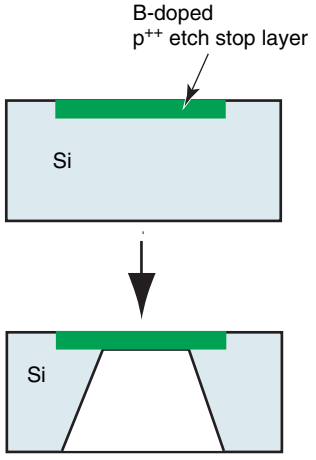

Figure 29 p^{++} etch stop technique applied to fabricate a membrane on a wafer surface.

Highly doped silicon shows high residual stresses. In the case of boron, the residual stress is in the tensile region. Microstructures having internal stresses distributed in the thickness direction show a significant amount of bending or warping deformation. Minimization of the internal stress is thus of

importance. It is reported that germanium as an impurity also shows etch stop properties, whereas the residual stress is compressive. A combination of boron and germanium doping is reported to achieve etch stop and low residual stress at the same time (Seidel *et al.* 1990).

Controllability of an etch stop with p^{++} heavy doping is not perfect. When the doping concentration profile in the depth direction is not sharply defined, e.g., by the annealing process after doping, the thickness of the etch stop layer is not clearly defined.

1.07.4.1.5.(vi).(b) Electrochemical etch stop using p–n junction Contrary to the drawbacks of the p^{++} etch stop technique, the electrochemical method allows a perfect etch stop with an accuracy of about 0.1 μm in thickness. The principle of this technique is as follows. When a wafer is etched in an alkaline solution the electric potential of the wafer is balanced in a range of −1.5 to −1.1 V depending on the dopant type of silicon, illumination, etc. This potential is called open-circuit potential (OCP). When a positive electric potential is applied to a silicon wafer that is higher than that of the etching solution by 2–3 V, silicon oxide is generated on the surface and etching stops. To form the oxide film, electric current is required to flow from the wafer to the solution. For the purpose of achieving the etch stop, p-type substrate having an n-epitaxial layer is placed in the etching solution so that the etching advances from the p-type side, as shown in **Figure 30**. The p-substrate is etched until the etching front reaches the p–n junction, because electric current cannot flow to the solution because of the existence of the p–n junction. Once the etching front meets the n-layer, current start to flow and passivation is completed. The membrane thickness is determined by the n-type layer that can be well controlled by the epitaxial growth process (Kloeck *et al.* 1989).

In order to perform this technique for production, the following practical techniques are needed as engineering skills. Leakage current at the wafer periphery must be strictly avoided. It will cause an etch stop at an earlier stage of etching than expected. Good surface finish and protection from electric shortage are required at the periphery of the wafer, where the p–n junction is exposed to air. Also, the potential of the p-doped substrate should preferably be monitored and controlled for the stabilization of the process. Making an electrical contact with one of the silicon layers needs a specially designed wafer holder equipped with a good sealing against etchant and must be easy to operate.

By applying this technique, Epson has developed an ink-jet head having densely arrayed membrane pumps. They fabricated a Si membrane, 2.15 μm thick, with an accuracy of ±0.35 μm in production, where the deviation 3σ of the thickness over a wafer was reported as only 0.35 μm (Kamisuki *et al.* 2000). The cross-sectional view of the membrane is shown in **Figure 31**. The substrate was Si (110), allowing deep etching for making a dense array of ink reservoir chambers.

1.07.4.1.5.(vi).(c) SOI wafer SOI wafers have been introduced rather recently to the MEMS community due to the increase in the supply boosted by the large scale integration (LSI) applications.

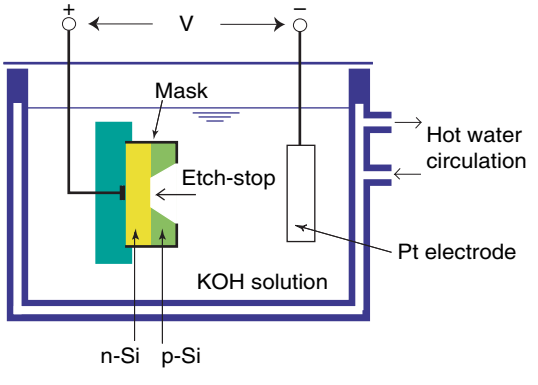

Figure 30 Electrochemical etch stop technique using p–n junction.

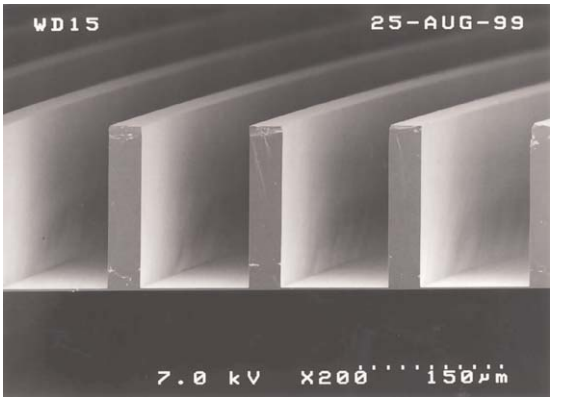

Figure 31 Membrane structure 2.15 μm thick etched on Si (110) fabricated by using electrochemical etch stop technique. It is used in a commercial ink-jet printer head as a membrane pump. Conf. on Micro Electro Mechanical Systems*, Miyazaki, pp. 793–8.)

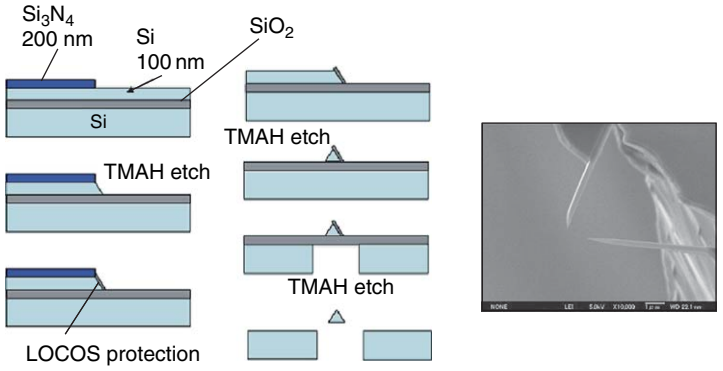

Figure 32 Twin probe of 200 nm diameter fabricated on a silicon-on-insulator (SOI) wafer. (Source: Kakushima K, Mita M, Kobayashi D, Hashiguchi G, Endo J, Wada Y, Fujita H 2001 Micromachined tools for nano technology – Twin nano-probes and nano-scale gap control by integrated microactuators. *Tech. Dig. 14th IEEE Int. Conf. on Micro Electro Mechanical Systems*, Interlaken, pp. 294–7.)

The wafer has a layered structure, i.e., single-crystal silicon layer, buried silicon oxide layer, and silicon substrate.

When etching is applied from the rear side of the substrate, etching stops at the buried oxide layer. Thus the micromechanical structures in the top silicon layer can be easily released from the substrate, after removal of the oxide layer.

Figure 32 shows a fabrication process to make a twin probe on a SOI wafer. The top layer is 200-nm-thick silicon. Probe tips are formed by applying two steps of TMAH etching from the front side. The structure is then released from the substrate by etching applied from the rear side. Thus a very thin probe 200 nm thick was fabricated (Kakushima *et al.* 2001).

1.07.4.1.5.(vii) Combination of wet etching with other processes Limitation in the etched profile using wet process is partly caused by a slow etching orientation, i.e., (111) emerging in the etching holes. This is the reason why a deep narrow hole cannot be etched on Si (110), while a narrow deep groove is possible to etch on (110). If the (111) or any other slow etching orientation is destroyed prior to etching, the limitation in the etched profile can be removed to some extent.

Büttgenbach and coworkers (Alavi *et al.* 1991) proposed the use of laser, and Shikida *et al.* (2004) proposed mechanical machining both for preprocessing the wafer before etching.

1.07.4.1.5.(vii).(a) Combination with laser beam processing Laser beam irradiated on the silicon wafer can remove the material by melting. However, the crystalline structure can be destructed with less energy than that needed for melting. By irradiating a laser beam in an area of mask aperture, single-crystal silicon structure can be destructed to some depth in the colored region, as shown in Figure 33. The wet etching is then applied as usual. The etched results are schematically shown in the figure. The colored regions are easily etched. Thus microstructures can be fabricated deep into the wafer. Note that the etched profiles are well defined by the mask aperture pattern width w, and not by the diameter of the spot size of the laser-influenced area. Also the laser-destructed regions are entirely removed after etching.

1.07.4.1.5.(vii).(b) Combination with mechanical dicing Conventional micromachining for fabricating silicon microstructures basically employs the following three technologies, mask material deposition, patterning the mask materials to define the etching area, and etching to form 3D structures. Such approach has the following two problems:

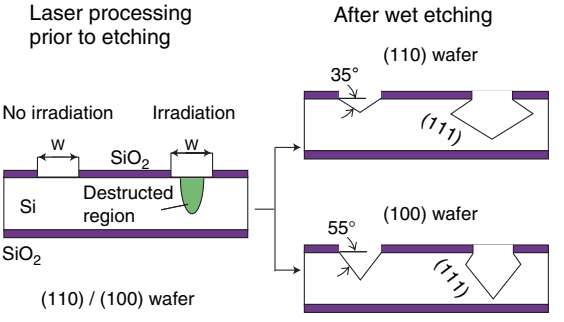

Figure 33 Combined process of laser processing and wet etching.

(1) Requirement of expensive equipment – The process needs an expensive photolithography machine, which is one of the most expensive equipments in MEMS fabrication, to be used to define the etching area on a Si wafer surface. It also requires that an expensive photomask be used in designing the microstructures. The number of masks required depends on what kind of devices MEMS researchers design from Si wafers. At least a few masks are required to fabricate 3D structures.
(2) Difficulty of high aspect ratio microstructure – The two factors, the crystal orientation of the Si wafer and the etch rate diagram, dominate the etched shape in the anisotropic wet etching process (Shikida *et al.* 2002). The wet etching process is intrinsically hard to fabricate high aspect ratio microstructures, because the etched shapes are determined by the crystal orientations of the Si wafer.

To overcome these problems, a different type of approach, which consists of mechanical diamond grinding with a dicing saw and anisotropic wet etching, in microstructure fabrications is proposed (Shikida *et al.* 2004a, b, 2006a, b). Mechanical dicing is used to form a 2.5D structure into a Si wafer instead of using the photolithography process, and anisotropic wet etching is then applied to transform it into 3D structures. The examples of biomedical applications to the microneedle formation are shown in the following.

The process is able to fabricate various shaped needle structures, for example pyramidal-, candle-, and spike-shaped needles, by repeating the use of the dicing and the wet etching process (**Figure 34**). The dicing process basically determines the height and density of the arrayed needle structures, and the succeeding wet etching forms the final needle shape. The process sequences of the needle formations are as follows:

(a) Pyramidal-shaped needle formation – The etching mask is formed on both sides of the silicon wafer, and then grooves on the wafer are made with a dicing saw. The wet etching process is then applied to the diced silicon wafer. The etching proceeds in the direction of the side and bottom of the grooves. The plane located at the saddle point on the etch rate diagram appears during undercutting and defines the etched shapes. As a result, a pyramid-shaped needle is formed by the wet etching process.
(b) Candle-like needle formation – A candle-like needle structure is formed by applying the second dicing process.
(c) Spike-shaped needle formation – A concave shape is formed under the needle tip by the same undercutting principle, and a spike-shaped needle structure is formed during the wet etching process. The groove walls formed at a candle-like formation determine the final height of the spike-shaped needle and the undercutting area.

The proposed principle of combined process allows MEMS society fabricating a variety of shapes in microstructures even without applying expensive photolithographic equipment, by multiplying the number of mechanical dicing and wet etching processes.

1.07.4.1.6 Comparison of wet and dry etching

In the field of MEMS micromachining, wet and dry processes are both useful for fabrication. Pros and cons of those two approaches are compared in **Table 3**.

It is apparent that a dry process like RIE is superior to a wet process for versatile applications, because any 2D mask patterns can be deeply etched in the substrate. Also a dry process has less chance of contamination than a wet process. However, a wet process is advantageous in the following issues.

(1) Controllability and uniformity in etching depth.
(2) Potential for special types of etching profile.
(3) Equipments costs required are of magnitudes lower than for dry etching.

Point (1) is valid for both with and without etch stop layer techniques. Without an etch stop layer, (100) Si etch depth variation on a total wafer is within 1 μm for 200–300 μm deep etching using KOH by a time control combined with monitoring the depth during process. On the contrary, etch depth of deep RIE is not controllable depending on the mask opening size.

The electrochemical etch stop technique mentioned in Section 1.07.4.1.5.(vi) allows excellent control in the etched structure thickness. When the thickness of an epitaxial n-silicon layer is controlled in a range of ±0.05 μm, the variation in the thickness of the membrane obtained is in the same range. On the other hand, a buried oxide layer is used as an RIE etch stop layer of SOI wafer, the thickness variation depends on that of the top silicon layer of the SOI, which at the moment is not superior to the n-epitaxial layer mentioned above.

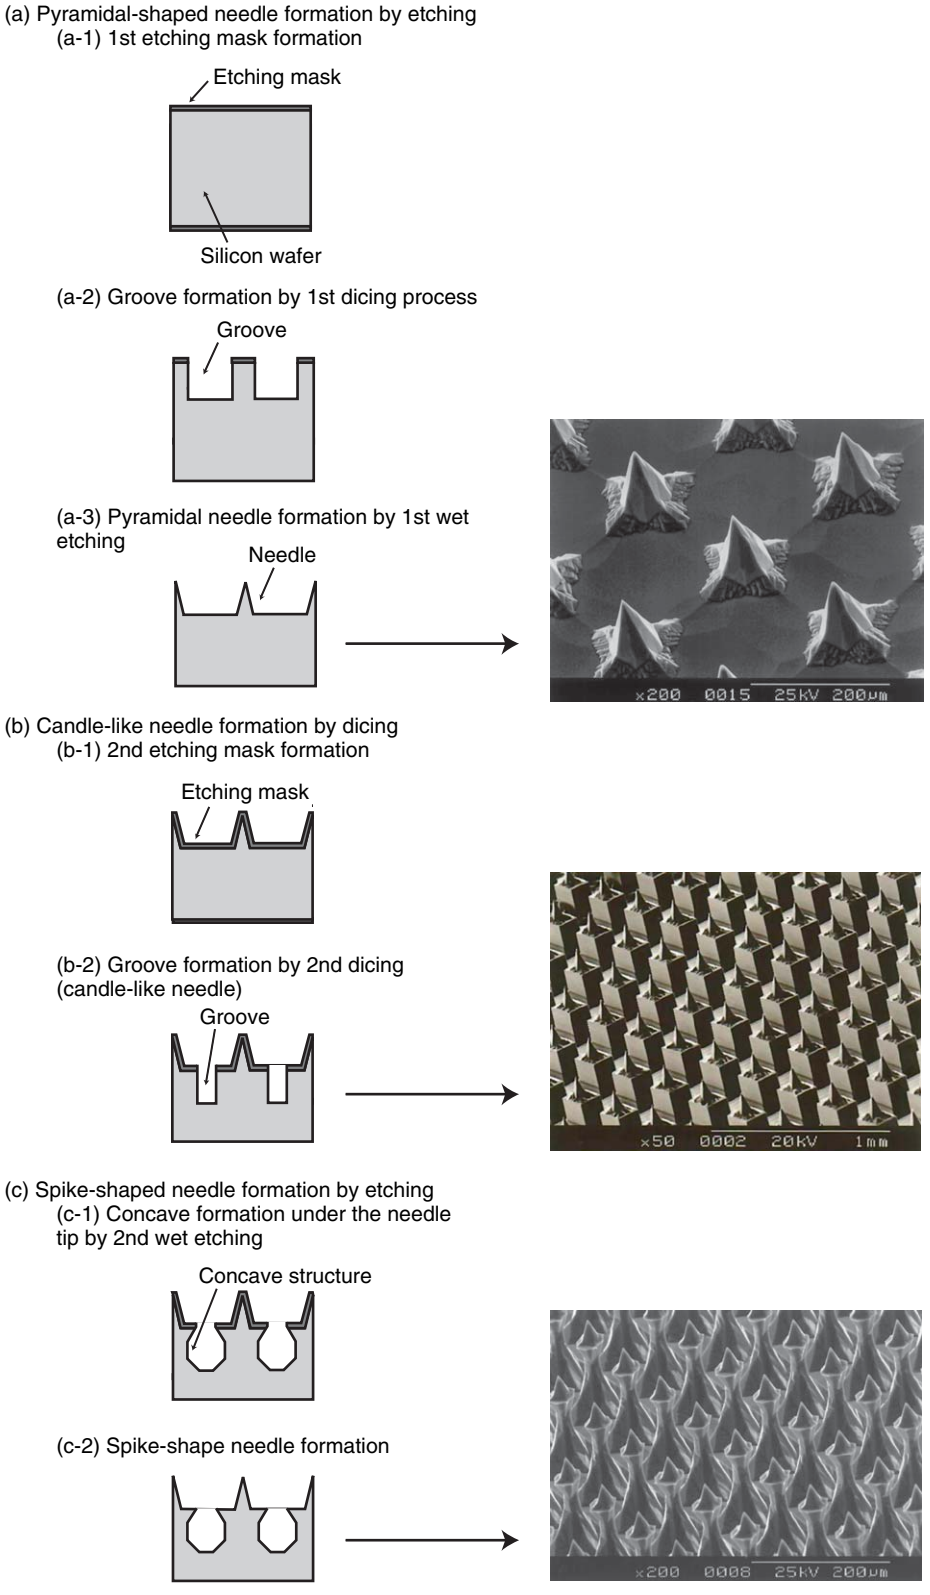

Figure 34 Fabrication of various needle structures by repeating dicing and wet etching processes. Actuators A***116**, 264–71.)

Table 3 Characteristics of wet and dry processes for anisotropic etching

	Wet etching	*Dry etching*
Fineness of the etched dimension	+	++
Cleanliness of the process, IC-compatible	−	++
Applicability for any 2D mask patterns	− − −	+++
Controllability in etching depth	++	+
Uniformity in etching depth	++	−
Potential for special types of etching profile	++	+
Equipments costs required	+++	− −

Plus (+), superior; minus (−), inferior.

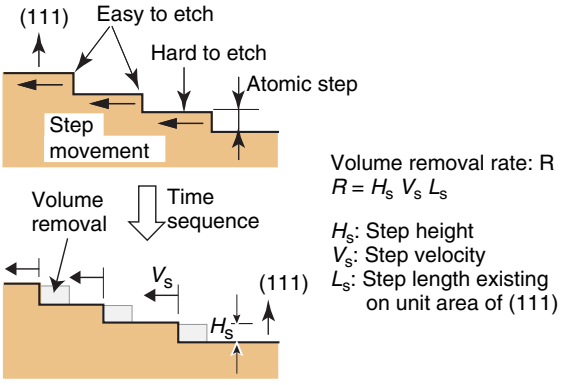

Figure 35 Step flow model for the etching in the vicinity of Si (111). Cross-sectional view of a wafer showing receding motion of atomic steps.

Point (2) includes the fact that an excellent flatness of the polyhedral etched profile can be obtained by the wet processes. Also, it includes a high repeatability in the product dimensions compared to that in dry processes.

1.07.4.2 Etching Model and Simulation Systems

1.07.4.2.1 Step flow model for variable anisotropy

It was discussed in the previous section that the anisotropy in etch rate varies based on a small change of etching conditions. However, the reasons are not clear because of a lack in knowledge on the etching mechanisms. The purpose of this section is to give an etching model for an alkaline solution etching system.

A conventional explanation for why (111) is stable against etching was based on the number of dangling bonds, as already explained using **Figures 7 and 8**. However, atom removal from perfectly flat (111) is a minor case actually occurring on a crystal surface. In most of the cases, a large number of atoms are removed from atomic steps and kinks. This is the weak point of the dangling bond model. The etch rate must be quantitatively discussed based on dynamic models.

This was first pointed out by Elwenspoek (1993), who proposed a step flow model as an etching mechanism of Si (111) and its vicinity. Atom removal starts with a nucleation of a pit and the propagation of atomic steps, as shown in **Figure 35**. Nucleation actually occurs from a perfectly flat (111). However, major atom removal occurs continuously at steps or kinks. This is visible resulting in the movement of steps. This was proved experimentally by Allongue *et al.* (1993) by *in situ* STM (scanning tunneling microscope) observations of Si (111) etching using NaOH solutions. Though anisotropic nature was explained by this model, changes in anisotropy by etching conditions, like differences between KOH and TMAH, have never been discussed in relation to the etching mechanism.

Let us consider why KOH and TMAH show a difference in the etch rate contour map pattern (see **Figure 19**) in the vicinity of (111). Though triangular contour lines surrounding (111) appeared for both etchants, the directions of vertexes of the triangles differed by 60° between the two. Sato *et al.* (2003) observed etch pit growth on Si (111) silicon, i.e., movement of a cluster of atomic steps, and found that the difference in etch rate contour map between KOH and TMAH was due to the difference in movement of atomic steps on Si (111), as discussed below.

1.07.4.2.1.(i).(a) Etch pit observation on Si (111) Sato *et al.* observed shallow etch pit growths on a (111) surface. They introduced defects on the wafer surface by a thermal treatment prior to etching. When the surface is exposed to an etchant, etch pits grew centered by the artificially introduced defects. A single pit was watched with time increments using an optical microscope and a 3D surface profiler. **Figure 36** shows top views of etch pits and those cross-sectional profiles taken by time increments. Etch pits for both KOH and TMAH are basically of hexagonal profiles, and three of the six sides of the hexagon were aligned to $[11\bar{2}]$ and the remaining

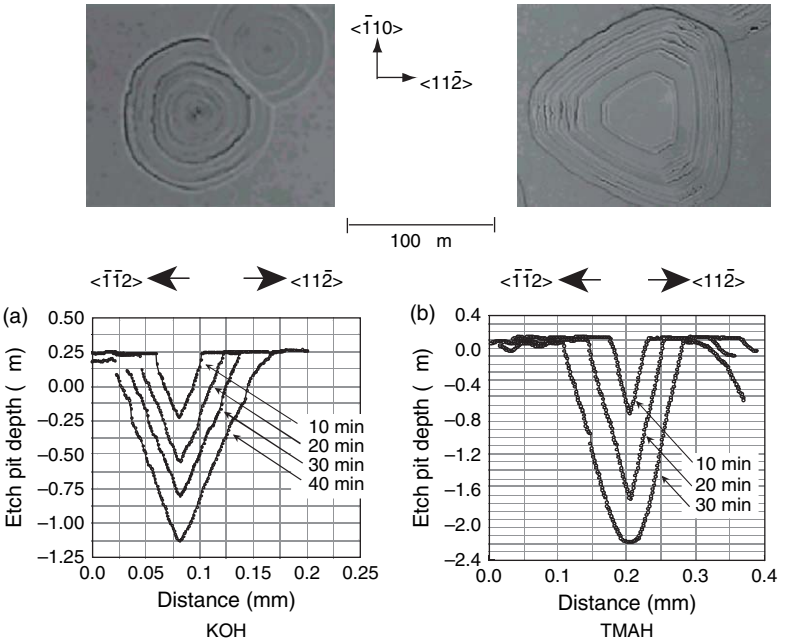

Figure 36 Mirror relationship of etch pit profiles growing on Si (111) during etching in (a) 40% KOH at 70°C, and (b) 25wt.% TMAH at 80°C. In the top are photographs of top views of the pits, and the bottom views are of cross sections measured with time increments. (Source: Sato K, Masuda T, Shikida M 2003 Difference in activated atomic steps on (111) silicon surface during KOH and TMAH etching. *Sens. Mater.* **15-2**, 93–9.)

three to [$\bar{1}\bar{1}$2], respectively. However, the side lengths of those two groups are different. Thus the pit profile becomes triangular in shape. Although both KOH and TMAH etch pits are triangular, note that the orientation of triangle is in mirror relationship between the two etchants.

The etch pit growth in the cross section is shown in the same figure. Both diameter and depth of the pit proportionally increased with an increase of the etching time, though the pits were quite shallow. The increase in the depth saturated when it reached 1–2 μm corresponding to the depth of the defects, while the diameter of the pit kept on increasing in proportion to time. The gradient of the sidewall equaled the ratio of lateral step velocity to the increase in etch pit depth. Lateral step velocity was estimated to be 100 times larger than the increase in pit depth. From an atomic force microscopy (AFM) observation, the step heights were on the order of tens of nanometers. They were regarded as bunched atomic steps. When comparing left- and right-hand sidewalls, the gradients of sidewalls were different. This is because opposite sidewalls are composed of different types of atomic steps as shown in **Figure 37**. A pit nucleated on (111) propagates by a receding movement of atomic steps. It becomes hexagonal

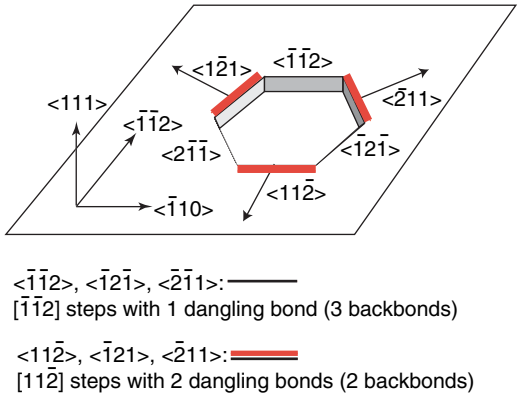

Figure 37 Schematic configuration of a pit on Si (111) composed of two types of stable atomic steps.

profiles composed of stable steps perpendicular to [112]. However, there are two types of steps, one perpendicular to [11$\bar{2}$] and another to [$\bar{1}\bar{1}$2]. They have a different number of dangling bonds and backbonds. Based on the difference in the step velocity of those two types of step, the hexagonal profile becomes triangular. It should be noted that steps having less number of backbonds do not always recede faster than steps having more dangling bonds.

The triangular pit orientation is determined by the relative step velocity of the atomic steps on (111), i.e., by the competition between velocities receding in directions of $[11\bar{2}]$ and $[\bar{1}\bar{1}2]$. The ratio of the velocities for two different steps are actually reversed between KOH and TMAH. The three-backbonded step edge $[11\bar{2}]$ was more stable than the two-backbonded $[\bar{1}\bar{1}2]$ in case of KOH etching. However, in the case of TMAH, two-backbonded steps were more active than three-backbonded steps. As a result, the etch pit profile forms mirror relationships as schematically shown in **Figure 38**.

The step flow model considering step velocities, which is variable, based on the etching conditions, can explain the changeable anisotropy that was observed on the hemispherical specimens discussed in Section 1.07.4.1.4.

Orientations in the vicinity of (111) having a miscut angle can be modeled by a step and terrace model as shown in **Figure 35**. The more the miscut angle, the more the number of atomic steps that exist on a surface in proportion to the miscut angle. Depending on the miscut directions, some surfaces have $[11\bar{2}]$ steps and others have $[\bar{1}\bar{1}2]$ steps. This causes an asymmetric increase in the etch rate by the deviation angle from (111). This results in the triangular contour map pattern on the etch rate diagram shown in **Figure 19**. At the same time, the reason for the triangular contour map patterns rotating 60° between KOH and TMAH has been clarified (Sato *et al.* 2003).

It was further found that the ratio of the step velocities perpendicular to $[11\bar{2}]$ and $[\bar{1}\bar{1}2]$ on Si {111} can also be reversed by a change in solution concentration as well as the difference in etching species such as KOH and TMAH (Cheng *et al.* 2006). The rotation of etch pits is a function of the solution concentration. In case the KOH concentration is extremely high, with values more than 60% KOH, the orientation of the triangular etch pit becomes the same as that of 25wt.% TMAH. On the other hand, in case the TMAH concentration is weak in such a range, i.e., lower that 10wt.% TMAH, the orientation of the triangular etch pit becomes like that of KOH with normal concentrations.

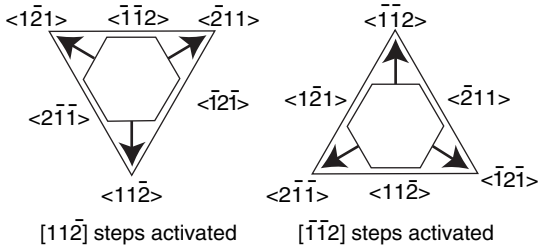

Figure 38 Oriented pit growth on Si (111) governed by the difference in activated step systems.

The critical concentration at which the triangular etch pit rotates is not the same for KOH and TMAH, even if one compares the value in molar concentration. The reason of such reversible anisotropy is considered due to the role of positive ions such as K^+ and TMA^+.

Atom removal from the {111} surface using atomistic Monte Carlo simulation based on first principle calculation (Gosálvez and Nieminen 2003) was recently reported. Simulation results for silicon surfaces having different off-angles in the vicinity of {111} clearly showed the pit nucleation and step propagation processes. Triangular pits growing on {111} were simulated, and the possible rotation in the triangular ridge orientation was predicted as a change of anisotropy in etching.

1.07.4.2.2 Etch profile simulation system

Etching profile simulation is of less importance for making simple MEMS structures such as grooves and diaphragms, which can be fabricated in a single etching step. On the other hand, it is indispensable for designing processes, fabricating microstructures having convex profiles or round profiles composed of many crystallographic orientations.

There are two approaches for the etch profile simulation. One is a macroscopic geometrical approach having knowledge of etch rate as a function of crystallographic orientation. Wulff–Jaccodine's construction (Jaccodine 1962) can be applied to predict the advancement of etching front by time increments, as long as the etch rates for different orientations are known. A few simulation systems have been developed from an early period in MEMS history. Assuming that only three orientations appear as an etch profile, Buser and de Rooij developed a graphical simulation system ASEP (Buser and de Rooij 1991). Sequin (1991) discussed the algorithm of 3D etching profiles appearing at the intersections of different orientations. Than and Büttgenbach (1994) developed a code based on cellular automata considering etch rates for three orientations. Commercially available AnisE (in the system IntelliSuite, a product of IntelliSense) is an etching simulator based on the same principle using cellular automata. SIMODE (Frühauf and Zielke 1996) and MICROCAD (Sato *et al.* 1993) are the systems that use a large number of etch rate data for the analysis, based on experimental characterization of etch rates for a number of crystallographic orientations.

Consequently, the simulated results are satisfactory as long as the database covers the etching condition. The latter will be described in detail later in this section.

Another approach is an atomistic approach considering every atom removal from silicon surface. Palik *et al.* (1985) have proposed a model that Si–Si bonds are broken by the attack of an OH^- ion penetrating from the silicon surface. Moktadir and Camon (1997) simulated atom removal on (111) silicon considering that once the OH is attached to a silicon atom, the strength of the Si backbonds weakens. Gosálvez (2003) calculated backbond weakening based on first principle calculation, and made a simulation code named TAPAS calculating a large number of atoms removed from silicon surfaces by using the Monte Carlo method. It gives qualitative agreements with experimental facts, such as etching profiles and etched surface morphologies that strongly depend on the orientations. He assumed the attachment ratio of OH on the silicon surface as a parameter, although the parameter, of course, needs fitting using experimental data. There is still room for multiscale approaches considering phenomena both in the solid and in the liquid phase, i.e., diffusion in liquid, role of positive ions like K^+, and TMA^+. However, such an atomistic approach is of importance for analyzing etching mechanisms.

Since characterization of anisotropic etch rates is possible by using hemispherical silicon specimen mentioned in Section 1.07.4.1.4, etch rates as a function of orientations for industrial etching conditions were measured (Sato *et al.* 2000, 2001, Shikida *et al.* 2000). Combined with the database, an etching simulation system MICROCAD that predicts etching profiles under a wide range of etching conditions has been developed (Sato *et al.* 2000). The system is linked with the above-mentioned etch rate database ODETTE. The etched profiles are analyzed by using Wulff–Jaccodine's graphical method. Variable parameters in the simulation are surface orientation of the silicon wafer, the shape of the mask pattern, the species of etchant, and its concentration and temperature. It is not restricted for a single etching process, but a series of etching processes using different mask patterns or etching solutions can also be analyzed.

The MICROCAD (current name is FabMeister-ES distributed by Mizuho Information & Research Institute Inc.) allows the designing of process parameters such as size and shape of mask patterns, the number of etching steps, and the etching conditions. Examples of the process design using the system are as follows:

(1) Compensation mask design minimizes undercut etching of the mask.
(2) Successive etching process design provides 3D structures including smooth round etch profiles among polyhedral ones.
(3) Optimization of etching parameters: etching medium, concentration, and temperature are optimized in terms of the desirable etching profile.

Etch profile analysis is robust even when etching is applied deep from both sides to penetrate the wafer. **Figure 39** shows such robustness calculated by comparing experimental and predicted etch profiles. Wafer orientation is (100). Sides of square mask apertures are aligned to (110). Etching fronts first penetrate the wafer thickness, and then they advance laterally. Finally, through-holes are connected in lateral directions. Multistep etching process also can be analyzed with MICROCAD (FabMeister-ES) system.

1.07.4.3 Anisotropic Etching of Quartz

Single-crystal alpha-quartz is a material showing piezoelectric effects, and is applied to oscillators, filters, and some MEMS devices such as rotational angular rate sensors (rate gyro).

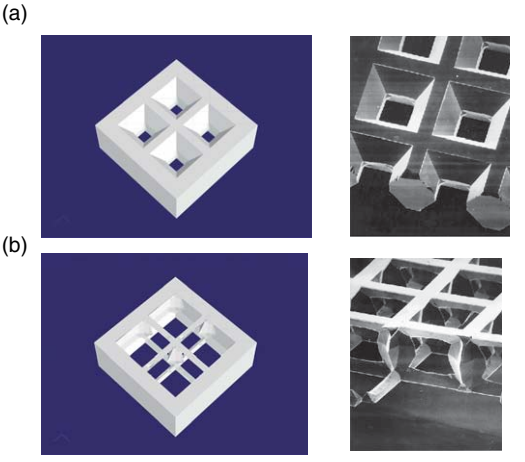

Figure 39 The etch profile simulation results compared to the actual silicon chip. The etching was applied from both sides of the (100) wafer using a KOH solution. (a) Etching fronts meet in the middle of the wafer and (b) further advance in lateral directions resulting in the through-holes also in lateral directions. (Source: Sato K, Asaumi K, Kobayashi G, Iriye Y, Shikida M 2000 Development of an orientation-dependent anisotropic etching simulation system MICROCAD. *Electron Comm. Jpn. Part 2* **83–4**, 13–22.)

Orientation-dependent etching is applicable to quartz, though it has a crystal lattice system quite different from that of silicon. The atomic component is SiO_2. It can be etched with NH_4HF_2 (ammonium bifluoride)-saturated solution. The chemical reaction is given below:

$$SiO_2 + 3NH_4HF_2 \rightarrow SiF_6^{2} + 2H^{+} + 3NH_3 + 2H_2O$$

The mask material is Au on Cr. Cr is a binding layer enhancing adhesion of the Au layer to the quartz wafer. The film thicknesses are typically 300 Å Cr and 1500 Å Au.

Single-crystal alpha-quartz has a hexagonal system as shown in **Figure 40**. Since the crystal system is different from a cubic lattice, expressing the orientations using the normal Miller index is not appropriate in the case of quartz. For example, the crystal properties of the a1- and a2-axis directions are physically identical, but with the Miller index they are expressed as [110] and [100]. Therefore, when expressing a hexagonal crystal system like quartz or Zn, one usually uses a special index, the Miller–Bravais index. As shown in **Figure 40**, there are four axes in a hexagonal system crystal structure: three axes (a1, a2, and a3) on one base plane meet at angles of 120°, and the other axis (Z) is perpendicular to this plane. This crystal structure is represented accurately by the Miller–Bravais index because it has four parameters (h, k, i, l) corresponding to the four axes. Three parameters for a base plane are not independent, and are in a relationship as given below:

$$h + k + i = 0 \qquad [1]$$

Because of this, one can also express the Miller–Bravais index as ($hk\bullet l$).

The principal crystal planes of alpha-quartz after crystal growth are shown in **Figure 41**. Some principal orientations have idiomatic names, as given below:

$$\text{m} : \{10\bar{1}0\}$$
$$\text{R} : (10\bar{1}1), (\bar{1}101), (0\bar{1}11)$$
$$\text{r} : (\bar{1}011), (1\bar{1}01), (01\bar{1}1)$$
$$\text{s} : (1\bar{2}11), (\bar{2}111), (11\bar{2}1)$$
$$\text{x} : (51\bar{6}1), (\bar{6}511), (1\bar{6}51)$$

In the following sections the set of orientations perpendicular to the Z-axis, including the m-planes will be referred to as the equator. The fastest crystal growth has an orientation of (0001), suggesting that etching may be the fastest at this orientation.

In the same manner as for single-crystal silicon, Cheng *et al.* (2005) have characterized the etch rates as a function of orientations by making spherical quartz specimens whose diameter was 33 mm. It has a top oriented to Z-axis (0001), and the equator including m-planes $\{10\bar{1}0\}$. To cover the areas near $\{10\bar{1}0\}$, the specimen, unlike silicon, was designed more as a spherical body than as a hemisphere.

The etch rate contour maps at 70°C and 80°C are shown in **Figure 42**, and etch rates for 13 different crystallographic orientations including Z-, R-, r-, s-, and x-planes are listed in **Table 4**.

It is observed from the contour maps that the etch rate of quartz has threefold symmetry around the (0001) axis as a reflection of the hexagonal system. Although the (0001) orientation is located in a high

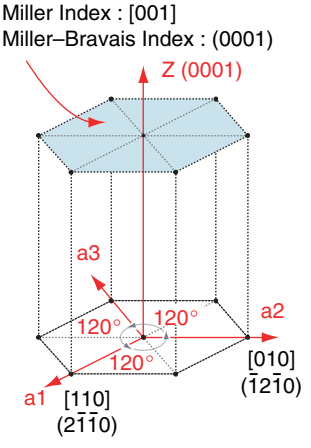

Figure 40 Hexagonal system crystal structure of quartz expressed by the Miller–Bravais index.

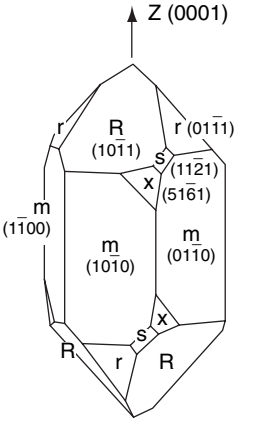

Figure 41 Principal orientations appearing after crystal growth and their Miller–Bravais index.

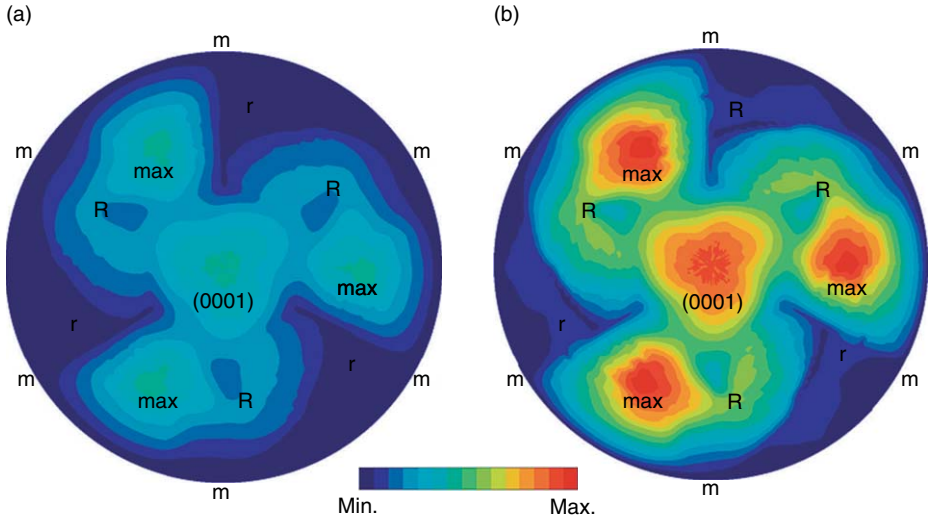

Figure 42 Etch rate contour maps of alpha-quartz at temperatures of 70°C (a) and 80°C (b). The center is oriented to the *Z*-plane (0001), and *m*-planes are on the equator line. (Source: Cheng D, Sato Ka, Shikida M, Ono A, Sato Ke, Asaumi K, Iriye Y 2005 Characterization of orientation-dependent etching properties of quartz: Application to 3-D micromachining simulation system. *Sens. Mater.* **17-4**, 179–86.)

Table 4 Etch rates for 13 different crystallographic orientations of alpha-quartz at etching temperatures of 70°C and 80°C

	Etch rates ($\mu m\ min^{-1}$)	
Crystallographic orientation	*70°C*	*80°C*
(0001) Z	0.571 (1.00)	1.261 (1.00)
$(\bar{1}2\bar{1}2)$	0.565 (0.99)	1.270 (1.01)
$(\bar{1}2\bar{1}0)$	0.013 (0.02)	0.032 (0.03)
$(\bar{1}102)$	0.347 (0.61)	0.755 (0.60)
$(\bar{1}101)$R	0.242 (0.42)	0.608 (0.48)
$(\bar{1}100)$m(Min.)	0.002 (< 0.01)	0.003 (< 0.01)
$(\bar{2}112)$	0.256 (0.45)	0.631 (0.50)
$(\bar{2}111)$s	0.512 (0.90)	1.177 (0.93)
$(\bar{2}110)$	0.043 (0.08)	0.094 (0.08)
$(\bar{5}16\bar{1})$x	0.054 (0.09)	0.116 (0.09)
$(\bar{1}012)$	0.120 (0.21)	0.297 (0.24)
$(\bar{1}011)$r	0.059 (0.10)	0.143 (0.11)
$(\bar{2}42\bar{3})$Max.	0.590 (1.03)	1.432 (1.14)

In parentheses are normalized values relative to (0001) orientation (Cheng *et al*. 2005).

etch rate region, the value was not the highest as speculated from the crystal growth shape. The maximum etch rates exist at these three positions at equivalent crystallographic orientations. The location of maximum is at an angle of 56° measured from the top (0001), and threefold symmetry in a circumferential direction. The Miller–Bravais index of this orientation can be $\{\bar{2}42\bar{3}\}$.

On the other hand, extremely low etch rates were measured along the equator, even as low as close to zero. This means that a (0001) wafer can be etched perpendicular to the wafer surface by wet etching with minimal side etching in the same manner with deep RIE.

Cheng *et al.* (2005) have analyzed the etching profiles on a (0001) quartz wafer using the MICROCAD (FabMeister-ES) system by implementing the etch rate distribution obtained above. **Figure 43** shows the mask pattern and the etched profile obtained by the simulation system. It is clear that the sidewalls of the cavity are steep and mask undercut was quite little in omni directions. This is the reflection of extremely low etch rates including *m*-planes.

An example of a recent application of quartz anisotropic etching is introduced below. Hida *et al.* (2005) have designed a quartz tuning fork to be applied to noncontact mode AFM systems. The tuning fork is a pair of quartz beams oscillating in plane. One of the beams is used as an AFM probe. Quartz AFM probe so far did not have sharp tips integrated in a single body like silicon probes because of the difficulty in micromachining. Hida *et al.* have designed a probe having a sharp tip at the end of the beam as shown in **Figure 44**. By utilizing a MICROCAD (FabMeister-ES) system, they designed an etching process that fabricated a tip and beam on the same body. It became possible to fabricate a micromachined tip structure on a quartz chip, as shown in the figure.

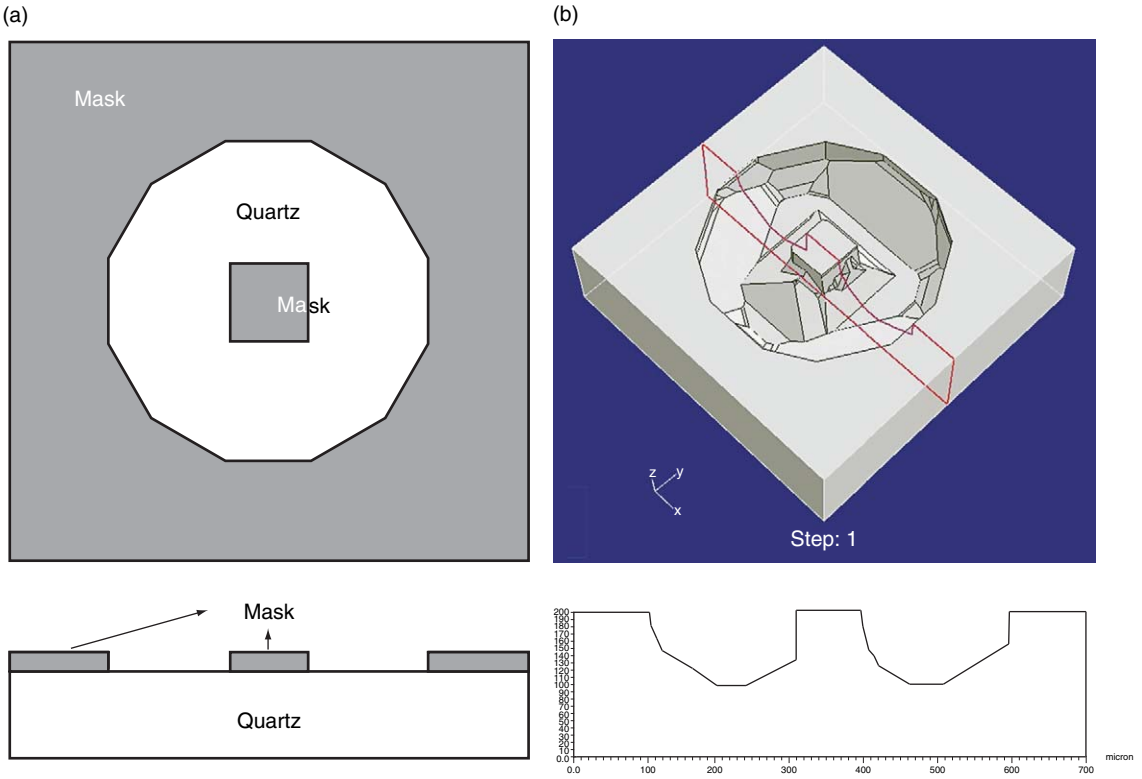

Figure 43 Etch profiles of (0001) quartz wafer analyzed using MICROCAD (FabMeister-ES) system linked with etch rate database of quartz. (Source: Cheng D, Sato Ka, Shikida M, Ono A, Sato Ke, Asaumi K, Iriye Y 2005 Characterization of orientation-dependent etching properties of quartz; application to 3-D micromachining simulation system. *Sens. Mater.* **17-4**, 179–86.)

1.07.5 Anodic Etching of Silicon in HF

Silicon etching is modulated by applying a potential between silicon and the etching solution. Without an external biased potential, silicon wafer during etching is in a state of OCP. When the applied potential between silicon and solution becomes more positive, more holes are supplied to the silicon surface, and the etching speed increases. When the potential reaches the passivation potential, an oxide starts to form at the silicon–solution interface. Thus etching stops in alkaline etching solutions like KOH and TMAH, as mentioned in the previous section. However, in case of HF solutions, the generated oxide is ready to dissolve in HF, and etching advances further. This is called anodic etching, or anodization.

The following two conditions are both indispensable for the silicon to be etched in HF solution, i.e., (1) charges (holes) are supplied in silicon (2) OH^- ions are transported from the solution. Depending on the conditions in the supply of the holes and in the transportation of OH^- ions, etched surface morphologies are variable in HF systems.

1.07.5.1 Electropolishing

For the purpose of smoothening a silicon wafer surface, photoelectrochemical etching using highly concentrated HF solution is used. The etching bath is basically the same as the one shown in **Figure 30**, providing regulated potentials to silicon wafer, though an apparatus illuminating wafer surface is additionally attached to the system.

When the applied potential is low, microporous silicon is formed on the wafer surface, as described in the next section. When the current supplied exceeds a certain value based on the increase in applied potential, the porous film delaminates and bright electropolishing occurs (Lehmann 1993).

The electropolishing advances under a condition in a concentrated HF solution, where the OH^- ion is depleted. The mass transport in the solution limits

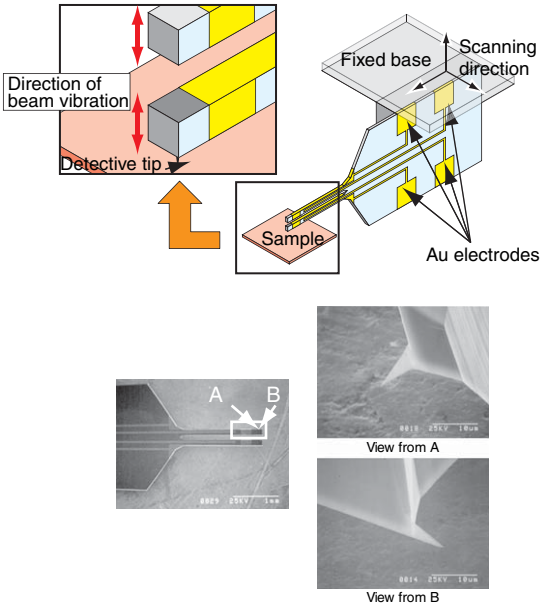

Figure 44 Quartz tuning fork having a sharp tip etched in a single body to be applied to non-contact AFM system. (Source: Hida H, Shikida M, Fukuzawa K, Ono A, Sato Ke, Asaumi K, Iriye Y, Cheng D, Sato Ka 2005 Proposal of new type of micro-machined quartz tuning fork AFM probe. *Proc. IEEE Int. Conf. on Micro Electro Mechanical Systems*, Miami Beach, FL, USA, pp. 323–26.)

the reaction. The hills of rough silicon surface can get more OH^- ions than can the valleys; thus smoothening of the surface occurs.

1.07.5.2 Porous Silicon

Porous silicon formation was first found by Uhlir (1956). Pore size and porosity can widely range from nanometers to tens of microns by etching conditions such as current density, illumination intensity, and silicon types.

Porous silicon has been investigated aiming at following applications.

1. Quantum structures
2. Photo- and electroluminescent devices
3. Oxide films of several microns thick or more, due to the ease of oxidization; sacrificial layer for releasing MEMS structures; dielectric isolation of integrated circuits
4. Cleavage layer in SOI production (ELTRAN method)
5. Mold for tubular MEMS structure

Porous silicon is categorized into two classes, microporous and macroporous silicon, by the differences in size and formation mechanism.

1.07.5.2.1 Microporous silicon

Microporous silicon is formed both on p- and on n-type silicon under low current density in highly concentrated HF. In such a condition, the holes are depleted, while HF is accumulated at the silicon–solution interface. The depletion in holes due to quantum confinement in the fine pore structure is the basis of the formation mechanism. The pore diameter ranges 4–20 nm (Arita and Sunohara 1997, Lehmann 1996).

Such a microporous layer can be thermally oxidized in a short time, allowing a thick layer of oxide film for the purpose of electrical isolation or sacrificial layer for micromachining. Yoshida *et al.* (1992) proposed utilizing p–n junction allowing photo-induced holes to make microporous silicon in the p-layer, eliminating metal wiring for applying positive potential to the p-layer. They have fabricated an n-type silicon beam released from the substrate by removing the sacrificial layer of oxidized microporous silicon. The process is illustrated in **Figure 45**, where the silicon beam structure is of n-type, the sacrificial layer of p-type, and the substrate of n-type.

Porous silicon remains a single crystal. Epitaxial growth is still possible on the porous silicon. This allows the fabrication process of SOI wafer, which is called the ELTRAN method. The process consists of bonding two wafers, one having an epitaxial

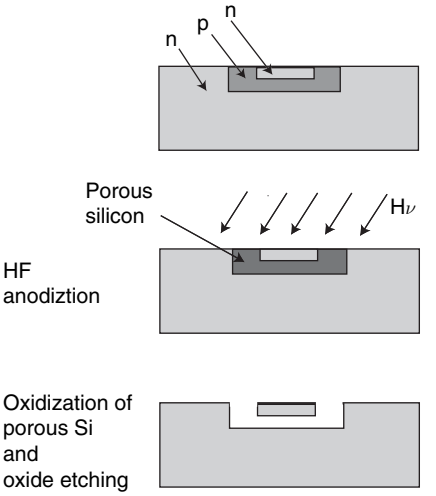

Figure 45 Photo-induced selective anodization of p-silicon for the purpose of sacrificial layer. (Source: Yoshida T, Kudo T, Ikeda K 1992 Photo-induced preferential anodization for fabrication of mono-crystalline micromechanical structures, *Proc. IEEE MEMS '92*, Travemünde, Germany, pp. 56–62.)

layer on porous silicon and the other having oxide on top, followed by cleavage at the porous silicon layer making the bonded wafers apart, with the epitaxial layer remaining on top of the oxidized wafer.

1.07.5.2.2 Macroporous silicon

Pore diameters of up to 10 μm can be fabricated to the depth of hundreds of microns by using a special etching bath illuminating the rear side of a wafer during etching. An example of an etching bath is shown in **Figure 46**.

Macroporous silicon is only available with lightly doped n-type silicon under higher applied potentials than those for microporous silicon in diluted HF (less than 10wt.% HF) solution (Zhang 1991). One of the advantages of this process is that the location of the pore can be determined by giving a seed of pore using photolithographic method. When pyramidal recesses are made on a Si (100) wafer surface using anisotropic chemical etching prior to HF anodic etching, the macropore grows, starting from those recesses in a direction of illumination coming from the rear side of the wafer as shown in **Figure 47**. The reason for such directional pore growth is that carriers are generated in silicon by illumination and holes are localized at the bottom tip of the pores.

As an example of applications of such a macropore having a large structure height, a large number of small glass cells for the purpose of microchemical analysis systems were fabricated by Homma *et al.* (2004). They first made macropores like those in **Figure 47**, then the pore walls were totally oxidized. By removing the silicon substrate from the rear side, transparent cuvettes having a square cross section were fabricated. The diameter of the cuvette was typically 10 μm and the length was more than 100 μm.

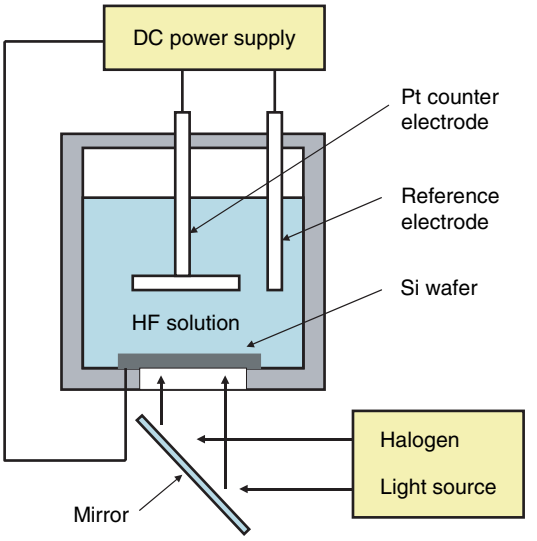

Figure 46 Etching bath having rear-side illumination for macroporous silicon process.

Biographies

Kazuo Sato received a BS degree in mechanical engineering from Yokohama National University in 1970, and a Ph.D. degree from the University of Tokyo in 1982. He worked with Hitachi Ltd. from 1970 to 1994. He has been a professor at Nagoya University since 1994.

He started MEMS research in 1983, and cochaired the IEEE MEMS-97 workshop. His research interests include chemical anisotropic etching, microsensors, microactuators, characterization of MEMS materials, and micro/nanophysics. He is a Fellow of the Japan Society of Mechanical Engineers (JSME), a senior member of IEE, and a member of JSPE and IEEE.

Mitsuhiro Shikida received his BS and MS degrees in electrical engineering from Seikei University, Tokyo, in 1988 and 1990, respectively. He received a Ph.D. from Nagoya University in 1998. From 1990 to 1995, he worked at Hitachi Ltd., Tokyo. In 1995, he joined the Department of Micro-System Engineering at Nagoya University as a research associate. He was an assistant professor from 1998 to 2004 and has been an associate professor since 2004. He joined the EcoTopia Science Institute at Nagoya University in 2004. His research interests include microfabrication of 3D microstructures for medical applications and micro total analysis systems for biotechnologies.

1.08 Dry Etching

Franz Laermer, Corporate Sector Research and Advance Engineering, Robert Bosch GmbH, Stuttgart, Germany

1.08.1 Introduction

In the early days of microelectromechanical systems (MEMS), wet etching with potassium hydroxide and other alkaline solutions was the most important method of fabricating silicon microstructures (Petersen 1982). In the beginning, these etchants were mainly used to fabricate membrane-type devices, like pressure and mass flow sensors. Due to its crystal orientation-selective etching behavior, with fast etching crystal planes like (100) and slow etching crystal planes like (111), anisotropic wet etching yields cavities, which are limited by walls of (111) crystal orientation. The etch practically stops in the vertical direction also when a cavity reaches a V-form (Bean, 1978, Seidel *et al.* 1990). Its accuracy and repeatability over many wafers processed is due to the anisotropic nature of the etch. Precise V-grooves found some applications in the micro-optic field, mainly for fiber couplers and fiber positioners. Supporting techniques for vertical etch depth control were introduced at that time, e.g., dopant-selective etch stop at heavily boron-doped silicon layers (Palik *et al.* 1982) and potential-selective electrochemical etch stop (Kloek *et al.* 1989) at reversely biased p–n junctions in silicon.

This degree of accuracy is not provided by an isotropic wet etchant, which would etch at the same speed in all directions, including underetching of the mask in the lateral directions. This is one of the reasons why well-known isotropic wet etchants for silicon like HNA (a mixture of hydrofluoric, nitric and acetic acid) have been utilized only as a limited microstructuring technology for MEMS (Robbins and Schwartz 1976). Another reason is that masking of the HNA etch requires thin film layers that are chemically very resistant, e.g., silicon carbide.

Although successful in a number of applications requiring low-cost technologies for cavity etching, the anisotropic etchants of the classical MEMS technology show severe limitations with regard to required masking materials (hard mask materials like silicon oxide, silicon nitride, or carbide needed), their incompatibility with semiconductor manufacturing (especially in the case of monolithic integration of mechanical and electrical functionalities), the limited etching speed, the dependence of the etch on crystal orientation, generally nonvertical sidewalls, and the extremely fast etching of convex corners. For structures of higher complexity, for example, membranes or beams containing extra features like seismic masses, geometries exposing

convex corners during the etch are unavoidable. To protect convex corners from fast etching attack, various corner compensation techniques were suggested (Mayer *et al.* 1990, Menz and Mohr 1997, Sandmaier 1991, Wu and Ko 1989), some of them containing rather complicated sacrificial structures. The complexity of corner compensation together with the dependence on crystal orientation significantly restricts design flexibility and application range of the classical microstructuring technology. People could often not or only under large efforts realize the microstructures they were dreaming of. Clearly a more flexible technology, free from these restrictions, was urgently needed as a key enabler for MEMS devices of enhanced functionality.

The LIGA technique was the first step toward this goal, offering freedom of design for a wide range of microsystems. LIGA stands for the German term Lithographie, Galvanik, Abformung (Ehrfeld 2002, Menz and Mohr 1997) and was developed at the Research Center Karlsruhe, Germany. A thick layer of polymethyl methacrylate (PMMA) resist is exposed through a mask to X-ray radiation from an electron synchrotron and is developed after exposure. The high optical quality of the X-ray beam from the electron synchrotron together with the small absorbance and the dispersion of X-rays within the PMMA film yield extremely precise 3D structures, defined by the 2D patterns used for masking the polymer. Thus, polymer structures of several hundred micrometers in depth and with aspect ratio of 100:1 can be produced. Galvanoforming of the polymer negative form and subsequent demolding yields positive structures in metal, e.g., nickel. Various replication techniques such as molding or hot embossing in polymer, and again galvanoforming of metal, and combinations between different molding and demolding techniques are used for fabricating a large number of metal or plastic parts from a single LIGA masterform. Given the extremely high manufacturing costs for a LIGA masterform, successful replication to produce extremely high volumes was identified as the key to reach acceptable costs at the product level. Although LIGA demonstrated breathtaking microstructures and microstructuring capabilities at that time, the technology has for long been limited to a small number of applications providing sufficiently high market volume, mainly because of the extreme costs related to this technology. However, LIGA showed to the world what MEMS could be if only the right technologies were there. The challenge was to fabricate microstructures similar to LIGA, but with a process technology closer to industrial standards, and at a more reasonable cost level.

1.08.2 Silicon Etching from the Gas Phase

Plasma etching or reactive ion etching (RIE) was already well established in semiconductor technology at that time (Manos and Flamm 1989, Oehrlein 1990, Schwartz and Schaible 1979). The classical tool, which was used in the early RIE work, is the diode reactor shown in **Figure 1**. Detailed descriptions of different plasma reactors and processes can be found in Chapman (1980). The scheme depicts the key elements of the typical RIE configuration: a number of reaction gases provided to the chamber by adjustable mass flow controllers, a grounded showerhead electrode as a gas inlet, a substrate electrode carrying the wafer, and a power supply to the substrate electrode by radio frequency (RF) via a coupling capacitor (which is mostly part of a more complex matching unit to adapt RF impedances). Radio frequencies generally used are in the low-frequency (380 kHz), mid-frequency (2 MHz), or high-frequency (13.56 MHz) regime, in most cases 13.56 MHz is used as a standard for plasma generation.

Pumping produces the low-pressure conditions in the reactor chamber needed for the electrical discharge to form between the powered and the

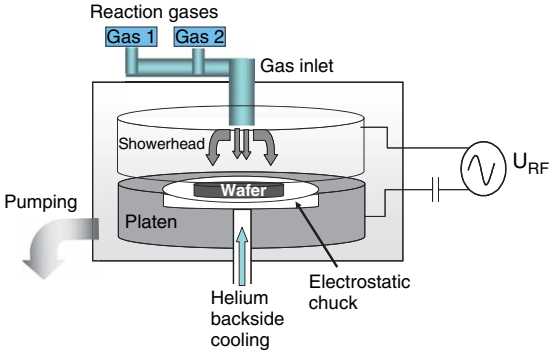

Figure 1 Typical reactive ion etching (RIE) configuration. The RIE reactor is pumped to low-pressure conditions. Reaction gases are supplied to the chamber via the upper showerhead electrode. The lower electrode is powered by radio frequency (RF) to drive the plasma discharge and accelerate the ions toward the substrate.

grounded electrode, which builds up the plasma in an atmosphere of one or more compound gases, at a pressure ranging from 0.1 to 100 Pa.

The coupling capacitor allows the powered electrode to float at a DC potential, which is generated from the applied RF voltage, together with the different mobilities of negative charges (electrons) and positive charges (ions) in the plasma. This is the so-called DC bias voltage, which accelerates the ions toward the powered substrate electrode.

Isotropic, vertical, and all different kinds of tapered profiles could be etched into silicon for applications like trench isolation, contact hole formation, dynamic random access memory (DRAM) trench cells (trench capacitors for memory) and many more, during the manufacturing of electronic circuits. A general overview on RIE can be found in Oehrlein (1990) and a review on silicon RIE is given in Schwartz and Schaible (1979). The capabilities of RIE, mainly its independence on crystal orientation and the potential to fabricate arbitrarily shaped geometries, made plasma etching a promising candidate as a new microstructuring technique for the MEMS field. Early work has demonstrated that micromechanical elements containing shallower pattern features could well be realized using the classical RIE approaches, which were adapted from semiconductor manufacturing technique (Diem *et al.* 1995, Juan *et al.* 1996, Li *et al.* 1995, Sung and Pang 1993). Although still insufficient for deeper structures, and limited by low etching speed and mask selectivities, the intrinsic potential of plasma technology for etching deeper structures at a higher speed was already felt within the MEMS community.

1.08.2.1 Isotropic Etching

With regard to etching, a reactive plasma consists of two relevant kinds of species: the dominating part in numbers, by orders of magnitude, is the chemically active neutral species, the so-called radicals. They are produced by the decomposition of gas molecules into fractional parts after collisions between gas molecules and energetic electrons in the plasma. In most cases, an electron–neutral collision breaks up the neutral molecule into neutral radicals. Being electrically uncharged, radicals reach the substrate with no or only little directionality, bond to the surface, and react more or less readily with the material to be etched to produce more or less volatile compounds. If the reaction takes place instantaneously and the volatility of the reaction products is high enough, the volatile compounds leave the etch surface quickly and take away the material to be etched, yielding isotropic etching behavior. This so-called chemical etch depends much on the properties of the materials involved, yielding high selectivities between different materials and making it in general easy to find appropriate etching masks (e.g., SiO_2 for masking a Si etch).

Fluorine radicals formed in a plasma discharge from fluorine-rich gaseous compounds, such as sulfur hexafluoride (SF_6), carbon tetrafluoride (CF_4), or nitrogen trifluoride (NF_3), show isotropic etching behavior toward silicon. Once adsorbed to the silicon surface, fluorine radicals react immediately with silicon atoms to form silicon fluorides SiF_x ($x = 1,2,3,4$). The reaction products, finally SiF_4, are volatile enough to leave the surface without a need for physical assistance, taking away the silicon material from the etched surface. In contrast to that, etching masks like SiO_2 or photoresist are not or only slowly attacked by fluorine radicals. Since there is no directionality constraint in the mechanism, silicon etching proceeds with no preferential orientation, and the profiles are isotropic. This is an ideal behavior for underetching micromechanical structures in a so-called sacrificial etching or release-etching step for the fabrication of freestanding and moveable elements on top of a wafer. A number of advanced micromachining technologies make use of combinations of anisotropic and subsequent isotropic silicon etching: first etch deep in the vertical direction, then protect the structures and underetch in the lateral direction (de Boer *et al.* 1995, Muenzel 1994). A well-known process example is SCREAM (Shaw *et al.* 1994, Sung and Pang 1993).

For the purpose of silicon sacrificial etching, it is not even necessary to use a plasma as a source of fluorine radicals. A number of gaseous compounds are well known for the ability to etch silicon spontaneously, without a need for plasma excitation. XeF_2 (Chang *et al.* 1995, Flamm 1984), BrF_3 (Wang *et al.* 1997), and ClF_3 (Saito 2002) produce fluorine radicals once adsorbed onto a silicon surface, thus leading to spontaneous isotropic etching of the silicon. The main advantage of plasmaless silicon processing is the very high selectivity toward most nonsilicon materials, because of the pure chemical etch and the lack of physical impact from a plasma discharge, with selectivities, which may well exceed values of 100 000, e.g., for most metals and dielectrics. In a recently published paper, a high selectivity was demonstrated for the first time for selectively etching

a SiGe sacrificial layer with respect to Si functional structures in chlorine trifluoride gas (Leinenbach *et al.* 2007). This finding makes any need for passivation and protection of the functional silicon during the release step obsolete and enables even more challenging MEMS in the future.

1.08.2.2 Anisotropic Etching

The second important kind of species generated from the plasma, less prominent in number but responsible for any directionality and anisotropy of the etch, is the positively charged ions or the so-called cations. They are formed by the ionization of neutral gas molecules by collisions with energetic electrons in the plasma, taking away an electron from the molecule and leaving it back with a positive charge. Being electrically charged, ions can be accelerated toward the substrate by biasing the latter with DC or RF voltage, and by hitting the material in a more or less perpendicular orientation. The ion impact is the only relevant directional contribution provided by the plasma, and all approaches to create anisotropic plasma etching are based on a more or less perpendicular orientation of the ion flow to the surface to be etched. Resulting from their directionality, ions do preferentially hit the bottom of a structure and only to a lesser extent hit their sidewalls. The incoming ions transfer their kinetic energy to the local area of impact. Although the number of ions is small compared to the number of chemically active neutral species, their energetic impact can significantly affect or drive the progress of the etching reaction locally. Ion-assisted directional etching can be caused by one or several of the following mechanisms:

- Induction of chemical reactions between adsorbed radicals from the plasma and the material to be etched by the provision of activation energy with the ion impact, especially if the reactivity of the etching species with the material is low or hindered by an energy barrier.
- Desorption of reaction products from the surface by sputtering action of the incoming ions, especially if the volatility of the reaction products is low and the latter stick to the material surface, forming an inhibiting film there. In this case, ion impact removes the inhibiting film of reaction products from the surface.
- Desorption of other inhibiting films by sputtering action of the incoming ions, e.g., polymer films formed from polymerizing additives to the plasma, or films formed from nonvolatile reaction products between the material to be etched and certain additives to the plasma.

In the case of silicon, typical anisotropic semiconductor etching processes are based on chlorine or bromine, combined with potential additives to the main chemistry for fine-tuning the desired process properties and suppressing the undesired effects. Radicals produced in the plasma from the halogens of lower reactivity, like chlorine and bromine, react slowly with silicon to produce less volatile reaction products, which stick to the surface. Ion impact both activates and induces the formation of silicon chlorides or bromides from silicon and the respective adsorbed halogen radicals, and also removes the inhibitive films of reaction products. In particular, silicon bromides are of very low volatility and need energetic ion bombardment to assist their removal from the silicon surface. In addition to these intrinsic anisotropic properties of the halogens of lower reactivity, oxidation or nitrification of unbombarded silicon surfaces by addition of small amounts of oxygen or nitrogen gas to the plasma can be done to enhance sidewall passivation. As an alternative, sidewall protection is improved by deposition of chlorocarbon or bromocarbon films formed by the addition of chlorocarbon or bromocarbon gases to the plasma, which are ready to polymerize after plasma activation. Ion bombardment breaks up the passivation or the protection of the bombarded surfaces, i.e., the bottom structure, leading to a directional and vertical etching.

Etching based on the halogens of lower reactivity is strongly ion-driven, which gives anisotropy to the process; it, however, limits achievable etch rates (typically below $1\,\mu m\,min^{-1}$), achievable etch depth (a few micrometers), and mask selecitivities (e.g., 20–30:1 for SiO_2 hard mask). Since significant physical impact of the ion flow on the substrate plays a key role in the etch, selectivity as a result of individual chemical properties of the involved materials decreases. There is a fundamental trade-off between increasing the anisotropy by stronger ion bombardment on the one side and maintaining mask selectivity sufficiently high on the other side. In particular, photoresist stability in chlorine- and bromine-based process chemistries is insufficient

for deeper etches, and silicon oxide hard masks must be used in place of or in addition to photoresist (Sung and Pang 1993).

1.08.3 Deep Reactive Ion Etching

Fluorine-based plasma etching processes for silicon are superior in etch rate, achievable etching depth, and mask selectivity, and in particular enable photoresist masking with good selectivity between silicon and photomask removal. However, as already described in this chapter, for the high chemical reactivity and spontaneous etching nature of the fluorine radicals, and for the high volatility of the silicon fluorides as reaction products, the etch should be intrinsically isotropic. Since fluorine radicals do not need ion activation to initiate or enhance their reaction with silicon, nor to remove the reaction products from the silicon surface, anisotropy can be achieved only by the inclusion of sidewall passivation schemes to the process. The existing different DRIE technologies are mainly distinguished by the way sidewall passivation is achieved, which is the key to anisotropy and influences the overall performance of the etch process. In the following, three approaches for deep reactive ion etching (DRIE) are described in detail: the black silicon method, cryogenic dry etching, and the so-called Bosch process with alternating etch and passivation cycles.

1.08.3.1 Black Silicon Method

The black silicon method described in Jansen *et al.* (1995) is a significant improvement over passivation concepts relying on sidewall oxidation in competition with fluorine-based etching of the silicon (Parrens 1981). Fluorine radicals are produced from SF_6 in the plasma discharge and serve as the main etching species, which would readily and isotropically remove silicon wherever it is unprotected and accessible. Oxygen radicals are produced in the plasma in parallel from oxygen gas (O_2) added and serve for oxidation of the silicon surface. Oxidation saturates dangling bonds on the silicon surface and builds up a passivating silicon oxide film, which inhibits fluorine attack of the silicon. The key improvement of the black silicon method consists of the introduction of an oxide scavenging gas, after following a deterministic procedure to detect the best working point of SF_6 to O_2 gas flow ratio, finally to achieve stable anisotropic etching.

To experimentally find out this point of critical balance, the inventors describe a procedure that gave name to the method: the amount of oxygen gas with respect to the amount of SF_6 gas is steadily increased until black silicon (for illustration of black silicon see **Figures 5** and **6**) appears on the etched surface. This blackening of the surface is due to microroughness or microneedles formation, starting at the point of critical passivation. At this point, anisotropy of the etch would be perfect; however, oxide residues at the etch bottom give rise to micromasking effects. To overcome micromasking, a silicon oxide scavenger is added in small amounts to the plasma, e.g., trifluoromethane (CHF_3) gas. The amount of additive is steadily increased until the black silicon surface disappears again. Trifluoromethane is known as an effective compound for ion-assisted etching of silicon oxide, with an oxide removal rate increased by a factor of 5–10 when compared to fluorine radicals (van Roosmalen 1984):

$$2CHF_3 + SiO_2 \rightarrow 2COHF + SiF_4$$

The effect of carbon acting as an attractive reaction partner for oxygen from SiO_2 is a reason for this increased oxide removal rate, compared to fluorine radicals alone.

As a consequence, the ion-bombarded bottom is cleared from the masking oxide and can be etched by the fluorine radicals from SF_6, while the unbombarded sidewall passivation remains unaffected by CHF_3 addition and protects well against fluorine radical attack. Anisotropic etching with vertical sidewalls in silicon can thus be achieved. Photomask selectivity suffers from the presence of both oxygen and fluorine radicals in the plasma, in combination with the energetic ion impact needed to break the bottom silicon oxide. Ion-enhanced photomask erosion by oxygen and fluorine radicals is the undesired consequence. A similar statement holds for SiO_2 mask selectivity, with the silicon oxide mask suffering from the ion-enhanced action of the oxide scavenger together with fluorine radicals.

The black silicon method has potential as a DRIE technique; however, a critical balance has to be maintained between passivants, scavengers, and etchants, which compete with each other in the same process. A high percentage of oxygen flow is needed in the process for effective sidewall passivation, further reducing etch rate and mask selectivity. The process window is narrow.

1.08.3.2 Cryogenic Dry Etching

Cryogenic dry etching is a variation of the passivation technique based on sidewall oxidation. For cryogenic temperatures typically around 175 K (−98°C), which can be realized by liquid nitrogen (LN_2) cooling of the substrates, chemical stability of the inhibiting silicon oxide film in a fluorine-based plasma process is strongly increased, mainly because desorption of the reaction products of silicon oxyfluoride-type from unbombarded surfaces are frozen by the low temperature. Ion bombardment on the etch floor removes the passivating film there by sputtering off most of the chemical compounds. The enhanced oxide film stability at low temperature reduces the flow of oxygen gas required for anisotropic etching to a small percentage of the flow of SF_6, the fluorine radical supply gas. Perfectly vertical etching in silicon can be achieved with a strong overweight of etching fluorine radicals, compared to the passivating oxygen radicals, yielding high etch rates and a relatively wide process window, in comparison to the black silicon method. Impressive results were achieved with cryogenic dry etching in inductively coupled plasma (ICP) tools like the Alcatel reactor, with silicon etch rates reaching 4–6 μm min^{-1}, and mask selectivities of 100:1 for SiO_2 hard masks (Bartha *et al.* 1995). Use of photomasks is difficult, however not impossible if special resist treatment for stress adjustment is performed before the etch, for prevention of cracking and delamination at the low substrate temperatures. The main drawback of the cryogenic etching method is related to the low substrate temperature and the critical dependence of process properties on the latter temperature, given the strong heat impact from the plasma on the substrate and the exothermic etching reaction between silicon and fluorine radicals. In addition, the substrate as the coldest part in the whole configuration acts as a cryopump, freezing out compounds from the plasma, which act as hard-to-remove micromasks on the wafer surface. Micromasking is responsible for the formation of microneedles and micrograss on the silicon surface (black silicon, see **Figures 5** and **6** for illustration), which is observed in most of the deeper cryogenic etches as a disturbing, often unacceptable factor. Nevertheless, cryogenic dry etching has maintained its place as an important silicon microstructuring technique, e.g., in micro-optical applications, where smooth sidewalls on a nanometer scale are of key importance.

1.08.3.3 The Bosch Process

1.08.3.3.1 Process technique

The etching techniques described before make use of relatively hard-to-remove compounds as passivating layers, such as the silicon oxides or oxyfluorides resulting from silicon surface oxidation. Their complete removal from the etch floor without leaving back micromasking residues requires energetic ion impact, eventually in combination with the added scavenging agents. Excessive ion sputtering and the use of scavengers reduce the selectivity toward the masking materials. This is especially true in the case of photoresist masking. Again there is a fundamental trade-off between a clean trench bottom and a high mask selectivity.

To overcome this trade-off and reach both high mask selectivities and a trench bottom free from residues, hard-to-remove passivating compounds must be avoided in the process.

A technique that avoids the formation of such compounds is the deposition of smooth polytetrafluoroethylene (PTFE)- or Teflon®-like films on the silicon surface during etching. Mogab *et al.* (1979) describes the importance of balancing between etching and polymerizing species, and effects of changing this balance for both Si and SiO_2 etching.

Plasma polymerization can be achieved by the generation of $(CF_2)_n$-type radicals in the plasma, starting from precursor gases like trifluoromethane (CHF_3), or preferably hexafluoropropene (C_3F_6) or octafluorocyclobutane (RC318®, C_4F_8), the latter being a nontoxic and stable dimer of tetrafluoroethylene (TFE, C_2F_4). The deposited smooth passivating film consists of a network of long linear $(CF_2)_n$ chains with only little cross-linking, which can be easily removed from the etch floor by low-energetic ion bombardment without leaving back residues. A mixture of SF_6 gas for the fluorine radical supply and C_4F_8 gas for the supply of polymer forming radicals can be used in the plasma to achieve both passivation at the sidewall and etching at the etch floor, yielding anisotropic profiles in silicon. In addition, the presence of fluorocarbons in the process to some extent scavenges the undesired hard passivation from the floor, like silicon oxides from oxygen background gas or oxygen precipitates in the silicon material itself. However, the presence of fluorine radicals as etching species and of Teflon forming monomers as depositing, film-forming species together in the plasma, at the same time, leads to recombination and mutual

extinction of both kinds of species. This makes a mixed process difficult to control for deeper etches and lowers process performance mainly with respect to etch rate. These drawbacks appear more relaxed for plasma sources of very high excitation density like the ICP (see later), but still the potential of the mixed process approach remains limited to shallow trenches with a depth on the order of 10 µm.

The recombination problem was overcome by the patented Bosch process technology (Laermer and Schilp 1992), which is a variation of the Teflon-based sidewall passivation technique. **Figure 2** illustrates the process mechanism. Passivation and etching gases are introduced separately and alternatingly into the process chamber and exposed to a high-density plasma during so-called passivation and etch cycles, respectively. The high-density plasma is generated by microwave surfatron or inductive RF excitation. During each passivation cycle, a thin Teflon-like film is deposited onto the walls of etched structures from C_4F_8 precursor species. Scavenging of some oxides from the silicon etch floor can also happen during or after the Teflon deposition step. During the subsequent etching cycle, part of this film is removed from the coated sidewall by off-vertical ion impact and is driven deeper into the trench, at the same time the trench bottom is cleared from fluorocarbon polymer and etched by fluorine radicals released from SF_6 in the plasma. Switching times between steps normally range from a few seconds up to one minute, depending on the tolerated sidewall roughness. Since the passivating polymer film can be removed by only little ion sputtering impact, mask selectivity reaches very high values, e.g., 150:1 for photoresist and $\gg$300:1 for SiO_2 hard masks. If harder passivating polymers were used, more aggressive ion impact would be required, and as a consequence selectivity toward the masking material would be reduced.

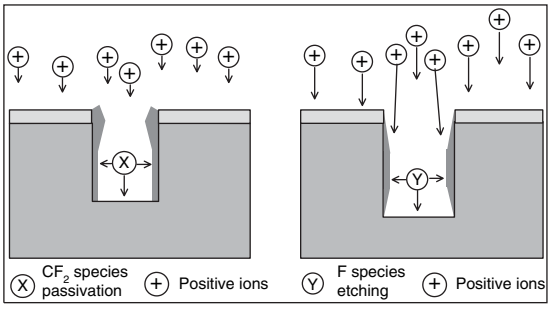

Figure 2 Basic mechanism of the Bosch process. The protecting Teflon®-like film deposited onto the structures during the passivation step is cleared from the trench floor and is driven deeper into the trenches during the (intrinsically isotropic) fluorine-based etching step.

Transport of the sidewall film, i.e., removal and redeposition of Teflon material, makes the etching steps anisotropic, which would otherwise be completely isotropic, in the vicinity of the sidewall, but it does not adversely affect the main etching reaction away from the sidewall. Sidewall roughness is thus reduced despite the discontinuous process. Since plasma polymerization is nonconformal in narrow trenches and film formation preferentially takes place at the trench opening, leaving deeper sidewall regions with less-deposited passivating film, the flow of polymer material along the sidewalls toward the trench floor also provides a more uniform sidewall passivation over the trench depth. **Figure 3** shows typical structures, profile forms, and characteristic sidewall scalloping as the result of standard Bosch DRIE process recipes.

The discontinuous nature of the process overcomes a number of general problems involved with anisotropic etching: firstly recombination loss of reactive species that will not coexist, by gas-phase reactions causing their pairwise extinction, is excluded by separating them in the time domain. This is most important for the volume of the plasma source itself, where the species are generated at high concentration levels and where recombination would be strong. Outside the high-density source area, in a more diluted state, coexistence of species is easier to achieve and some mixing, in the space between the source and the substrate, can be tolerated there. This allows to reduce switching times to below 1 s, e.g., down to 100 ms, keeping passivating and etching species separate in the limited volume of high-density plasma excitation, but overlapping them partly on their way from the source to the substrate. The so-called ultrafast gas-switching conditions yield very smooth sidewalls with hardly any remaining sidewall scalloping at all, as is depicted in the scanning electron microscope (SEM) pictures of **Figure 4**.

Secondly, a vertical etching process having a high mask selectivity bears an inherent risk for micromasking the trench floor. Even minor contamination on the etch surface can lead to formation of residues, microroughness, and even microneedles. Having a sidewall with a periodic nanostructure or ripple on the order of 10 nm in size is an advantage in this respect: micromasks smaller than the characteristic dimension of the scallops are undercut and extinguished from the surface, leaving back no etch residues. Only if the size of a micromask exceeds

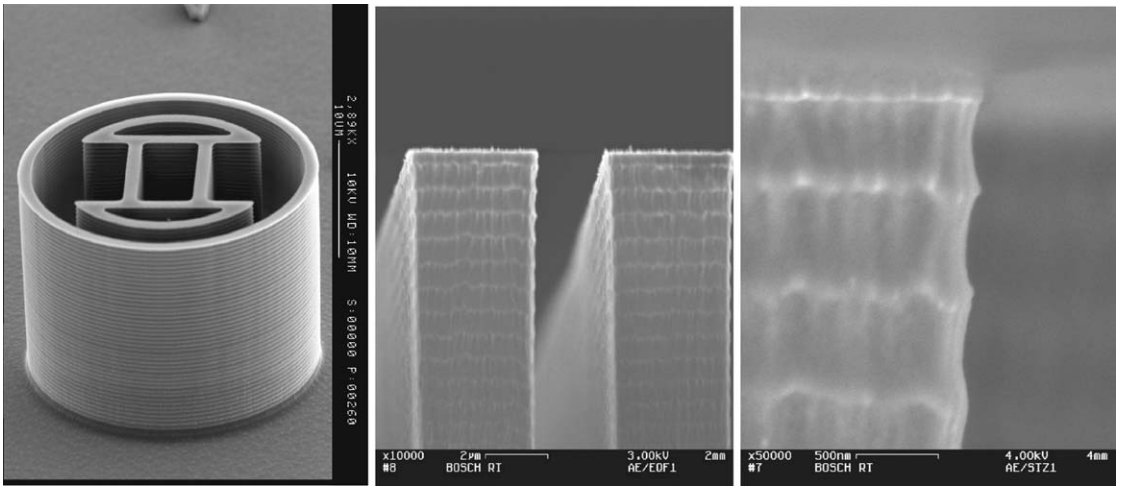

Figure 3 Trench profiles and sidewall structure resulting from a typical Bosch deep reactive ion etching (DRIE) process recipe.

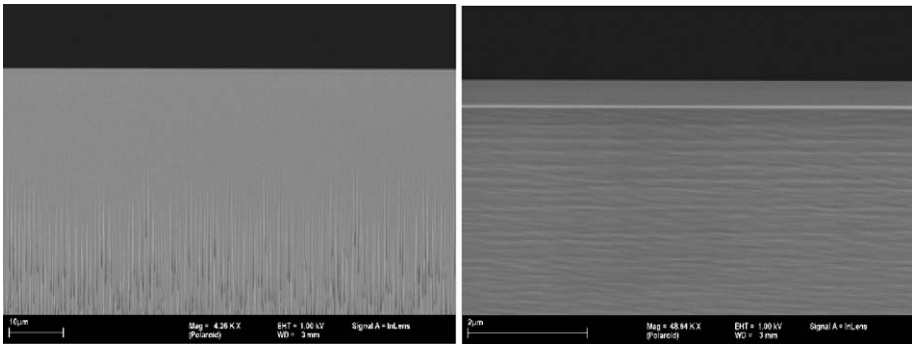

Figure 4 Scanning electron microscope (SEM) pictures of the sidewall resulting from a Bosch process using an ultrafast switching recipe: hardly any horizontal scalloping is visible at the sidewall anymore. Some vertical striations are visible in the lower part of the left-hand side SEM picture, indicating the beginning of microroughness formation at the trench bottom, which does also affect the sidewall.

the critical dimension limit, which the process can tolerate by undercutting, it causes a potential residue problem. This has to be considered in connection with the before-mentioned ultrafast gas switching where the sidewall scalloping is practically gone: the latter process recipes are more critical with respect to the formation of microroughness, resulting from micromasking effects. **Figures 5** and **6** show top views and cross sections (SEM pictures), respectively, of an etching floor with severe microroughness (micrograss or black silicon), resulting from a Bosch DRIE process recipe heavily overloaded with passivation. The excess passivation results in the formation of the characteristic microfeatures, starting from a random distribution of incidental contaminants on the etched surface.

The wide process window, simple control of process characteristics, and the high performance have established the Bosch process as a leading silicon microstructuring technique for MEMS. One of the first papers describing some of the new applications enabled by this technology is given in Klaassen *et al.* (1995). There has been a continuous progress in the technology, with a number of established equipment suppliers offering dedicated equipment tools for a wide range of purposes, from research to mid-volume up to high-volume manufacturing. Starting from a few micrometers per minute in the early days of DRIE, etch rates have meanwhile reached values in excess of 50 µm min^{-1} in silicon, and are even driven further by new requirements coming from through-wafer interconnect and chip-stacking technologies

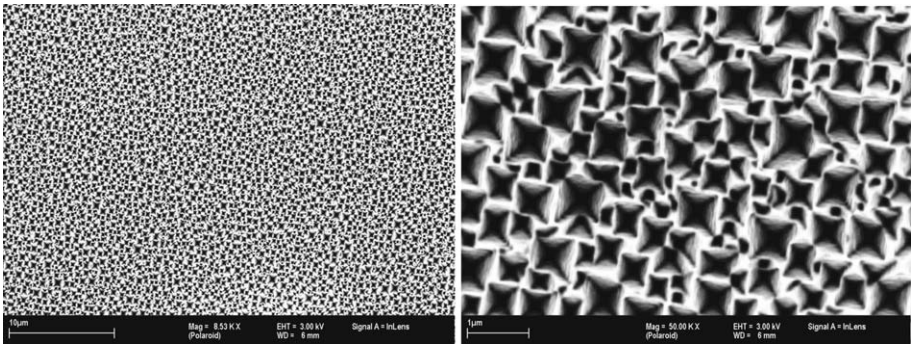

Figure 5 Top-view scanning electron microscope (SEM) pictures of etch bottom with pronounced microroughness (black silicon or micrograss), resulting from a Bosch deep reactive ion etching (DRIE) process heavily overloaded with passivation.

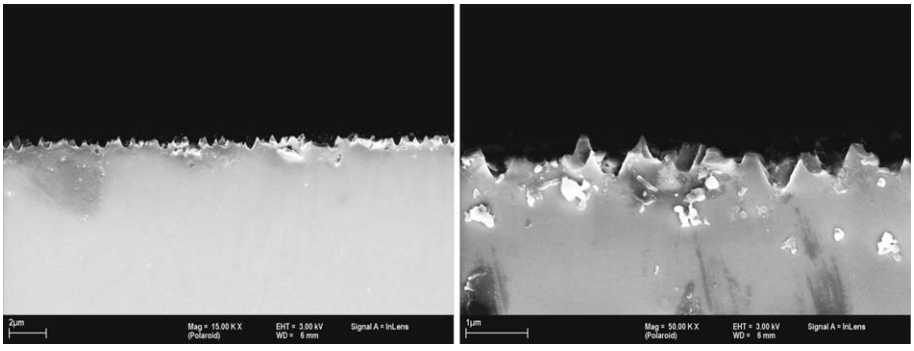

Figure 6 Cross-sectional scanning electron microscope (SEM) pictures of etch bottom with pronounced microroughness (black silicon or micrograss), resulting from a Bosch deep reactive ion etching (DRIE) process heavily overloaded with passivation.

emerging in the semiconductor field. This means that a full silicon wafer can be etched completely from its frontside to the backside within a few minutes. Progress results from the improvement of both process and equipment technology. Having originally started from the microwave surfatron plasma source (a microwave guide in the form of a dielectric tube or a horn, which draws the plasma and the microwave radiation along the guiding structure, see e.g., Laermer and Schilp 1992), the leading equipment for DRIE of today, under industrial conditions, is clearly the ICP source. ICP technology has been developed so far to fulfill all key requirements of the Bosch DRIE approach.

1.08.3.3.2 Plasma equipment for deep reactive ion etching

A high-density plasma tool with so-called remote or decoupled plasma is necessary to make the DRIE technology work, which is mainly based on the chemical activity of the plasma. Chemical activity means firstly to reach sufficiently high concentration of polymerizing radicals for strong sidewall passivation, secondly to reach sufficiently high concentration of fluorine radicals for high etch rates. For a high density of chemically active species, a process pressure regime of typically between 1 and 10 Pa is the most appropriate. Energy of the ions flowing to the wafer surface must be controlled independently of the plasma excitation, through substrate electrode biasing. The latter can be done by a RF or low-frequency bias generator. For a good control of ion acceleration independent of plasma excitation, the plasma potential should be kept sufficiently low, as close as possible to the ground potential. The latter requires decoupling of the plasma excitation zone from the substrate region.

Traditional plasma sources for RIE fail in one or more of these requirements. Diode and triode reactors show insufficient plasma excitation density, below $10^{10}\,\mathrm{cm}^{-3}$. Electron cyclotron resonance (ECR) sources are inappropriate for the very

low-pressure regime (<0.1 Pa) tolerated by the cyclotron resonance mode. ECR is a typical ion current type of source and lacking sufficient chemical activity, mainly for the low-pressure argument. Microwave surfatron sources (a tube or a horn made from dielectric material to guide the microwave field along the interface between the dielectrics and the plasma burning inside the tube or the horn, down to the process chamber, see Laermer and Schilp 1992), helicon sources, and ICP sources open the pressure window up to 10 Pa and even higher pressures. Amongst these alternatives, the ICP emerged as the most appropriate source technology for this kind of processing and as the industry standard. **Figure 7** shows a schematic of a simple configuration of an ICP wafer processing tool.

In principle, an ICP is generated inside a magnetic coil, which is driven by RF power. In most cases, RF of 13.56 MHz is used for driving the ICP, but also 2 MHz and lower frequencies can be found in some places. The coil of one or several turns, depending on the chosen frequency, is wound around a dielectric vessel. By feeding RF power to the coil, a high-frequency oscillating magnetic field is generated inside the coil, with a corresponding oscillating electric field resulting from Maxwell's induction law. The electric field can excite and drive a high-density plasma within the dielectric vessel. Since the plasma is not able to shield itself effectively from this inner driving electric field by the formation of sheaths, extremely high densities of charged particles (electrons and ions $\sim 10^{12}$–10^{14} cm^{-3}) can be provided by the inductive technology. The electrons are heated by the RF electric field and generate the ions and chemically active species by collisions with gas molecules. Before the plasma of charged and neutral species reaches the substrate, the hot electrons need to cool down and as a rule the distributions of ions and neutrals need some kind of readjustment and rearrangement for homogenization of etching results. Mechanical apertures (Laermer *et al.* 1999), gas flow guides, and gas flow redirectors, in combination with balanced excitation of the inductive coil (Becker *et al.* 1999) and magnetic lenses for plasma collimation (Breitschwerdt *et al.* 2000), are useful and found in this place.

RF power levels used today have reached values of 5 kW at 13.56 MHz for the high etch rate conditions, imposing severe challenges on the stability of RF matching mimics (capacitors, variocaps, inductors, BALUN cables, etc.) and on the decoupling, cooling, and homogenization of the plasma at the substrate location. **Figure 8** shows a scheme of a typical advanced remote ICP tool configuration, as an example for illustration.

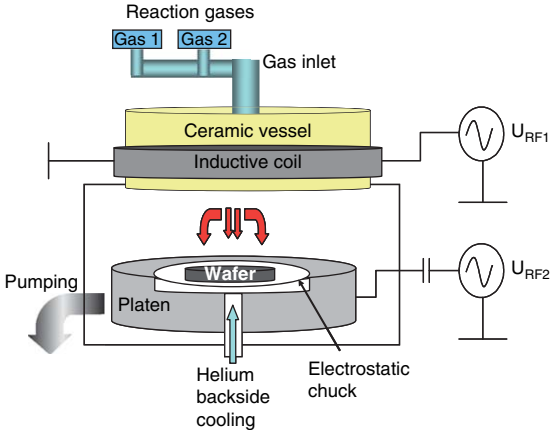

Figure 7 Schematic of an inductively coupled plasma (ICP) tool. Radio frequency (RF) generator 1 powers the inductive coil, wound around the dielectric reactor vessel, to generate a high-density plasma within the reactor. Mostly ceramic materials are used for the vessel. RF generator 2 powers the substrate electrode for biasing and accelerating ions to the wafer. Electrostatic clamping and helium backside pressure serve to cool the wafer during processing.

1.08.4 Special Issues Related to Bosch DRIE

1.08.4.1 Control of RIE Lag

RIE lag is a common and well-understood transport phenomenon in plasma etching, see the review given in Gottscho *et al.* (1992). Etching speed and profile evolution with etching progress depend on the depth:width ratio of the trench, the so-called aspect ratio. In general, the etch in narrower trenches progresses at a lower speed than in wider trenches, i.e., higher aspect ratio trenches lag behind the lower aspect ratio trenches. The amount of the lag effect depends mainly on the mean free path of the gaseous species, which determines their transport in etched trenches, compare, for example, with the conductance model described in Coburn and Winters (1989). In addition, interaction and change of balance between etching and passivating species during their transport in etched trenches are important, which is again related to mean free path and process pressure. Changes in the balance of etching and passivating species with increasing aspect ratio also affect

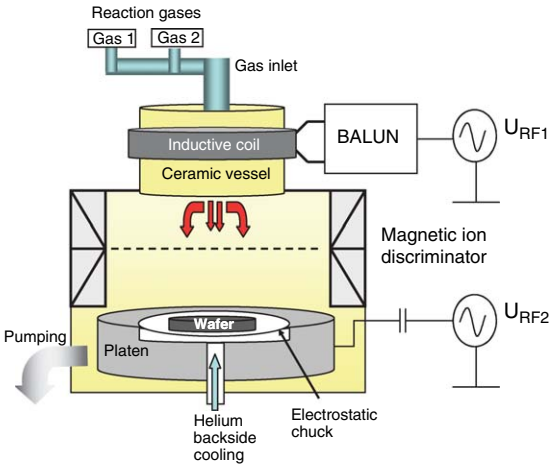

Figure 8 Advanced decoupled high-density plasma tool for deep reactive ion etching (DRIE). Inductive coil symmetrically powered by RF1 from BALUN transformer generates the high-density plasma within the dielectric reactor vessel. Drift zone with magnetic ion discriminator: decoupling of the plasma and homogenization of neutrals flow, and readjustment of spatial ion distribution, e.g., through magnetic lenses, respectively. Application of RF2 power to the substrate electrode for biasing and accelerating the ions toward the wafer substrate. Electrostatic chuck (E-chuck) and He backpressure serve for wafer cooling.

anisotropy and profile form. Figure 9 illustrates a characteristic example for RIE lag in a typical Bosch process.

In a discontinuous process with separate etching and passivating cycles, which can be controlled independently from each other, there is an individually controllable lag effect both for the etching and for the passivating part of the overall process. For the etch step, the higher the aspect ratio of the trench the less the number of ions and fluorine radicals that can reach the trench floor per time unit and etch the silicon, the size of the effect depending mainly on the etch step pressure. For the deposition step, the higher the aspect ratio of the trench the less the polymer formers that can reach the trench floor per time unit and build up an inhibiting film on the floor, the size of the effect depending again mainly on the deposition step pressure. Since a thinner inhibiting film on the etch floor increases the rate for the subsequent etch step, this involves some compensation for the rate decrease with aspect ratio, resulting from the reduced fluorine radical supply. Deposition step lag and etching step lag can compensate each other to reach a lag-free overall process over a wide range of aspect ratios. This is achievable by individual control of the etch step and deposition step parameters, mainly by the pressure values set for the different process steps.

Setting the pressure higher for the individual step increases its lag effect and setting the pressure lower decreases its lag effect. Increasing the deposition step pressure with respect to the etch step pressure, even to values higher than the etch step pressure, reduces the overall RIE lag of the total process and even inverts it at some stage, with higher aspect ratio trenches, i.e., narrower gaps, etching faster than smaller aspect ratio trenches, i.e., wider gaps. However, compensation for RIE lag is always at the expense of a reduced etch rate in the wider trenches, which approaches the low etch rate in the narrow trenches.

On the other hand, running a deposition step at a pressure lower than the etch step pressure will cause a significant overall RIE lag of the total process, however at the benefit of higher overall etching rates in the wider trenches. This is the normal process regime,

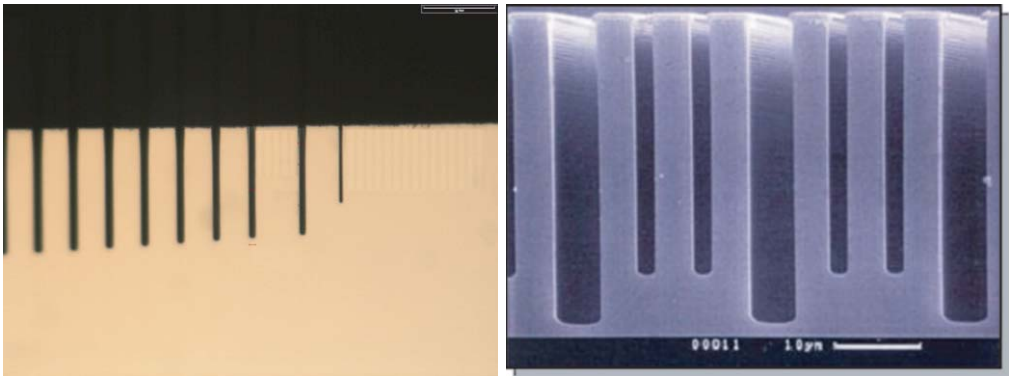

Figure 9 Examples for illustrating the reactive ion etching (RIE) lag effect. Etch rate and etch depth decrease with narrower gaps corresponding to higher aspect ratios.

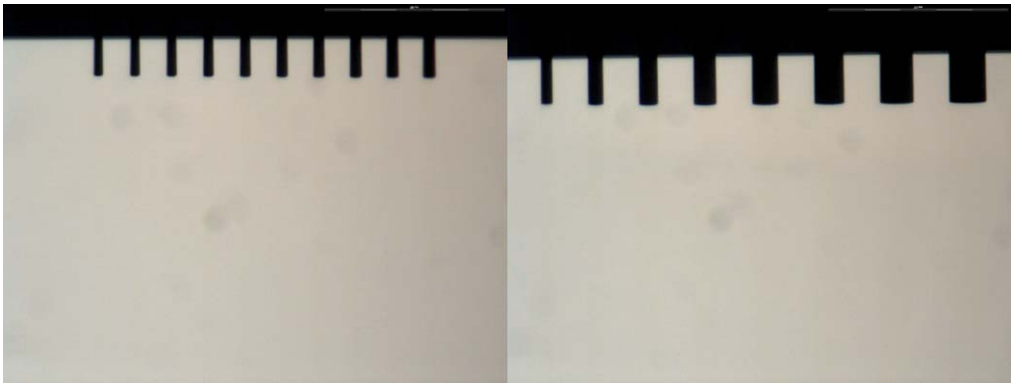

Figure 10 Example to illustrate reduction of reactive ion etching (RIE) lag. Etch depth varies moderately with trench width by a higher-order functional dependence.

which is used in most cases, in the interest of higher rates. **Figure 10** shows some results from a Bosch process modified for reduced RIE lag effect.

Since the stability of the polymer deposited onto the etch floor is an important weight factor in balancing etch and deposition lags, the amount of achievable compensation depends also on the substrate temperature. Lowering the substrate temperature makes the floor polymer more robust and increases the weight of the deposition step in the overall lag balancing. Hence, a substrate temperature of 0°C or even lower, instead of 40°C (under etching conditions, i.e., including heat flow from the plasma to the wafer), was found beneficial to achieve lag-free etching over a wide range of aspect ratios (Becker *et al.* 1998).

1.08.4.2 Parameter Ramping for High Aspect Ratio Etches

As mentioned before, in the fabrication of high aspect ratio trenches, different lag effects for etch and deposition steps yield a changing net etch rate with increasing aspect ratio. In general, for a normal process without the above-described compensation for RIE lag, e.g., for rate arguments, net etch rate lowers with increasing aspect ratio of the trenches. There is a changing balance between the passivating and the etching species, and a trend toward more passivation with the higher aspect ratios is reached during the etch. In addition, the amount of ions reaching the trench floor slowly diminishes due to the aperture effects at the trench opening, in combination with the angular distribution of the ions. As a consequence, profiles tend to develop positive slopes and trenches end up tipping when their aspect ratios typically reach values greater than 20:1.

Given that all trenches have a similar range of widths, the following procedure is adopted. During the progress of the etch, the process recipe is adapted stepwise or continuously (Hopkins *et al.* 1999, Hynes *et al.* 1999), e.g., to reduce the amount of passivation in the process. For example, passivation cycle time or passivation gas flow can be ramped down steadily. As an alternative, etching cycle time or etching gas flow can be ramped up steadily. Although other options like source power, bias power, or pressure ramping do exist, changing cycle times is the most obvious parameter ramping strategy to affect the etch:deposition balance in a predictable and straightforward manner. By using parameter ramping, trenches with aspect ratio >50:1 can be fabricated, while keeping the sidewalls straight and vertical.

1.08.4.3 Notching at Dielectric Interfaces

The notching effect is relevant for all cases where the silicon etch terminates on a dielectric insulating layer. This can be an etch stop for silicon oxide e.g., in surface micromachining, or for a polymer material like photoresist or adhesive foils in through-wafer etching. In surface micromachining, a silicon film is structured on top of a silicon oxide interlayer. This oxide interlayer serves both as a sacrificial layer to be removed later during a so-called release etch in hydrofluoric acid, to produce freestanding silicon structures, and as an electrical insulator to separate different structural parts from each other and from the substrate wafer.

When the dielectric etch stop is reached and an overetch takes place, charging of the trenched pattern features occurs (Arnold and Sawin 1991).

Charging of the dielectric trench floor with respect to the silicon sidewalls is a consequence of the different angular distributions of the predominant negatively charged species, the electrons, with no or only little directionality, and of the positively charged species, the ions, which reach the substrate with an orientation perpendicular to the surface. Thanks to their directionality, a large fraction of the incoming ions reach the dielectric bottom of a high aspect ratio trench, and a part of them get stuck and accumulate there. In contrast to the ion behavior, most of the incoming electrons get trapped by the structural sidewalls. Strong electric fields build up between the positively charged dielectric bottom and the negatively charged silicon sidewalls, redirecting incoming ions to the interface area between silicon and the dielectric layer. **Figure 11** illustrates this charging phenomenon.

Notching is a well-known consequence of the charging effect in high aspect ratio trenches (Hwang and Giapis 1997, Kinoshita *et al.* 1996, Nozawa *et al.* 1994). Where the redirected ions hit the structure sidewalls, deep notches are cut into the silicon near the dielectric interface. **Figure 14(a)** illustrates a typical example after overetching at the dielectric etch stop. The notches affect the mechanical properties of the fabricated silicon structures in an unpredictable way and represent a serious particle source in manufacturing. Many development efforts have been put into the suppression of notching for its strong practical relevance.

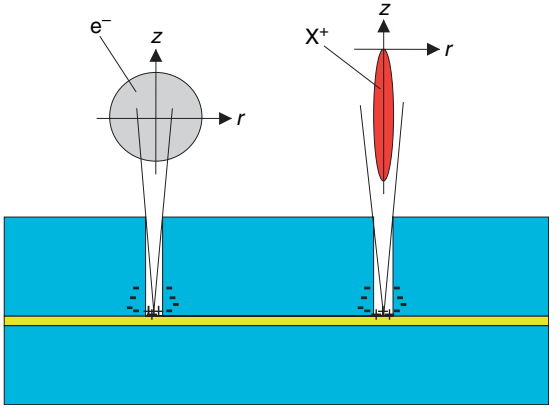

Figure 11 Charging of high aspect ratio trenches. Silicon sidewalls take up electrons with little or no directionality. The dielectric trench floor traps positively charged ions arriving at an orientation perpendicular to the surface. Strong electric fields build up between the accumulated positive charges on the dielectric bottom and the negative charges in the silicon material.

Since charging and the resulting electric fields are the driving forces behind notching, all technical solutions aim at a reduction of charge separation in high aspect ratio trenches. Pulsing the substrate bias as depicted in **Figure 12** gives accumulated charges in the structure a chance to neutralize. Bias breaks with no or little ion impact between the bias bursts with a strong ion impact must be long enough in relation to a characteristic time constant for the leakage currents to discharge. Pulsing is feasible for both RF (13.56 or 2 MHz) and LF (380 kHz) biasing. Low-frequency biasing has some intrinsic advantages with respect to less charging, because both electrons and ions are able to follow the (slowly) alternating electric field, the latter despite their heavy mass. As a consequence, in contrast to high-frequency biasing, the electrons are more directed toward the substrate and reach the dielectric trench bottom more easily. This results in a slower and somewhat reduced buildup of charges at the dielectric interface, which is further reduced by pulsing the bias voltage. The disadvantage of using low-frequency biasing, in contrast to higher frequencies, is that ion energies are less well defined and cover a wide spectrum of energies. The latter makes process control more difficult to achieve. In addition, matching units for low-frequency biasing are not as well established and stable as for biasing at the high-frequency standard of 13.56 MHz. Typical pulse repetition frequencies are in a range of 30–300 Hz, with duty cycles (pulse on per period time) between 5% and 50%.

A more powerful solution for the suppression of notching is described in Laermer (2001), which represents a combination of a sophisticated pulsing scheme for the substrate bias power and pulsing of the plasma source power. **Figure 13** illustrates this

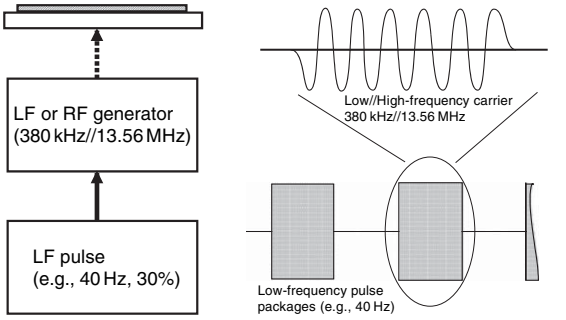

Figure 12 Suppression of notching by pulsed substrate bias power. Radio frequency (RF) substrate biasing (low, mid, or high frequency) is modulated by a train of short pulses, e.g., at 40-Hz repetition rate.

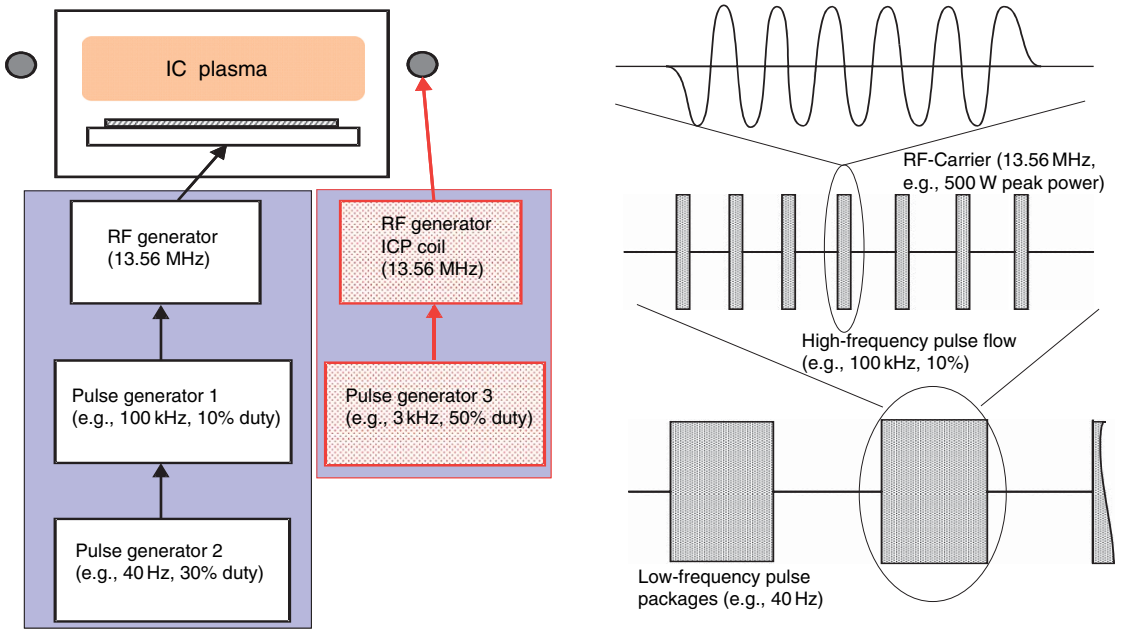

Figure 13 Antinotching scheme for combined pulsing of plasma source power and substrate bias power. *Left*: Hardware configuration for pulsed plasma source and substrate electrode. *Right*: Pulsing scheme at the substrate electrode: radio frequency (RF) carrier (13.56 MHz) is modulated by a fast train of short pulses (100 kHz) combined with a slow pulse modulation (40 Hz).

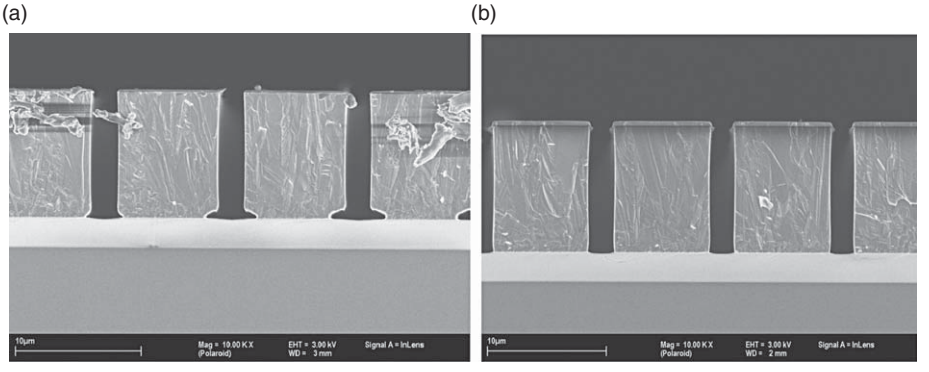

Figure 14 (a) Notching phenomenon from overetch at the dielectric etch stop of SiO_2, without appropriate countermeasures. (b) Notch-free etch stop on SiO_2 after 100% overetch, with the above-described countermeasures taken.

method, both the hardware configuration and the pulse train at the substrate electrode.

Switching off the plasma source power periodically yields peaks of negatively charged ions (anions), which are generated during the afterglow phases when the plasma breaks down and the cooling electrons are caught by neutral gas molecules. In contrast to the undirectional electrons, the anions do reach and effectively neutralize positively charged ions at the dielectric trench floor during substrate bias power breaks, i.e., when the substrate is not repulsive toward negative charges. Typical repetition rates for the plasma power are between 1 and 5 kHz, at a duty cycle of about 50%. Repetition rates for the substrate bias power are, for example, 100 kHz for the fast pulse train and 40 Hz for the slow pulse train. The depicted substrate biasing scheme is an attempt to emulate low-frequency biasing conditions into RF biasing, with higher peak voltage levels and lower average currents to the substrate electrode, and a reduced charge buildup resulting from the fast modulated pulse train at low duty cycle. The goal is

to emulate some of the advantages of using low-frequency biasing, without incorporating the disadvantages. Note that since the carrier frequency is still at 13.56 MHz, a standard RF matching unit can be utilized.

Extremely strong overetch is tolerated without notching using this approach. **Figure 14(b)** illustrates an example of a 100% overetch on silicon dioxide.

1.08.5 Conclusions

The Bosch process has emerged as the standard DRIE technology for microstructuring of silicon MEMS. Performance and flexibility, freedom of design independent of crystal orientation, IC compatibility, and the usability of standard masking materials like photoresist are the relevant success factors. DRIE enables the fabrication of various MEMS structures and fascinating new designs (Senturia 2001). From history, geometries like that were first demonstrated to the MEMS community by the LIGA technique in the 1980s, which attracted a lot of attention and caused enthusiasm for 3D microstructuring at the time. In contrast to LIGA, the DRIE technology is virtually what the MEMS community was dreaming of: reasonably low cost and close to semiconductor industrial standards.

Progress is driven by process and hardware evolution, and new upcoming requirements like through-wafer interconnects requesting even higher rates and accuracy. Developments are nowadays focused into more and more specialized directions. This is strongly supported by an established equipment supplier base defining their individual core competencies in dedicated fields, and covering the full scope of requirements from R&D level into high-volume mass manufacturing.

Biography

Franz Laermer was born in Waldsassen, Germany, in 1960. He studied physics and mathematics at the Technical University Munich, Germany, and physics at the Swiss Federal Institute of Technology (ETH) Zurich, Switzerland, from 1980 to 1986. He obtained a Diploma in Physics from ETH Zurich, Switzerland, in 1986 and a Ph.D. from the Technical University Munich, Germany, in 1989. He joined Corporate Research and Technology Center of Robert Bosch GmbH, Stuttgart, Germany, in 1990. Laermer worked on new microstructuring technologies and new silicon sensors for automotive applications, mainly surface micromachined accelerometers, gyroscopes, and pressure sensors. He is an inventor of the Bosch deep reactive ion etching (DRIE) process and of many patents in the fields of Bosch DRIE, silicon micromachining, and silicon microsensors. Since 2003, he has been a director of an innovation project for new microsystems, targeting new application fields outside the automotive industry. Together with his co-worker Mrs Andrea Urban, he was awarded by the European Patent Office and the European Commission with the prize 'European Inventor of the year 2007 – Industry', for the invention and the sustainable success of the Bosch DRIE process for MEMS.

1.09 Wafer Bonding

1.09.1 Introduction

Wafer bonding has been an important and critical technology in the development of micromachined sensors, actuators, microsystems, and their packaging for many decades (Alexe and Gösele 2004, Esashi 1995, Goesele *et al.* 1999, Iyer and Auberton-Herve 2002, Ko *et al.* 1985, Najafi 2001–2006, *Philips J. Res., Spec. Issue Direct Bonding* 49, 1, Schmidt 1998, Tong and Gösele 1999). It is also being used in the fabrication of integrated circuits (ICs) and the formation of composite materials and wafers needed in advanced circuit technologies (Alexe and Gösele 2004). Wafer, or die, bonding refers to the process whereby two or more wafers of similar or dissimilar materials are, often permanently, attached or bonded together. The individual wafers might have already been through previous fabrication steps to form various features on them, or might just be plain wafers.

Wafer bonding has been used for a variety of applications in both microelectromechanical systems (MEMS) and IC areas, including:

- *Sensor/actuator and MEMS fabrication.* The earlier application of wafer bonding in MEMS was for the fabrication of micromachined sensors, specifically pressure sensors (Ko *et al.* 1985), where its primary use was to provide a supporting substrate for the sensor die. It was also used for the fabrication of capacitive pressure sensors where it formed one of the sensing electrodes of a capacitor. The use of bonding for MEMS fabrication has grown significantly over the past 30 years and has become a major technology, which is an indispensable tool in both research and commercial activities.
- *Packaging and assembly.* As important as it has been for MEMS fabrication, wafer/die bonding has also been equally important and critical for packaging and assembly of MEMS and ICs. Whether it was used for the attachment of individual IC die to its package housing or for bonding pressure sensor wafers to a support glass substrate, bonding and die attachments have remained a critical aspect of packaging and assembly in both MEMS and IC industries.
- *Fabrication of 3D or high aspect ratio microstructures and complex microsystems.* Wafer bonding is also now widely used in the fabrication of multilayer 3D and high aspect ratio microstructures and microsystems. In these structures, the creation of large 3D features is possible only using wafer bonding since most planar fabrication techniques used for the fabrication of MEMS are not capable of producing either large and high aspect ratio structures or multilayer structures that have embedded or buried features.
- *IC and semiconductor device fabrication.* Die bonding and attachment have long been used for packaging and assembly of ICs. Recently, wafer bonding has also become a very important part of IC and semiconductor device fabrication. In IC fabrication, the main application of wafer bonding has been for the fabrication of three-dimensionally stacked circuits whereby multiple layers of silicon circuits are directly formed on top of the existing layers using integrated feedthroughs and interconnects. This is an important research area in both academia and industry that could solve the critical challenge of packing more transistors in a given area or volume without having to further reduce feature sizes. In the area of semiconductor device fabrication, wafer bonding has also become an indispensable technology since it allows the bonding of dissimilar materials like silicon and GaAs, thus allowing the fabrication of heterogeneous devices and circuits, which combines the best features of two or more technologies or materials without sacrificing the performance. Thus, some devices can be fabricated on one wafer using a given technology, and other devices on another wafer using another technology, and then the two wafers can be bonded to interconnect the devices and complete the system without disturbing or interfering with the individual processes.
- *Fabrication of composite wafers or materials.* Finally, wafer bonding has become a key technology in fabricating wafers that provide new capabilities and materials for both the IC and MEMS industries. Silicon-on-insulator (SOI) wafers are now routinely fabricated much more economically using wafer bonding rather than using previous methods such as oxygen implantation and silicon recrystallization. In addition, wafers consisting of thin films of a variety of semiconductor materials bonded to a host silicon wafer are also now in widespread use in microelectronics, optoelectronics, and nanotechnologies. In fact, wafer bonding is now considered as one of the most important and critical technologies for the future of the IC industry, and significant resources are dedicated to it to develop its technology into a high-volume and low-cost technology for the IC industry.

This chapter briefly reviews different wafer bonding techniques and discusses their advantages and disadvantages. Although the focus of the chapter focus is on the bonding of two wafers, the same wafer bonding

techniques are also applied for the attachment or bonding of small pieces and die. In fact, many wafer bonding techniques were adapted from earlier techniques developed for die attachment and IC die packaging. Wafer bonding is a very broad field and it is not possible to discuss all of the intricacies and issues involved in all the different bonding techniques in a single chapter. Therefore, this chapter focuses primarily on reviewing each specific bonding technique and its characteristics.

1.09.2 Essential Elements of Wafer Bonding

Wafer bonding involves the attachment, often permanently, of two or more wafers made of similar or dissimilar materials. To achieve this, three fundamental elements are required, as discussed below and illustrated in Figure 1.

1. Wafer preparation
2. External activation
3. Bonding mechanism

- *Wafer preparation.* In almost all wafer bonding technologies, the wafers to be bonded have to be prepared properly. This often involves two steps. The first is the initial cleaning of the wafers to remove organic or inorganic contaminants from the wafers' surfaces, and to remove any particulates that might get lodged in between the two wafers and prevent bonding. The second step involves surface preparation, and this could vary widely from one bonding technique to another. In some techniques, the wafer surfaces have to be devoid of any surface oxide, which requires either physical or chemical removal of the oxide. In others, the surface has to be treated so that it either includes or is free of some chemical species that could help in the bonding process; for example hydrogen plays a key role in direct wafer bonding (DWB) of silicon.
- *External activation.* Once the wafers are cleaned, their surfaces are appropriately prepared, and they are properly aligned and brought together; the environment surrounding the wafers has to be activated such that the bonding process can be initiated and completed. There are a number of different external activation procedures that are used, depending on the type of bonding and the required characteristics. Most wafer bonding processes require heat. Some need an applied electric field, pressure or force, and some use vibration. The role of these external factors is to facilitate and initiate the bonding process. Some bonding techniques differ from others just based on

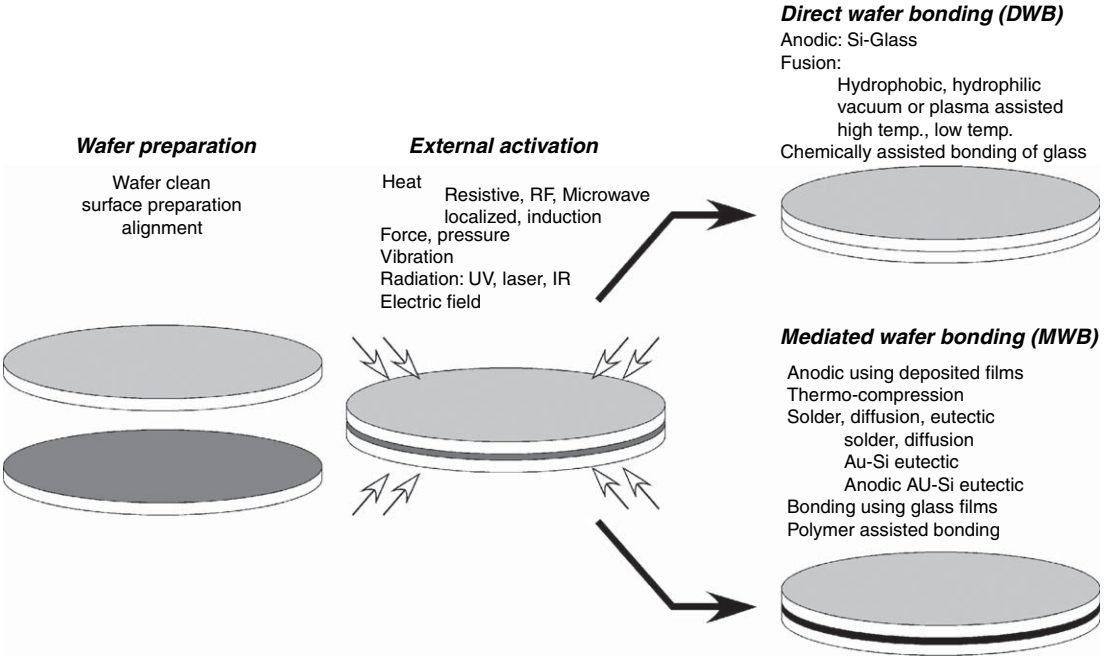

Figure 1 Three essential elements of wafer bonding: wafer preparation, external activation, and wafer bonding.

how this external activation is achieved. For example, heat can be applied to the bond region using a number of different techniques, including resistive heaters and microwave and radio frequency (RF) radiation. Wafer bonding based on all these techniques has been demonstrated and will be discussed.

- *Bonding mechanism.* The primary feature that differentiates different wafer bonding technologies is the intrinsic mechanism involved in the bonding process. The bonding process is initiated and progresses once all the external conditions are in place. For example, in DWB, the two surfaces of a cleaned and polished silicon wafer are brought into intimate contact thus allowing the atoms on the surfaces of these wafers to directly and covalently bond together and form a permanent bond. This chapter uses this distinction to categorize different bonding technologies, as discussed below.

1.09.3 Characteristics Desired in Wafer Bonding

Because of the various applications and materials used, it is difficult to develop a uniform set of requirements for wafer bonding technologies. Different applications have different requirements and demand different specifications for the bond. However, it is instructive to discuss what are typically considered desirable features for a successful wafer bonding technology. These desirable features include the following:

- *Low temperature.* Temperature is perhaps the most important factor in wafer bonding. As will be discussed later, most bonding technologies require the incorporation of some external energy to promote and initiate bonding between two wafers. This is usually done by heating the two wafers. It is very desirable that the bonding temperature be as close to room temperature as possible to reduce any detrimental effects due to such physical phenomena as thermally induced expansion and mechanical drifts.
- *Strong and high-quality bond.* Bond strength and the quality of the bond should be sufficient for the specific application. In most cases the bond should have very high strength not only to survive harsh environments such as external shock and stress due to subsequent processes, but also to minimize any fatigue or long-term drift. In addition to strength, the bonded interface has to be airtight and hermetic as most wafer bonding technologies are used for hermetic and vacuum packaging applications.
- *Low cost.* Needless to say, the cost of wafer bonding should be kept as small as possible. Although many bonding technologies have been, and can be, applied to individual dice or small wafers for many years at very low cost, some are not amenable to low-cost wafer-level processing. That is to say, the wafer bond is often more expensive than the die bond. For any wafer bonding technology to be successful, cost has to be minimized at all cost.
- *Minimum external disturbance.* Wafer bonding also often involves the application of pressure, force, or vibration to further promote interaction between two surfaces and to initiate the bonding process. These external mechanical disturbances should also be minimized in order to minimize the possibility of any damage to the wafers, or the devices that might exist when the wafers are bonded together.
- *Tolerance to particulates, surface preparation, surface topology, or roughness.* One of the most critical challenges in wafer bonding is proper surface preparation. Most bonds cannot be reproducibly and uniformly formed if the surface is not clean, has a thin oxide layer, has any particulates stuck to it, or has topography that could interfere with the bonding. For most bonds to be successful, the two surfaces either need to come into intimate contact or should have sufficient contact to facilitate their mixing and interaction. The role of the surface and surface properties cannot be underestimated.
- *Reproducibility, uniformity, high yield.* Many wafer bonding technologies exist, and many of them have been demonstrated in practice, illustrating the theoretical possibility. But not all wafer bonding technologies are practical or useful. In some cases, the bonds achieved are neither reproducible nor uniform across a given wafer. In other cases, the yield is unpredictable. These are very important characteristics of a successful bonding process and often dictate what the eventual cost will be.
- *Ability to bond patterned wafers.* Increasingly, wafers that either have patterned structures on them or have nonplanarities due to etched regions have to be bonded. Some bonding technologies are more suitable for bonding of patterned wafers than others.
- *Low void/defect density.* Some bonding techniques tend to create voids or defects at or close to the bond interface. Some of these voids are formed as a result of the bonding process itself as gases are trapped in between the two wafers, and others are created due to

thermal mismatch between the two wafers. For some applications, especially in microelectronics devices, it is critical that the density of these voids and defects be kept to a minimum.

- *Compatibility with IC processes.* In some applications the bonding technology has to be compatible with ICs already fabricated on one of the other wafers. This requirement usually imposes a limitation on the maximum temperature to which wafers can be exposed and the chemicals used for forming, cleaning, treating, and activating the bonding surfaces.

Although these features are desirable in most wafer bonding technologies, other requirements may also be needed by some specific applications.

1.09.4 Wafer Bonding Technologies

Many different wafer bonding technologies have been developed during the past few decades, and many of these are in practical applications today. In this chapter these bonding technologies are categorized by the primary mechanism that is used to bond the wafers. The chapter also reviews several bonding technologies that are identified by the different activation processes they utilize in initiating and completing the bonding process. Bonding processes are divided into two broad categories, as illustrated in **Figure 1**. The first requires only two plain wafers without the need for any intermediate layer; this approach is often referred to as DWB. The second requires the use of an intermediate layer between the two wafers, and in this chapter, we refer to this approach as mediated wafer bonding (MWB). DWB approaches can be further categorized into the following techniques:

- Field-assisted anodic bonding
- Fusion bonding
  - Hydrophobic, hydrophilic
  - High temperature, low temperature
  - Vacuum- or plasma-assisted
- Chemically assisted bonding of glass surfaces

MWB approaches can be further categorized into the following techniques:

- Field-assisted anodic using deposited films
- Thermocompression
- Solder, diffusion, and eutectic
- Bonding using glass films
- Polymer-assisted wafer bonding

Bonding technologies can also be categorized based on the external activation technique they utilize, and these are categorized as follows:

- Localized heating
- RF and microwave and electromagnetic heating
- Ultrasonic
- Rapid thermal processing (RTP)
- Laser

Each of these bonding techniques is reviewed with a short discussion of their advantages, capabilities, limitations, and disadvantages.

1.09.4.1 Direct Wafer Bonding

1.09.4.1.1 Field-assisted anodic bonding

One of the most widely used bonding techniques in MEMS is that of bonding between a glass wafer/structure and a polished silicon substrate through a process called electrostatic or anodic bonding (Albaugh 1991, Ando *et al.* 1997, Anthony 1983, Blasquez and Favaro 2001, 2002, Briand *et al.* 2004, Chavan and Wise 2001, Dokmeci *et al.* 1997, Dunn *et al.* 2000, Esashi *et al.* 1992, Fehlner *et al.* 1986, Frye *et al.* 1986, Go and Cho 1998, Hara *et al.* 1999, Harpster and Najafi 2002, Henmi *et al.* 1993, 1994, Kanda *et al.* 1990, Lee *et al.* 2000, Meindl 1980, Pomerantz and Daniel 1968, 1969, Qingfeng *et al.* 2002, Rogers 1992, Rogers and Kowal 1995, Schjolberg-Henriksen *et al.* 2003, Spangler and Wise 1987, 1990, Tatic-Lucic *et al.* 1997, Wallis 1970, Wallis and Pomerantz 1969, Ziaie *et al.* 1996). This technique was first discovered and patented by Pomerantz (Pomerantz and Daniel 1968). This patent describes bonding of insulators to metals and semiconductors, and his work primarily focused on the bonding of metals to ceramics. In a later patent he also described the bonding of liquid metals to ceramics (Pomerantz and Daniel 1969). Later, the MEMS community and industry used the same approach to bond silicon and glass wafers with great success.

This bond can be achieved when two polished wafers of silicon and glass are brought into intimate contact and a high voltage is applied across this sandwich to form a permanent covalent bond, as illustrated in **Figure 2** (Najafi 2001–2006). The glass–silicon sandwich is heated to temperatures of about 300–400°C, which tends to soften the glass and lower its electrical resistivity (the softening point of Pyrex #7740 glass is 821°C and its annealing point is 560°C). Bonding should be achieved below these two temperatures to prevent any permanent distortions in

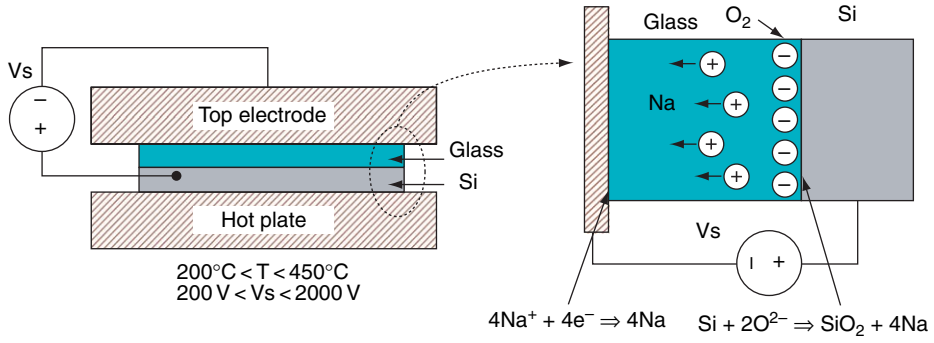

Figure 2 Anodic silicon–glass bonding. (Source: Najafi K 2001–2006 Wafer bonding. Lecture notes for Introduction to MEMS, A course taught at the University of Michigan.)

the glass that could compromise the shape of the final structure being formed. However, the temperature should be high enough to cause slight softening of the glass and to allow it to conform to minor topographical variations that could inhibit intimate contact between the glass and silicon wafers. A DC voltage of 800–1500 V is also applied across the glass–silicon combination for a period anywhere between 5 and 30 min depending on the wafer thickness, the series impedance, the interface planarity, and the bonding equipment. Typically, the wafers are pressed together with a uniform force to make sure that they are in good contact across the wafer. The positive terminal of the voltage source is connected to the silicon wafer, and the negative terminal is connected to the glass wafer. At room temperature, the glass wafer is a relatively good insulator, but at elevated temperatures it becomes a weak conductor. The electric field created within the glass forces the mobile alkali ions (sodium) to be pulled away from the bond interface and to the back surface of the glass where the electrode contact is located. They leave behind fixed positive ionic oxygen charges at the interface between glass and silicon. The applied voltage also generates a very high electrostatic attractive force, which pulls the silicon and the glass into intimate contact. The combination of the good contact and the availability of oxygen and silicon atoms at the interface promotes and forms a strong SiO_2 chemical bond between the two wafers right at the interface. During the bonding process, a current of a few milliamperes per square centimeter flows between the two electrodes, signifying the movement of ions and the completion of the process. Once the bond is complete, the structure is cooled down to room temperature. Figure 3 shows two photographs. The first

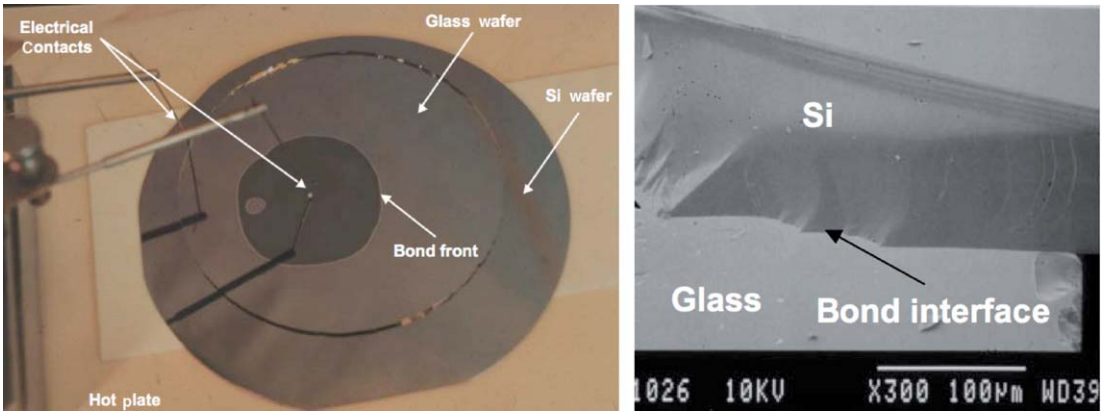

Figure 3 *Left*: View of a silicon–glass bond in progress. The glass wafer is on top of the silicon wafer, and both are on top of a hot plate. Electrodes provide electrical voltage to the two wafers. The dark circle in the middle shows where the two wafers are bonded and as bonding proceeds the circle gets darker. Note that if there are particles between the two wafers, they get trapped and engulfed by the bonded interface. The bond is stronger than either silicon or glass.

is the top view of a silicon–glass bond in progress. The glass wafer is on top of the silicon wafer, and both are on top of a hot plate. Electrodes provide electrical voltage to the two wafers. The dark circle in the middle shows where the two wafers are bonded; as bonding proceeds the dark circle enlarges. Note that if there are particles trapped between the two wafers, they get engulfed by the bonded interface. The other photo in **Figure 3** is a scanning electron microscope (SEM) view of a broken interface showing the glass and silicon films. The Si–O bond is stronger than the Si–Si bond and the glass. In order to minimize intrinsic stresses generated within the structure and at the silicon–glass interface, the thermal expansion coefficients of the glass and silicon have to be as nearly matched as possible. Therefore, Pyrex glass code #7740 is often used for silicon–glass bonding applications since this glass has not only an expansion coefficient very close to that of silicon, but also a low softening point that helps lower the bonding temperature. Alignment between the two wafers can be easily achieved using standard wafer bonding equipment.

There are several parameters, such as surface preparation, contact load, temperature, time of applied voltage, and magnitude of the applied voltage, that control the bond quality, which should be monitored during the anodic bonding process. Go and coworkers provide an analysis on glass–Si samples and calculate the effect of contact load, voltage, temperature, and time on bond strength; the results are summarized in **Table 1** (Go and Cho 1998). The data show that the bonding temperature affects bond strength, i.e., higher temperatures result in stronger bonds. The applied voltage and the bonding time contribute to bond strength to a lesser extent. Typical cleaning procedures in bonding include a hot acetone bath followed by an isopropyl alcohol (IPA) rinse and deionized (DI) water rinse.

It is also possible to bond silicon to a number of other types of glasses. More conductive glasses like the Pyrex #7740 glass that have a reasonable content of sodium and boron have lower melting and softening temperatures and are more suitable for anodic bonding. As the glass becomes more pure, its electrical conductivity decreases, which will reduce the electric field strength and lower the electrostatic attraction that exists between the two wafers. Therefore, lower conductivity glass wafers typically need a higher bonding temperature and higher applied voltage to achieve a successful bond. For example, Spangler and Wise reported in 1987 the use of Pyrex #1729 glass (Spangler and Wise 1987, 1990). This high temperature Corning Code #1729 glass is an alkaline-earth aluminosilicate glass that has an anneal point of 853°C and has an excellent match to the thermal expansion coefficient of silicon. For the experiments that Spangler conducted, a bond temperature of 670°C was used along with an applied voltage of 900 V for about 30 min between the silicon and the glass. This glass has a much lower content of sodium and is therefore more compatible with wafers containing circuits.

Table 1 Influence of process parameters on bonding strength

Process parameter	*Contribution to strength (%)*
Bonding temperature	67.7
Applied voltage (V)	18
Bonding time (min)	12
Bonding load (gf cm^{-2})	2.3

Source: Go and Cho (1998).

The anodic silicon–glass bond offers several advantages. It is a relatively low-temperature process, it needs a very simple setup and is extremely reliable and uniform, and the glass can be selected to minimize thermal mismatch between it and the silicon wafer. It is possible to form this bond on more than two wafers and form sandwiched stacks of silicon and glass that are useful for wafer-level packaging or multilayer complex microstructures. The glass substrate is a thermally and electrically insulating substrate and transparent to light, which makes it very suitable for sensing and optical applications. The electrostatic force allows the bond to progress in spite of some local nonplanarities and forces the bond to engulf small particulates that might be trapped between the two wafers. This makes the bonding process quite tolerant to the existence of small particles. Because the silicon and the glass surfaces have to be in contact, nonplanarities and surface topologies must be limited to less than ~500 Å in height, otherwise they will prevent the formation of a good bond. Although most devices and processes can tolerate the large electric field and applied voltage, in some the high electric field could cause a problem. However, techniques have been devised to circumvent this problem by placing appropriate shield metals on the surface of glass to shield the silicon from the high field. There is a substantial body of literature on various aspects of silicon–glass bonding. This technology has been applied to both the fabrication and the packaging of MEMS in many different application fields. Glass to

metal anodic bonds have also been used in MEMS devices and applications (Briand *et al.* 2004).

This technique has also been used for bonding silicon–silicon and glass–glass wafers using sputtered and evaporated thin films of glass or silicon at temperatures as low as 135°C. This approach is discussed in more detail in Section 1.09.4.2.

1.09.4.1.2 Fusion bonding

Fusion bonding is referred to as both DWB and the process of bonding two polished silicon wafers together at a high temperature (Barth 1990, Harendt *et al.* 1990, 1991, 1992a, b, Lasky 1986, Mehra *et al.* 1999, Mitani *et al.* 1991). In this chapter we refer to the bonding of two wafers, silicon and otherwise, as fusion bonding. The name simply refers to the fact that when two surfaces that are polished are brought into intimate contact, they will fuse and will instantly bond. For this to happen the surfaces have to be polished, free of any roughness or damage, free of any polymers, or any other contaminants so that they can be chemically active and form covalent bonds when brought into intimate contact and annealed. Fusion bonding can be used to bond a number of different types of wafers, silicon-to-silicon, oxidized silicon-to-silicon, two oxidized silicon wafers, GaAs-to-silicon, quartz-to-silicon, silicon-to-sapphire, silicon–germanium-to-silicon with oxide, and silicon-to-glass, quartz-to-quartz, and a variety of other materials (Barth 1990, Harendt *et al.* 1990, 1991, 1992a, b, Lasky 1986, Mehra *et al.* 1999, Mitani *et al.* 1991).

In order to achieve a strong bond, the wafer surfaces have to be chemically prepared and activated. This can be achieved in a number of ways, including using wet chemistry, plasma activation, or in ultra-high vacuum (UHV) environments. Fusion bonding can be achieved between two silicon surfaces with either hydrophilic or hydrophobic surfaces, depending on the surface preparation used. These surfaces can also be treated in dry chemistries using plasma activation. In all these cases, after surface preparation, the wafers have to be brought together and then annealed at either high or low temperature. Therefore, fusion bonding techniques can be divided into the following categories:

- Hydrophilic, hydrophobic
- Vacuum- or plasma-assisted
- High temperature, low temperature

Each of these approaches are reviewed briefly. The high-temperature bonding process is sometimes referred to as fusion bonding, and it has become the most widely used silicon–silicon bonding technique in the MEMS community and is reviewed first (Alexe and Gösele 2004, Goesele *et al.* 1999, Tong and Gösele).

When two polished surfaces are brought together, they will tend to stick together with relatively weak intermolecular attraction forces, such as van der Waals' forces or forces associated with hydrogen bridge bonds. If this weakly bonded sandwich is annealed at a high temperature, the bond strength increases significantly due to the formation of strong covalent bonds between atoms on the surfaces of the two wafers. The nature of the bond depends heavily on the surface property and chemistry and on whether bonding is performed in vacuum or in atmosphere. Fusion bonds that are not performed at UHV can be categorized into two broad categories, namely hydrophilic and hydrophobic bonds. When discussing these two methods, the primary focus is on wafer bonding of silicon wafers.

1.09.4.1.2.(i) Hydrophilic fusion bonding In a silicon wafer, when the surface is hydrophilic (meaning it attracts water), as shown in **Figure 4**, strong Si–O–Si bonds can be formed between the two wafers after the wafers are brought into initial contact and annealed at an elevated temperature (Najafi 2001–2006). After a typical wafer cleaning and rinsing process, a thin layer of native silicon oxide is formed on the surfaces of the two wafers, and these oxide surfaces are terminated with OH groups, and hence the surface is hydrophilic. The dried wafers are brought into contact at room temperature and a weak bond is initiated at some point across the interface. The wafers are then heated to anneal the bond. Heating removes the water molecules, leaving behind a Si–O–Si bond, which is very strong. The strong Si–O–Si bonds are shown schematically in **Figure 4**. Obviously in this type of fusion bonding, a thin layer (a few nanometers) of silicon oxide is formed between the two wafers. This thin layer of silicon oxide may not be desirable in applications where a direct contact between the two silicon wafers is needed.

1.09.4.1.2.(ii) Hydrophobic fusion bonding For some applications, the insulating oxide layer at the bond interface can disrupt device operation. For example, if electronic devices such as p–n junctions are produced, good electrical contact is desired between the two surfaces, so wafer bonding should

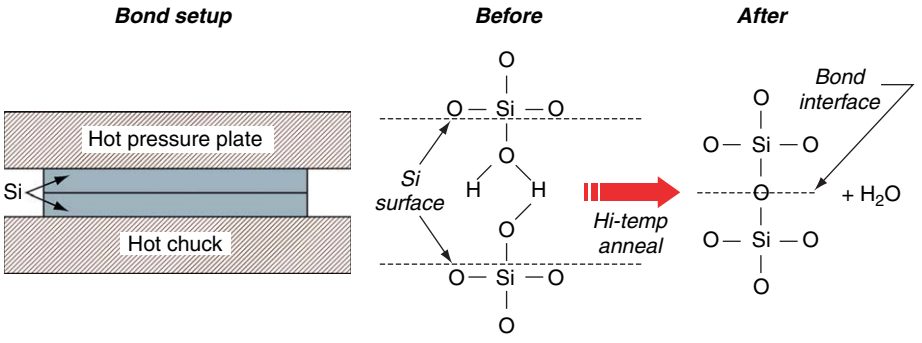

Figure 4 Hydrophilic fusion bonding between two wafers. The surfaces of two silicon wafers are covered with a thin layer of native silicon oxide and are hydrated with OH groups. After contact and high-temperature annealing, Si–O–Si bonds are formed forming a strong bond interface. (Source: Najafi K 2001–2006 Wafer bonding. Lecture notes for Introduction to MEMS, A course taught at the University of Michigan.)

be performed using hydrophobic surfaces that are free of any oxide. The native oxide can be first removed using diluted hydrofluoric acid (HF) or ammonium fluoride, which produce a surface that is temporarily covered with covalently bonded hydrogen. This surface is hydrophobic, and can be easily contaminated by hydrocarbons, which means that the two wafers should be bonded quickly after surface treatment. After the initial bonding, the wafers are again annealed at elevated temperatures whereby the hydrogen leaves the bonds and very strong covalent Si–Si bonds are formed at the interface. This bonding process is illustrated in **Figure 5** (Najafi 2001–2006).

Figure 6 shows a set of photographs showing a fusion bond in its various stages (Harendt *et al.* 1991). The four photographs on the left-hand side show infrared images of two silicon wafers that are bonded using fusion bonding. The bond formation starts on the top left corner where the two wafers are pressed together, and then proceeds until the two wafers are completely bonded. The two photographs on the right show voids that are formed due to the existence of particles between the two wafers. This is a major challenge for fusion bonding in that it is sensitive to particulates. This requires the wafer surfaces to be properly cleaned and to be free of any particulates. In fusion bonding there is no applied electric field, and therefore there is no force to pull the wafers together, as there is in anodic bonding.

The bond strength increases as the annealing temperature increases. The activation temperatures for hydrophilic bonding are lower than for hydrophobic bonding because hydrogen is easier to remove from the interface than are water molecules. The bond energy between silicon wafers at room temperature and with increasing temperatures has been measured for hydrophilic and hydrophobic bonds and has been shown to increase with temperature (*Philips J. Res., Spec. Issue Direct Bonding* **49**, 1). For hydrophilic bonds, the bonding energy increases starting around

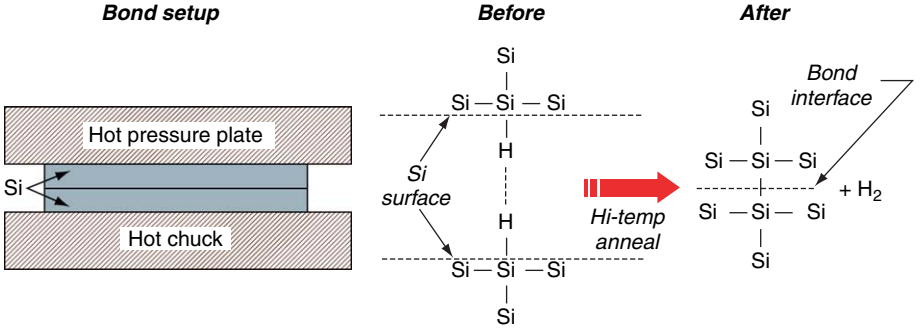

Figure 5 Hydrophobic fusion bonding between two wafers. The surfaces of two silicon wafers are etched to remove any native oxide, and are treated, so the silicon dangling bonds are occupied with hydrogen. After a high-temperature annealing, the hydrogen is removed and the two surfaces permanently bond to form covalent Si–Si bonds. (Source: Najafi K 2001–2006 Wafer bonding. Lecture notes for Introduction to MEMS, A course taught at the University of Michigan.)

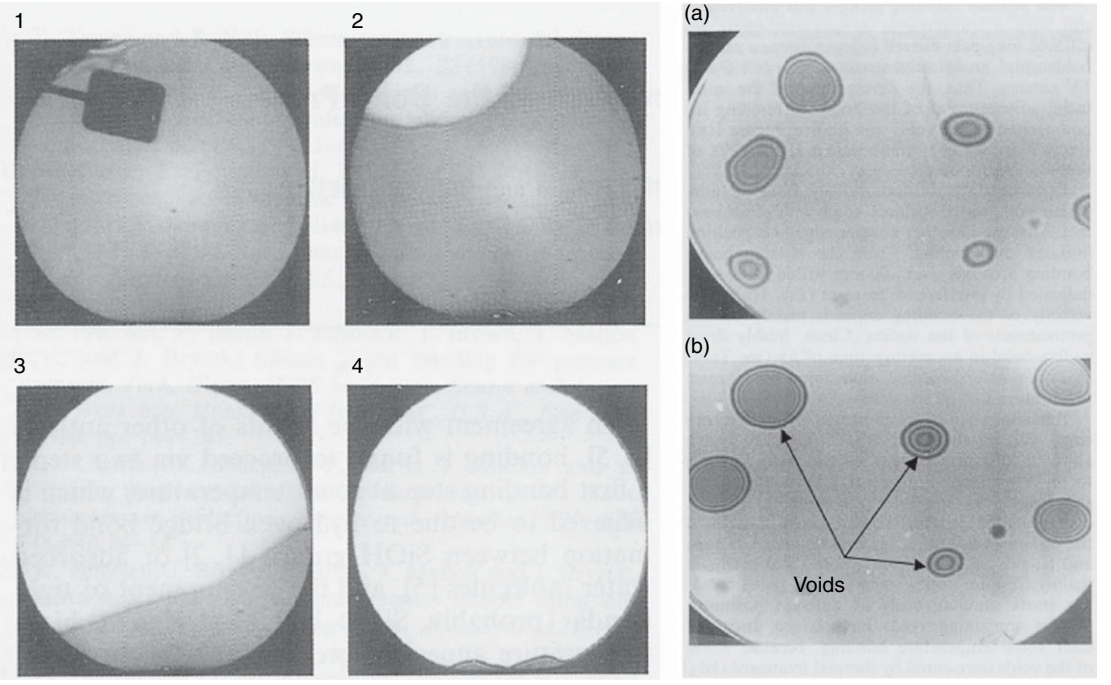

Figure 6 Through-wafer infrared images showing the progression of a typical fusion bond starting from the top corner of the wafer pair. On the right-hand side, the two images show the formation and existence of voids in fusion-bonded wafer. These voids are formed due to particulates or surface irregularities. (Source: Harendt C, Höfflinger B, Graf H G, Penteker E 1991 Silicon direct bonding for sensor applications: Characterization of the bond quality. *Sens. Actuators A Phys*. **25**–**27**, 87–92.)

120°C, and then achieves its highest value when the temperature increases over 900°C. For hydrophobic bonds, the bond energy starts increasing around 300°C, and will be very high at temperatures around and above 700°C. Wafers bonded using the hydrophobic approach are prone to the formation of voids during annealing.

1.09.4.1.2.(iii) Fusion bonding in vacuum As discussed above, the surfaces of wafers have to be prepared to ensure that strong chemical bonding is achieved between atoms on these surfaces. In hydrophobic bonding, especially, the surface is prepared such that after annealing, hydrogen-terminated bonds are removed and replaced with Si–Si bonds. It is also possible to prepare these surfaces in very high-vacuum environments. Wafers are placed inside a high-vacuum chamber and are treated to remove any surface oxide and to expose the silicon atoms on the surface. This treatment could be done by using plasma etching and treatment, by sputtering a thin layer of material from the surface, by ion beam bombardment, or by laser treatment. The high-vacuum environment ensures that the surface atoms are not reoxidized. The wafers are then brought into contact where they bond at room temperature. The bond strength is already high after this room temperature bonding since the surfaces are clean and free of any other species. This technique is referred to as UHV or surface-activated bonding (SAB) (Akatsu *et al.* 1999, Chung *et al.* 1997, Hosoda *et al.* 1998, Suga and Otsuka 2001, Suga *et al.* 1989, 1993, Takagi *et al.* 1996, 1999, Yang *et al.* 1997). This technique has several advantages in that it can be applied to many materials including metals, alloys, and semiconductors. This technique has been of particular interest to the semiconductor industry because it exposes the wafers only to low temperatures during surface treatment, and the bond itself can be formed at room temperature. However, because of the lack of high-temperature annealing, wafer surfaces have to be polished, free of any oxide, and have to be maintained in a very clean environment before they are bonded.

1.09.4.1.2.(iv) Plasma-activated fusion bonding In plasma-activated wafer bonding, the surfaces of the wafers to be bonded are treated and cleaned before bonding by exposing them to plasma (Amirfeiz *et al.* 2000, Benoit *et al.* 2006, Bower and Chin 1997, Bower *et al.* 1993, Eichler *et al.* 2006, Farrens 2005, Farrens *et al.* 1995, Galchev *et al.*

2007, Itoh *et al.* 2003, Morra *et al.* 1990, Suni *et al.* 2002, Wiegand *et al.* 2000). The plasma activation step alters the surface chemistry in a similar manner as the hydrophilic chemical treatment discussed earlier without the wet processing step. The surface chemistry is selected such that the maximum bond strength is obtained at low temperatures. Obviously this process has to be carried out in a vacuum environment and inside a plasma chamber. It is also possible to chemically treat the surfaces using a barrier discharge method where plasma is formed in the atmosphere (Eichler *et al.* 2006, Galchev *et al.* 2007). Plasma-activated bonding has now been applied to various materials, including silicon, compound semiconductors, oxides, and polymers.

In plasma-activated wafer bonding, the wafer surfaces have to be activated by a plasma and cleaned off, and then the two wafers need to be brought into contact to initiate the bonding process. Usually, an annealing step at an elevated temperature of 100–400°C is needed depending on the required bond strength and the materials being bonded. Plasma activation can be performed in a standard plasma chamber, an reactive ion etching (RIE) etcher, or an inductively coupled plasma (ICP) chamber. It can involve plasma of different species, including oxygen, argon, nitrogen, or hydrogen. Oxygen plasmas creates a thin oxide layer on the interface and are used for applications that require electrical isolation at the interface. Hydrogen, nitrogen, or argon plasmas are used in applications where a direct bond interface without the oxide layer is needed. The type of plasma used, its power, and the post-treatment annealing all can have a major influence on bond strength, void or defect density at the interface, and the annealing temperature. Since wafers need to be aligned and then bonded, preferably without breaking vacuum, specialized tools are needed that combine the plasma activation chamber and the bond alignment and annealing into a single machine.

Typically plasma activation is performed in an RIE chamber for a very short duration. Another form of plasma activation, called dielectric barrier discharge (DBD), can also be used to treat surfaces at high pressure, as illustrated in **Figure 7** (Galchev *et al.* 2007). By applying an AC current between two electrodes surrounded by a gas flow, localized atmospheric pressure plasma discharges are created. This is achieved by flowing the desired gas between two electrodes surrounded by a dielectric. This whole electrode assembly is then scanned across the wafer surface, exposing it to the plasma discharges. The voltage can be applied only between the electrodes. In this indirect mode, electronic components on the wafer are protected. Alternatively, the wafer can be grounded, leading to a more energetic direct mode of operation. The interesting characteristics of DBD are that the discharge is too short to generate heat, and so sensitive substrates can be protected, and also unlike low-pressure glow discharge, there is little surface bombardment of the wafer by energetic species. The literature related to low-pressure glow discharge plasma treatment suggests that an optimum exposure exists with respect to power and time of exposure (Weigand *et al.* 2000). In other words, with exposure to plasma, the surface tension rises gradually; however, past a maximum, further exposure to low-pressure plasma reduces the surface tension. During DBD, power, number of treatments, distance between the wafer and the electrodes, and the scan speed can be varied. An optimum set for bonding of silicon wafers has been found to be at 400 W with 50

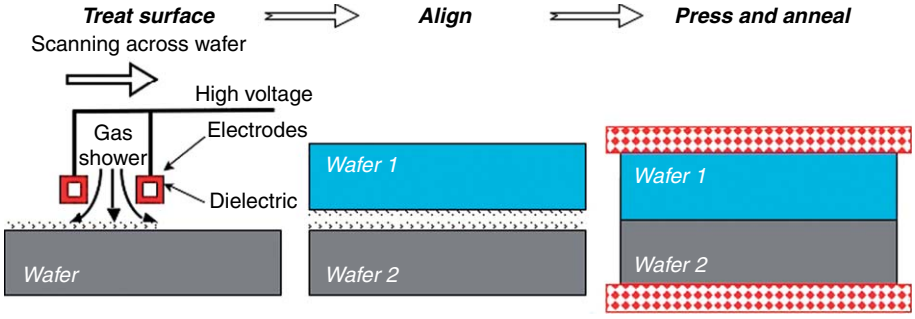

Figure 7 Dielectric barrier discharge (DBD) creates a uniform plasma discharge due to a high-frequency AC voltage applied between two electrodes. The discharge is scanned across the wafer surface. This process does not affect sensitive substrates. (Source: Galchev T, Welch WC III, Najafi K 2007 Low-temperature MEMS process using plasma activated silicon-on-silicon (SOS) bonding. *Proc. IEEE Int. Conf. Micro Electro Mechanical Systems (MEMS Conference)*, Kobe, Japan, January 2007.)

slpm N_2, applied 300 μm above the wafer surface while the electrodes are scanned at 20 mm s^{-1}. After surface treatment, the wafers are moved into the bond alignment chamber where they are aligned and eventually annealed to form the bond. Annealing is typically done at temperatures in the range of 200–400°C. Pressure is also applied during annealing to compensate for any bowing of the wafers.

1.09.4.1.3 Chemically assisted bonding of glass surfaces

In this last category of DWB, two wafers are bonded together by treating their surfaces with wet chemicals and allowing these wet chemicals to stay in the bond region and slowly evaporate off after a specific period of time. This technique is mostly used for bonding oxide surfaces together and has been applied to bonding of quartz, glass, and oxidized silicon surfaces (Mao and Han 2005, Nakanishi *et al.* 1997, 1998). In this process, the surfaces of the two wafers are first cleaned using standard organic and inorganic cleaning processes (such as sulfuric acid and hydrogen peroxide mixtures) and exposed to diluted HF to remove a thin layer of oxide from the surface. The wafers are then placed together and a small amount of diluted HF is dropped in between the two wafers. The HF solution is wicked up into the interface by capillary action (note that the surfaces of the wafers are oxidized and are hydrophilic). The wafers are then pressed together using a high pressure and are allowed to stay together for anywhere between 5 and 24 h. The bonded wafer sandwich is then rinsed and dried. The bond strength has been shown to be as high as a few megapascals. The same technique has been used with chemicals other than HF (Nakanishi *et al.* 1997). Successful bonding has been achieved using only those chemicals that have a reasonable etch rate of SiO_2. This technique is very attractive and has been used extensively for making microstructures for chemical and biological applications where high-temperature processing cannot be used (Mao and Han 2005). Obviously the lack of heat activation reduces the bond strength, but for many of the intended applications the bond strength is more than sufficient.

1.09.4.2 Mediated Wafer Bonding

The second category of wafer bonding involves the use of an intermediate, or glue, layer between two wafers to permit their bonding and permanent attachment. This class of wafer bonding is very broad and has been used in various applications. The glue layer can be metals, semiconductors, inorganic insulators (like glass, oxides, or nitrides), or organic insulators (like polymers, epoxies, and various epoxies and waxes). In this chapter this bonding technique is categorized and each category is reviewed as follows:

- Anodic using deposited films
- Thermocompression
- Solder and eutectic
- Bonding using glass films
- Polymer

1.09.4.2.1 Field-assisted anodic using deposited films

Two wafers of glass or silicon can be bonded using a deposited thin film layer of glass or silicon (Berthold *et al.* 2000, Brooks *et al.* 1972, Choi *et al.* 1996, 1997, Cozma and Puers 1995, Dokmeci 1999, Drost *et al.* 1998, Esashi *et al.* 1990, Krause *et al.* 1995, Liang 1979, Nese and Hanneborg 1993, Plaza *et al.* 1998, Quenzer *et al.* 1996, de Reus and Lindahl 1997, Sassen *et al.* 2000, Weichel and de Reus 1998). As mentioned earlier, anodic bonding has been a very reliable and widely used bonding process for MEMS applications. In its standard form, it requires a glass wafer and a silicon wafer. But in some cases when bonding of either two silicon or glass wafers is desired, an intermediate layer of deposited glass or silicon is used to achieve anodic bonding. The first bonding of two silicon wafers using a deposited glass was demonstrated in 1972 using a thin layer of sputtered glass (Mao and Han 2005). The glass layer had to be a few micrometers thick to produce a reliable bond. Since the deposition rate of sputtered glass was small, a fairly long deposition step was needed. The deposited glass can be patterned using standard photolithography and etching in buffered hydrofluoric acid (BHF)/HF. Because two silicon wafers are used, problems associated with mismatch in thermal expansion coefficient are avoided. In addition, since the glass layer is very thin, the voltage necessary for achieving a good bond is usually not above 50–100 V. Later, other researchers used evaporated glass instead of sputtered glass and achieved successful results (Choi *et al.* 1996, 1997, de Reus and Lindahl 1997, Weichel and de Reus 1998). Deposition rates of evaporated glass are much higher but the deposition conditions have to be controlled more carefully to produce a deposited layer of glass that is uniform and homogeneous in its composition. **Figure 8** shows the

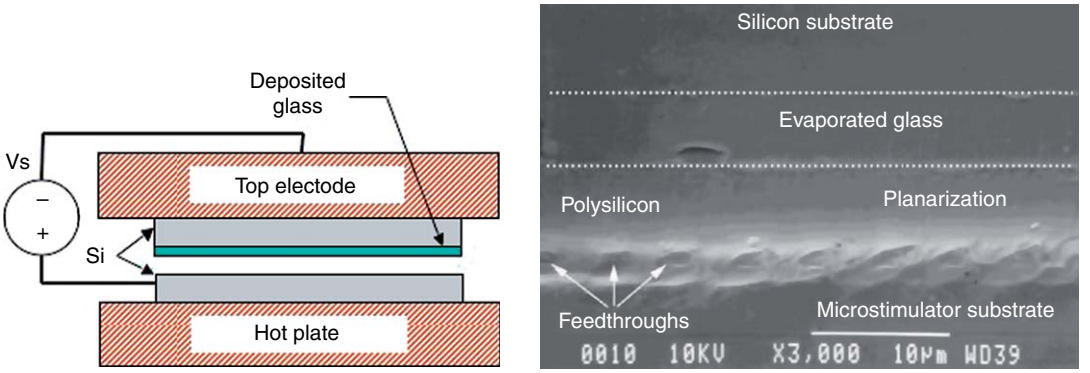

Figure 8 Si–Si anodic wafer bonding using deposited glass. *Left*: The basic setup for anodic bonding. (Source: Najafi K 2001–2006 Wafer bonding. The bond interfaces between the top silicon wafer and the bottom polysilicon layer and the evaporated glass layer are shown. (Source: Dokmeci M 1999 Hermetic glass–silicon micropackages and feedthroughs for neural prostheses. Doctoral dissertation, University of Michigan.)

bonding process and a photograph of a bonded silicon wafer pair formed using evaporated glass (Dokmeci 1999, Najafi 2001–2006). The glass was evaporated on top of a polished polysilicon layer that covered a series of electrical feedthroughs. The second silicon wafer is then electrostatically bonded to the bottom glass film (Dokmeci 1999).

Anodic bonding process can also be used for the bonding of two glass wafers with an intermediate deposited layer of silicon. The deposited silicon can be either sputtered or deposited using plasma-enhanced chemical vapor deposition (PECVD). These low-temperature processes ensure that the glass is not stressed too much during the deposition process. The deposited silicon has to have a smooth surface to form a good bond. It is also possible to bond two glass wafers using an intermediate silicon wafer. The technology of glass–silicon–glass bonding has been extensively used for making various 3D MEMS structures and for packaging of MEMS.

1.09.4.2.2 Thermocompression bonding

Metals have long been used as a glue layer for wafer bonding and die attachment. The most familiar of metal joining techniques is soldering, which is discussed in Section 1.09.3.2.3.(i). It is also possible to bond two wafers covered with a layer of metal using thermocompression (Condra *et al.* 1975, Furman and Mita 1992, Kim *et al.* 1995, Taklo *et al.* 2004, Tsau 2003, Tsau *et al.* 2004). This process is very similar to silicon–silicon fusion bonding in that it requires two clean and chemically active metal surfaces that are free of any particulates or oxide. Once these surfaces are brought together, pressed, and heated, they can permanently bond, as illustrated in **Figure 9** (Najafi 2001–2006). The heating of the surfaces softens them and provides sufficient energy to form a covalent bond at the interface. Almost any metal can be bonded via thermocompression. For metals such as Al or Cu the bonding surfaces must be treated to remove any oxide that could impede bond formation.

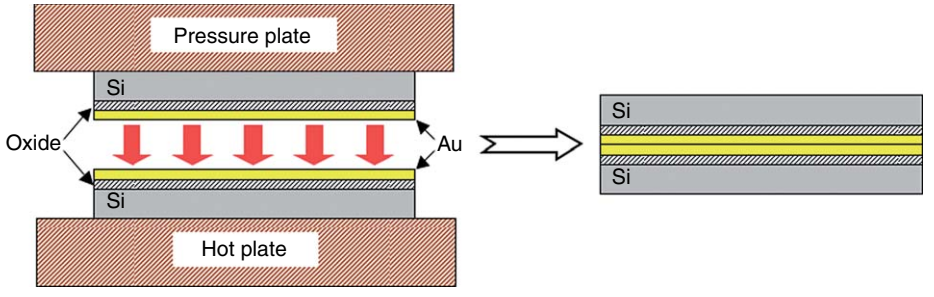

Figure 9 Thermocompression bonding of two wafers covered with a metal layer, like gold. (Source: Najafi K 2001–2006 Wafer bonding. Lecture notes for Introduction to MEMS, A course taught at the University of Michigan.)

Although it is possible to bond practically any two metals, thermocompression bonding of gold surfaces has received the most attention. This is primarily due to the inertness of gold, which makes its surface resistant to oxidation, and due to its softness, which enables it to deform under the applied pressure and form a strong bond. Thermocompression bonding has been a key technology for wire bonding in the IC industry and has also been used for die attach. However, it has only been recently used for full wafer bonding for MEMS applications. The challenge in full wafer bonding is achieving a uniform and reproducible bond without very high external forces or temperatures. The success of a gold thermocompression bond relies on many factors, the two most important of which are pressure and temperature. Pressures on the order of at least a few megapascals are needed and temperature has to be around 350°C–400°C. In most applications, the temperature should be reduced as much as possible, which then necessitates a higher pressure (Tsau 2003, Tsau *et al.* 2004).

Tsau and coworkers have described the process issues and techniques required for successful full wafer bonding in detail (Tsau 2003, Tsau *et al.* 2004). Their findings were the following:

(1) The gold film should be deposited on a diffusion barrier film such as oxide to prevent its reaction with the underlying silicon film.
(2) The gold surface should be as smooth as possible (rougher surfaces requires higher pressure and higher bonding temperature).
(3) The surface has to be treated to remove organics; UV exposure and cleaning have been shown to be effective.
(4) Bonding temperature and pressure of 260°C and 120 MPa, respectively, are recommended to ensure the level of repeatability and yield desired in manufacturing environments. Since the pressure may damage the underlying thin films or other structural materials, a tradeoff between pressure and temperature can be made.
(5) The bond time was not shown to significantly affect the bond quality. Given the preference for faster throughput, the bond time can be as short as 2 min.

Thermocompression bonding is quite attractive because it is relatively simple and requires only the deposition of a layer of gold on the surfaces to be bonded. The surface has to be clean and flat, and there are no complications due to metallurgical reactions as is sometimes the case for solder-based wafer bonding. The drawbacks of thermocompression bonding are the high pressures required and the need for very clean and polished surfaces for achieving a uniform and reproducible bond across a large wafer.

1.09.4.2.3 Solder, diffusion, and eutectic wafer bonding

In addition to thermocompression, metals have been used extensively for wafer bonding in the form of solder. Solders are formed either by using a mixture of various suitable metals or by forming a eutectic of a metal and a semiconductor, such as gold and silicon. These two approaches are discussed below.

1.09.4.2.3.(i) Solder wafer bonding Solder is a low melting point metal alloy (<450°C), typically containing tin or indium, which is used to join two metal surfaces together (Bosco and Zok 2004, Chuang and Lee 2002a, b, Gale 2003, Goyal *et al.* 2003, 2004, Humpston *et al.* 1994, Kim *et al.* 2006, Lugscheider *et al.* 2003, Park *et al.* 2001, Rogge *et al.* 1998, Singh *et al.* 1999, Sommadossi *et al.* 2003, Sparks *et al.* 2001, Welch and Najafi 2005, Welch *et al.* 2005a, b, c). It acts as a metal glue that adheres to each of the metal surfaces on two wafers and holds them together. A typical soldering process starts with three separate materials in contact: material A, the solder alloy, and material B as illustrated in **Figure 10** (Najafi 2001–2006, Welch and Najafi 2005, Welch *et al.* 2005a, b).

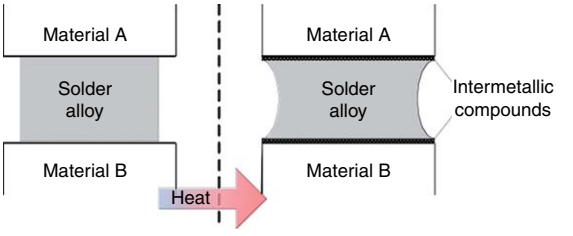

Figure 10 Illustration of the solder bonding concept. (Sources: Najafi K 2001–2006 Wafer bonding. Lecture notes for Introduction to MEMS, A course taught at the University of Michigan; Welch W C III, Najafi K 2005 Transfer of metal MEMS packages using a wafer-level solder sacrificial layer. *18th IEEE Int. Conf. Micro Electro Mechanical Systems*, Miami Beach, FL, USA, January 30–February 3, 2005, pp. 584–7; Welch W C III, Chae J, Najafi K 2005b Transfer of metal MEMS packages using a wafer-level solder transfer technique. *IEEE Trans. Adv. Packaging (IEEE Trans. Components Packaging Manufact. Technol. Part B Adv. Packaging)* **28(4)**, 643–9; Welch W C III, Chae J, Lee S, Najafi K 2005c Transient liquid phase (TLP) bonding for MEMS packaging applications. *Tech. Dig., IEEE Int. Conf. Solid-State Sensors, Actuators, and Microsystems, Transducers 2005*, Seoul, Korea, June 2005.)

When the whole assembly is heated, the solder melts, and in its molten state it wets the surfaces of materials A and B and interacts with them to form intermetallic compounds. After the solder wets both surfaces, the assembly is cooled down and the solder bond is complete. The low melting point alloy still exists in the solder joint, and so the service temperature of the assembly cannot exceed the bonding temperature (i.e., the melting temperature of the solder) or the solder will melt again and compromise the integrity of the joint.

The choice of the solder alloy is an important part of the solder process design. It determines the bonding and service temperature, the mechanical strength of the joint, the filling characteristics, and the material compatibility. There are several different solder alloys to choose from that suit different types of applications (**Table 2**). There is a large pressure in the industry to eliminate solders containing lead in order to comply with pending worldwide legislation.

The key to understanding the behavior of solder lies in two concepts: wetting and intermetallic formation. To understand the behavior of solder, it is necessary to understand how it behaves as a liquid. Most of the action in a soldering process occurs during its liquid state. The fluid behavior of the solder is dependent on the surface energies of the materials present in the solder joint. Each material has a certain surface energy, which is determined by the free energy from the unsatisfied bonds of the atoms on the surface of the material. This surface energy creates a surface tension force that keeps the liquid together. The definition of "to wet" for soldering purposes is a contact angle $<90°$, which means that the droplet has spread over the surface of the solid. The lower the contact angle, the greater the spreading effect. This contact angle and spreading effect during bonding have a great impact on many of the attributes of the final solder joint.

Table 2 Several widely used low melting point solder alloys

Composition (wt.%)

–	–	99.4	–	–	0.5	156
–	–	–	38.0	62.0	–	183
3.5	–	–	–	96.5	–	221
–	–	–	–	20	80	278

During the soldering process, the solder alloy interacts with the materials it is in contact with and forms new phases. The new phases consist of one of the metals in the solder alloy and the parent materials. For instance, when tin-based solders are used to bond gold surfaces together, the tin reacts with the gold to form Au_x-Sn_y phases. The new phases may form a new interface between the molten solder and the parent metal or they may diffuse into the molten solder. This intermetallic formation process consumes the parent metal. The consumption rate depends on the solder alloy, the parent metals, the temperature, and the amount of intermetallic phases already formed. The erosion rate and the presence of new phases in the solder joint must be considered during the design of the soldering process. The new phases can add desirable mechanical properties, such as ductility in the case of Ag–Sn, or they can make the joint more brittle in the case of Au–Sn. The erosion rate can cause problems when soldering to thin films, especially to thin films of gold.

Traditional solder bonding consists of a molten filler metal wetting two surfaces, then solidifying to form a strong metallic bond. For a successful solder bond, it is imperative that the solder wets the two surfaces and that the erosion of parent metals by the solder be accounted for in the design. As mentioned earlier, good wetting occurs when the surface tension of a solid is higher than the surface tension of the liquid in contact with it. Many pure metals have a high surface tension, but their oxides do not. Most metals react with the oxygen in the atmosphere to form a very thin native oxide film on their surface that prevents good wetting. Fluxes are highly reactive materials that are used in a soldering process to ensure good wetting. During the soldering process, they remove this native oxide and other contaminants from the bonding surface. Fluxes are a good way to achieve proper wetting and a reliable solder joint, but they are not compatible with MEMS processing. The liquid flux can cause stiction issues with released MEMS devices. Other alternative flux-free soldering processes must be used for MEMS packaging. There are several fluxless soldering processes. One approach, plasma-assisted dry soldering, uses a plasma pretreatment to alter the chemistry of the metal's native oxide to make it solderable without a flux. This approach is reliable, but it requires specialized equipment. Another fluxless soldering technique first removes the metal oxide with a chemical treatment, such as a light acid etch, and then coats the metal with a thin layer of gold, using

physical vapor deposition to electroplating, to prevent further oxidation. The gold layer does not oxidize, and many solder alloys consume it rapidly and reveal the clean metal surface underneath. Some process development is necessary to choose a compatible metal oxide etch. Also, care must be taken to limit the regrowth of the native oxide between the etch step and the gold deposition. It is also important to limit the amount of gold used to prevent any negative mechanical effects from the gold intermetallics. For reliable soldering to thin films, several different materials need to form the thin film stack. Each material performs a specific function: usually gold is the topmost layer to ensure proper wetting; below it there is usually a refractory metal, like nickel, that reacts with the solder slowly. The nickel prevents the solder from consuming the entire thin film during the process and revealing the underlying substrate to the molten solder. The erosion of parent metallizations and the formation of intermetallics are used in a relatively new technique called diffusion soldering to form bonds that are completely made up of intermetallics when they are finished.

Another type of solder bond, called diffusion soldering, combines the advantages of diffusion bonding and solder bonding. It has the planarization capabilities of a traditional solder bond, but it can survive much higher service temperatures than its formation temperature like a diffusion bond (Gale 2003, Humpston *et al.* 1994). It starts in much the same way a solder bond does. Two parent metals sandwich a low melting point interlayer. The bond formation process involves four stages (Welch and Najafi 2005, Welch *et al.* 2005b, c) (**Figure 11**). First, the two parent metals and the low melting point interlayer are brought into contact. Heat is then applied and the liquid interlayer melts and begins to react with the parent metals and forms intermetallic compounds. Third, the joint undergoes isothermal solidification as the last of the liquid interlayer is consumed in the formation of intermetallic compounds. After the consumption of the interlayer, the remelting temperature of the joint increases from the melting point of the interlayer to the melting point of the intermetallic compound. Last, further heating increases the quality of the bond as the intermetallic compounds diffuse away from the interface leaving behind the continuous pure parent metal.

Several factors need to be considered when designing a diffusion-soldered bond. The material system, the thickness of the parent and interlayer metals, the heating rate, and the pressure applied determines the final quality of the bond. The materials used to create the diffusion-soldered bond determines the bond formation temperature and the maximum temperature it can survive after completion. The bond formation temperature is just above the melting point of the interlayer and is thus dictated by the choice of this layer. Indium and tin are the most widely used interlayer metals because of their low melting points (156°C and 232°C, respectively) and high intermetallic reaction rates. For temperature-sensitive steps, indium is a better choice because it has a lower melting temperature, but it is more expensive. The choice of the parent metals

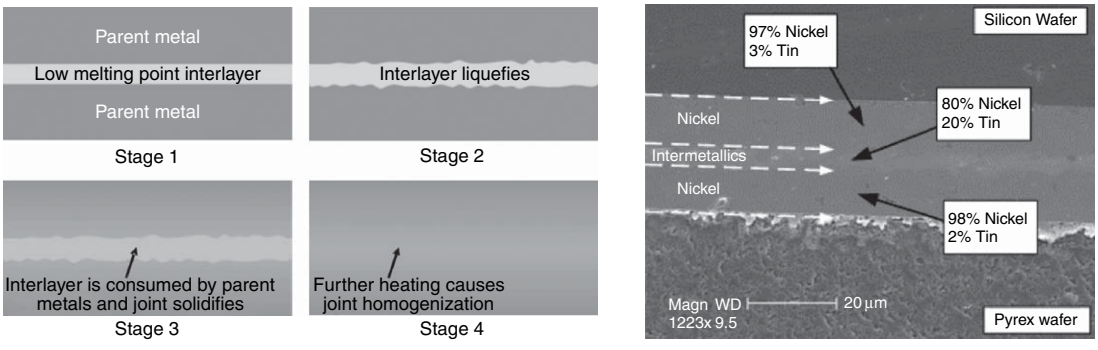

Figure 11 *Left*: The four stages of diffusion soldering. *Right*: Cross-sectional scanning electron microscope (SEM) view of a Ni–Sn–Ni diffusion solder bond. (Sources: Welch W C III, Najafi K 2005 Transfer of metal MEMS packages using a wafer-level solder sacrificial layer. *18th IEEE Int. Conf. Micro Electro Mechanical Systems*, Miami Beach, FL, USA, January 30–February 3, 2005, pp. 584–7; Welch W C III, Chae J, Najafi K 2005b Transfer of metal MEMS packages using a wafer-level solder transfer technique. *IEEE Trans. Adv. Packaging (IEEE Trans. Components Packaging Manufact. Technol. Part B Adv. Packaging)* **28(4)**, 643–9; Welch W C III, Chae J, Lee S, Najafi K 2005c Transient liquid phase (TLP) bonding for MEMS packaging applications. *Tech. Dig., IEEE Int. Conf. Solid-State Sensors, Actuators, and Microsystems, Transducers 2005*, Seoul, Korea, June 2005.).

determines the final melting temperature of the joint. Material systems like silver–indium and silver–tin offer the greatest increase in remelting temperature due to the high melting temperature of the silver intermetallics. The increase in melting temperature is 350°C for silver–tin and 705°C for silver–indium. The thickness of the metal layers and the heating rate are the most important factors in the formation of void-free bonds. A critical interlayer thickness exists that determines whether the final bond will be void-free or not (Welch and Najafi 2005, Welch *et al.* 2005a, b). If the interlayer is thicker than the critical value, the final joint will be void-free, if not, there is a chance of void formation during bonding. The critical thickness depends mostly on the heating ramp rate during bonding and the interaction rate between the interlayer and the parent materials. As the joint is heated, the interlayer begins to react with the parent metals and forms intermetallic compounds even before it melts. If the heating rate is too slow, this interaction completely consumes the interlayer before the melting point is reached. In this case, the interlayer never reaches its liquid phase and cannot fill any gaps in the joint between the parent metals, leaving voids in the final bond. A faster heating rate or a greater interlayer thickness increases the amount of the liquid phase during bonding and increases the planarization capabilities of the diffusion soldered bond.

Wafer bonding using solder is a very attractive technology. It can be done using a number of different material sets, offers a large range of bonding temperatures, the solder flows, and can therefore accommodate wafers that have large nonplanar features on their surfaces, including microfabricated structures or feedthroughs for packaging applications, and it can be used with various wafer materials. The major challenges in wafer bonding using solders are materials interactions and achieving good wetting without the use of flux. Wafers to be bonded must have suitable under-solder materials that will not only ensure that the solder is properly formed but also that its adhesion to the two wafer surfaces is adequate for the given application. Solder bonding has been used for die attach and for many electronics applications, and it is now being more extensively used in MEMS and wafer bonding applications as well.

1.09.4.2.3.(ii) Silicon–gold eutectic bonding

Gold–silicon eutectic formation occurs at 363°C for 19 at.% silicon and 81 at.% gold composition. The eutectic can be used to bond two wafers or for hermetic and vacuum packaging. To form the eutectic, silicon and gold have to be provided to the interface where two wafers are bonded. Typically, the gold is deposited on one of the wafers to a desired thickness, and the silicon is provided either from the bulk of one of the wafers or from thin films deposited on one or both wafers. When the two wafers are brought into contact and heated above 363°C, the films will react to initiate the eutectic liquid formation. Upon cooling, the bond consists of Au–Si hypereutectic phase and represents a typical strong diffusional bond.

Au–Si eutectic bonding has been investigated in depth in the past (Adachi 2002, Adams *et al.* 2003, Bruson and Gerl 1982, Chang *et al.* 1988, 2000a, Christensen and Bouwstra 1996, Dalton 1956, Harpster 2005, Harpster and Najafi 2003, Johnson and Johnson 1987, Johnson *et al.* 1987, Kato 1987, 1989, Mei *et al.* 2002, Mitchell *et al.* 2005a, b, Tiensuu *et al.* 1994, Valero 1984, Wang and Lee 1992, Wolffenbuttel 1997, Wolffenbuttel and Wise 1994, Xiao *et al.* 1998). Researchers have investigated such parameters as silicide formation, epitaxy, and fractal growth, and surface oxide formation for Au–Si films formed on the surface of a Si wafer. Others have studied Au–Si eutectic bonding for its application in chip bonding applications, applied it for wafer bonding applications, and even used it in the alignment of optical fibers.

The gold–silicon eutectic process has to be carried out carefully in order to ensure a good and solid bond between the eutectic and the underlying substrate. Mei and coworkers characterized the bonding and the adhesion quality of the gold–silicon eutectic on several different materials, including Si/Ti/Au to Au/Ti/Si; Si/Ti/Au to Si; Si/Ti/Au to polySi/Si; Si/Ti/Au to Oxide/Si; and Si/Ti/Au to nitride/Si. Of these, the bond quality and the uniformity between Au–Au, Au–Si, and Au–PolySi was the best. In particular, it was noted that the bond quality was at its best when the gold and the silicon were supplied from two wafers, instead of both from the same wafer. Test wafers where the Au–Si eutectic was bonded to a substrate covered with either oxide or nitride produced very nonuniform and poor bonds. This is illustrated schematically in **Figure 12(a)** (Mei *et al.* 2002, Mitchell *et al.* 2005a, b). The figure shows the cross-sectional view of a gold–silicon eutectic bonding two silicon wafers together. The gold in the eutectic mix is revealed after the silicon is etched away in a selective silicon etchant. The figure also shows the uniform mixture of the gold and silicon films.

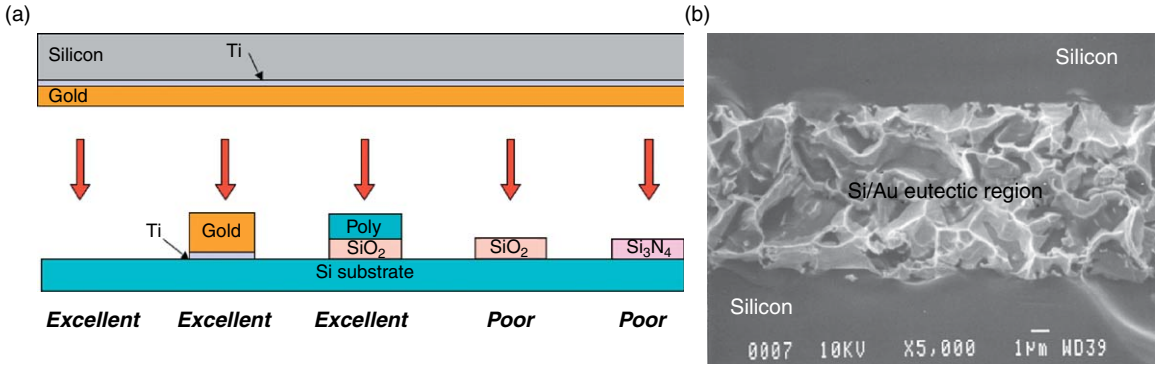

Figure 12 (a) The gold–silicon eutectic bond quality for different surfaces and layers. (Source: Najafi K 2001–2006 Wafer bonding. Lecture notes for Introduction to MEMS, A course taught at the University of Michigan.) (b) The cross-sectional view of a gold–silicon eutectic film bonding two silicon wafers together is also shown on the right. The gold in the eutectic mix is revealed after the silicon is etched away in a selective silicon etchant. The figure shows the uniform mixture of the gold and silicon films. (Sources: Mei Y, Lahiji G R, Najafi K, A 2002 Robust gold–silicon eutectic wafer bonding technology for vacuum packaging. *Solid-State Sensor, Actuator and Microsystem Workshop*, Hilton Head, SC, USA, pp. 772–4; Mitchell J S, Lahiji G R, Najafi K 2005a Encapsulation of vacuum sensors on a wafer level package using a gold–silicon eutectic. *Tech. Dig., IEEE Int. Conf. Solid-State Sensors, Actuators, and Microsystems, Transducers '05*, Seoul, Korea, June 2005; Mitchell J S, Lahiji G R, Najafi K 2005b Reliability and characterization of micro-packages in a wafer level Au–Si eutectic vacuum bonding process. *Proc., ASME/Pacific Rim Tech. Conf. Exhibit. on Integration and Packaging of MEMS, NEMS, and Electronic Systems, InterPack05*, San Francisco, CA, USA, July 2005.)

Mitchell *et al.* (2005a, b) have further characterized the process and used gold–silicon eutectic bonding for wafer-level vacuum packaging. In their baseline bonding process, they used one wafer with a layer of electroplated gold and another wafer with a thin layer of polysilicon deposited on top of a silicon–nitride layer. This process that produced uniform and reproducible bonds is schematically shown in **Figure 13(a)**. The 4″ diameter wafers were first held at 345°C under a vacuum pressure of 1 μtorr in order to allow for outgassing from the inner surface of the cavity. The wafers were then pressed together with a pressure of 1 MPa above the eutectic temperature for 40 min. Bonds were formed at

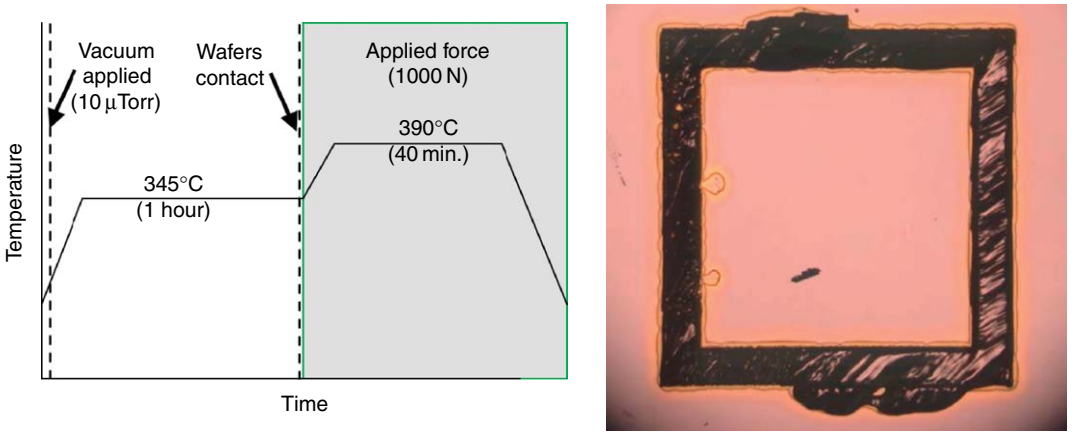

Figure 13 (a) The process recipe for successful and uniform bonding of two silicon wafers together. (Source: Mitchell J S, Lahiji G R, Najafi K 2005b Reliability and characterization of micro-packages in a wafer level Au–Si eutectic vacuum bonding process. *Proc., ASME/Pacific Rim Tech. Conf. Exhibit. Integration and Packaging of MEMS, NEMS, and Electronic Systems, InterPack05*, San Francisco, CA, USA, July 2005.) (b) Photograph of a bond ring used for vacuum packaging after the bond is broken, leaving pieces of silicon on the opposite wafer and illustrating the very uniform and strong nature of the gold–silicon eutectic bond. (Source: Mitchell J S, Lahiji G R, Najafi K 2005a Encapsulation of vacuum sensors on a wafer level package using a gold–silicon eutectic. *Tech. Dig., IEEE Int. Conf. Solid-State Sensors, Actuators, and Microsystems, Transducers '05*, Seoul, Korea, June 2005.)

temperatures ranging from below 390°C to 450°C and with bond pressures from 1 to 10 MPa (lower bond pressures were not investigated). One key parameter in this bonding process involved applying pressure before going above the eutectic temperature. It was also important to choose the correct thickness of the gold bond ring on the cap wafer. Using gold of a thickness <2.5 μm resulted in nonuniform bonds. That is, a strong bond was formed on some areas of the wafer and not on others. Another important factor for obtaining a good bond was the thickness of the polysilicon layer on the device wafer. In one set of experiments, 4- to 8-μm-thick gold bond rings were used on the cap wafer to bond to 0.8 and 2.2 μm of polysilicon on the device wafer. With very little force, caps were pried off fracturing in the polysilicon. In this work they were not able to determine why bonding to films of this thickness were problematic. Bonding to polysilicon films thinner than 0.5 μm alleviated this problem, resulting in consistently strong bonds.

1.09.4.2.3.(iii) Field-assisted anodic silicon–gold eutectic bonding As mentioned above, silicon–gold eutectic bonding requires that the surfaces be prepared and cleaned well. In addition, it is critical that during the bonding process, the gold and the silicon are supplied from two wafers, so that the interdiffusion of the two materials creates an intimate contact with both surfaces. It has also been mentioned that the bond quality of Si–Au eutectic to silicon oxide, nitride, or glass is typically not very good and nonuniform. Harpster and coworkers have developed a new bonding technique based on both Si–Au eutectic and anodic bonding (Harpster 2005, Harpster and Najafi 2003). It is found that by applying an anodic bias, as is typically done in direct Si–glass wafer bonding, in a standard Si–Au eutectic bond, a significant improvement in bond quality, uniformity, and reproducibility can be obtained. This new technique makes the following three very significant contributions to wafer bonding:

(1) The electrostatic forces ensure intimate contact between the Si–Au solder and glass interface uniformly over large areas, which is absolutely necessary for wafer-level bonding and hermetic sealing.
(2) A roadblock in obtaining hermetic and vacuum sealing using electrostatic methods is planarization of the bonding interfaces. The fluid Si–Au eutectic solder ensures instant and contiguous planarization over nonplanar substructures such as electrical feedthroughs.
(3) It is speculated that all the bonding materials are biocompatible, which open the arena for biomedical applications.

The bonding process is illustrated in **Figure 14(a)** (Harpster 2005, Harpster and Najafi 2003). A Ti/Au layer (200/10 000 Å) is evaporated onto the silicon wafer. A glass wafer and the gold surface, on the Si wafer, are kept at a fixed separation distance using spacers as typically found in wafer bonding equipment. Control of the diffusion of the Au and Si is critical to the formation of a hermetic bond and therefore the temperature of the wafers throughout

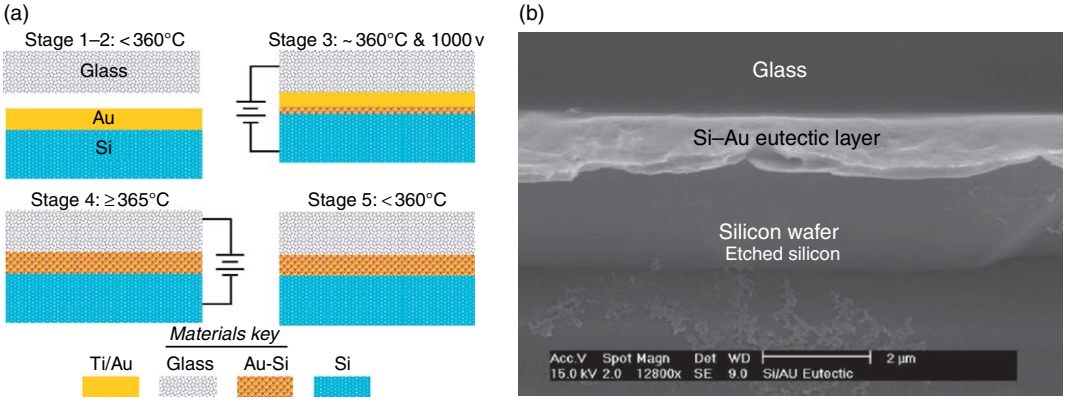

Figure 14 (a) Stages of the liquid Au–Si alloy formation and bonding process. (Source: Harpster T J 2005 Hermetic packaging and bonding technologies. Doctoral dissertation, University of Michigan; reproduced with permission.) (b) Scanning electron microscope (SEM) of bonded cross section. (Source: Harpster T J, Najafi K 2003 Field-assisted bonding of glass to Si–Au eutectic solder for packaging applications. *Proceedings, International IEEE Microelectromechanical Systems Conference (MEMS Conf.),* Kyoto, Japan, January 2003.)

this bonding process is a critical control parameter. In stage 1 the wafers must be heated to a temperature below the eutectic point of the Au–Si solder and allowed to come to equilibrium. A set temperature of 250°C is used prior to ramping to 345°C to reduce the overshoot on the stage-2 heating cycle. Reducing the ramp rate can also minimize the overshoot. In stage 2 the wafers are heated to a temperature below the eutectic temperature of the Au–Si alloy and the chamber is evacuated to ~10 μtorr. The transition to the eutectic temperature must be accurately controlled. Therefore to reduce the uncertainty of time at which the wafer reaches the eutectic temperature and to maximize the temperature uniformity across the wafer, the temperature step from the soak to bond temperature is minimized. The wafers are held at 345°C to allow the wafers and bonder to reach thermal equilibrium before the critical transition to the stage 3.

In stage 3, the wafers are brought into contact, and a force of 1000 N is applied. After a 3-min wait for the upper and lower wafers to reach thermal equilibrium a voltage of 1000 V is applied. The applied force is primarily used for overcoming wafer bow and for deforming the solder after its transition to the liquid state and thereby planarizing over micromachined structures. The wafers are then immediately heated to 365°C whereby the formation of a liquid-phase eutectic initiates at the Au–Ti–Si interface. The liquid Au–Si alloy layer increases in thickness or volume depending on the contour, as it consumes the Au and underlying Si and Ti layers. After the Au layer is consumed and correspondingly the eutectic composition ceases to grow, the Au diffusion into the underlying silicon will continue thereby leaving a Si-rich solder and as a result solid Si phases will crystallize. Solid phases in the liquid layer will likely increase the effective viscosity of the melt and may impede planarization of the glass surface, thus bond quality and uniformity will be compromised. Therefore, time and temperature above the eutectic temperature are critical. The diffusion rate should be kept low to ensure homogeneous mixing of Au and Si and to allow time for structures to be planarized before the solid Si phases form. Therefore, the bonding temperature must be kept near the eutectic temperature and a bias must be applied prior to a eutectic formation at the glass surface because this ensures that the electrostatic forces pull the liquid solder into contact with the glass before any solid phases can form.

When the Au–Si–Ti solder reaches the glass surface, the electric field at the glass–solder interface, due to the anodic reaction, pulls the solder into intimate contact with the glass surface. There are three competing reactions that play a role in forming the solder-to-glass bond:

(1) A Au–glass eutectic reaction (Katz *et al.* 1991)
(2) A glass–Si anodic reaction (as in a typical glass–Si anodic bond)
(3) Wetting of the solder to glass being promoted by Ti in the solder (Humpston 2004).

In stage 4 the wafers are held at 365°C for ~20 min to allow the liquid alloy to form and the glass–solder interface to bond. In typical glass–Si anodic bonding, a general rule of thumb is that the bond time is determined by the decay time of the anodic current. One of the proposed mechanisms for the glass–solder bond is the anodic oxidation of Si at the glass–solder interface; therefore, this rule of thumb is followed.

In stage 5 the wafers are cooled to ~220°C at a maximum cooling rate of 19.5°C min^{-1} (0.33°C s^{-1}) to ensure that the Au–Si alloy solder is solidified before the applied bias and contact pressure are removed. The resulting bond between the glass, thin-film solder, and the silicon wafer is robust and uniform and cannot be separated by mechanical prying. A section of the bonded wafer is cleaved for cross-sectional viewing. An SEM photograph of the bonded interface is shown in **Figure 14(b)**.

1.09.4.2.4 Bonding using glass films

In addition to metal solders, glass solders or films can also be used for wafer bonding. The advantage of these seals is that they are insulating and can be applied to insulate electrical feedthroughs for MEMS packaging (Cook and Liniger 1999, Deligeorgis *et al.* 2002, Dragoi *et al.* 1999, Drost *et al.* 1998, Ebert and Bagdahn 2004, Esashi *et al.* 1990, Kikuchi *et al.* 1997, Liu *et al.* 2003, Sparks *et al.* 2003, 2004). There are two common methods for wafer bonding using glass seals. The first method uses lead borate or solder glasses as an adhesive between wafers to be bonded, and the second method using spin-on-glasses that are deposited in liquid form and then cured and baked to form a final solid film.

In the first method, the glass compounds are manufactured as powder called frit and mixed into screen printable pastes. High temperatures are used to soften the glass frit, and pressure is used to ensure intimate contact forming a hermetic seal. The frit is then cooled

whereby it solidifies forming a permanent bond. The frit is made up of a base glass, a refractory filler, and a vehicle. The base glass forms a majority of the frit. The filler reduces the coefficient of thermal expansion (CTE), enhances the mechanical strength and the crack resistance of the frit. The vehicle is made up of a solvent that provides fluidity for screen printing and an organic binder. Many different types of glass frits are commercially available with different melting points, CTEs, organic binders, and screen printing properties. Almost all the low melting point formulations of glass frit contain some lead, which is a major drawback. Solder glasses are characterized as either vitreous or devitrifying, depending on whether they crystallize at a temperature within the sealing range. Although devitrifying glasses generally have higher strength, vitreous glasses soften at lower temperatures and thus are more attractive for MEMS device wafer bonding. Among the lowest temperature glasses are lead borates, generally of high lead oxide content with additions of B_2O_3, ZnO_2, SiO_2, and Al_2O_3. The eutectic of the $PbOB_2O_3$ system occurs at 490°C (87.5% PbO/12.5% B_2O_3). Phosphorus doping and the addition of other materials, such as low CTE refractory filler materials, are used to obtain acceptable CTE values, improve flow characteristics, increase strength, and lower the softening temperature. Glass compositions that allow bonding below 400°C without contaminating the integrated device are available. Frit glass is screen printed on to wafers about 10–25 μm thick. This thick layer is advantageous for mitigating defects such as particulates, planarizing over wafer topologies such as feedthroughs, and providing a standoff for moving MEMS structures. Glass frit is widely used for hermetic sealing of MEMS devices such as accelerometers and gyroscopes. Integrated Sensing Systems (ISSYS) has used this technology together with its NanoGetter technology to fabricate wafer-level vacuum packages for MEMS using glass frit bonding (Sparks *et al.* 2003, 2004). ISSYS has demonstrated that the frit is stable and can hold very high levels of vacuum for extended periods of time for a variety of devices and applications.

Drawbacks of glass frit bonding include relatively large footprint (>150 μm) due to limitations of screen print patterning. Additionally, outgassing the organic paste constituents require the use of getters for vacuum sealing applications.

Silicon on glass (SOG) is another glass seal wafer bonding technique whereby silanol (Si–OH) and methyl (CH_3) polymers are dissolved in an alcohol/acetone solvent to form a low-viscosity spin-on material often referred to as a sol–gel (Cook and Liniger 1999, Liu *et al.* 2003). Similar to glass frit bonding, polishing and etching to reduce roughness of the wafer surfaces before bonding is not critical because SOG can fill and smooth out the surface topology. SOG thicknesses are limited to 0.5–1 μm due to induced stress from the resulting glass film. The wafer pairs are bonded at low temperature (250°–400°C); however typically a secondary high-temperature step (~1100°C) is employed to improve the dielectric breakdown voltages. Advantages of SOG wafer bonding include controllable wafer gap for capacitive devices, hermetic sealing capability, ability to seal over limited topology (~<1 μm), and the ability to bond wafers of different materials. SOG patterning has been demonstrated using high-energy lithography techniques such as electron scanning, focused ion beam (FIB), and deep X-ray lithography (DXRL). SOG has been demonstrated in bond combinations of Si, Si with oxide, silicon with dielectrics, and even III–V materials. SOG with alkali components has also been used for field-assisted wafer bonding. The glass is cured prior to bonding thereby reducing glass outgassing during anodic bonding, thus high-vacuum packaging can be achieved. This method has been demonstrated for Si-to-Si and Si-to-GaAs wafers. Liu *et al.* (2003) uses a 500-nm SOG layer to form a low-temperature (~500°C) wafer bonds for optically pumped vertical cavity surface-emitting lasers (VCSELs). Thicker layers were demonstrated but they cracked under the mechanical-induced stresses from dicing. Historically, the high-temperature step used for curing has limited the use of SOG for many commercial applications. More recently, SOG films have been used for anodic bonding of silicon-to-silicon wafers. This is a useful technology since it allows thick layers of glass to be deposited to planarize over feedthroughs and then use anodic bonding to bond the second wafer on top of the first.

1.09.4.2.5 Polymer-assisted wafer bonding

Polymers are extensively used for bonding wafers together (Ageoroges and Ye 2002, Bayrashev and Ziaie 2002, Bilenberg *et al.* 2004, Chou 2001, Chou and Najafi 2001, Dragoi *et al.* 2003, Eaton *et al.* 1994, Folsom *et al.* 1999, Han *et al.* 2000, Hansford *et al.* 1998, Huang *et al.* 2004, Jeon *et al.* 2002, Kim 2006, Kim and

Najafi 2003, 2005, Lan *et al.* 1997, Lee *et al.* 1997, 2003, Meng *et al.* 2000, Mizuno *et al.* 2005, Niklaus *et al.* 2000, 2001, Noh and Hesketh 2000, Noh *et al.* 2003, 2004, Oberhammer *et al.* 2003, Oh *et al.* 2002, Owen and Smith 1995, Pantelidis *et al.* 1999, Smith 1993, Su and Lin 2001, Takahashi *et al.* 2000, Xu *et al.* 2003, Yang *et al.* 1999). Frequently they are used for temporary bonding of wafers where they simply play the role of glue. Therefore, in these cases the polymer need not be stable or provide long-term adhesion, it just has to keep the wafers together for a short while. More recently, however, polymers have been increasingly used for permanent bonding of wafers. They have to satisfy many more requirements and have to be stable and reliable. The primary advantage of polymer-assisted wafer bonding is the low bonding temperature and the ease with which polymers can be applied on a wafer. Other advantages include low cost, sealing over large topographies, bonding of dissimilar materials, and transparency to visible light. Although polymer bonding is used for many commercial devices, polymers are susceptible to water uptake and gas diffusion, which leads to delamination at the bond interfaces. Additionally, polymer bonding is not compatible with vacuum packaging because of outgassing during the curing step.

Various polymers have been used for wafer bonding, including parylene (Kim and Najafi 2003), SU8 (Bilenberg *et al.* 2004), benzocyclobutene (BCB) (Chou and Najafi 2001, Niklaus *et al.* 2000, 2001), CYTOP (fluorocarbon polymer) (Han *et al.* 2000, Oh *et al.* 2002), polymethylmethacrylate (PMMA) (Lee *et al.* 2003), polyimide (Bayrashev and Ziaie 2002), Mylar (Su and Lin 2001), many different epoxies and waxes, and liquid crystal polymers (LCP). Some of these polymers and their primary features are listed in **Table 3**. Polymers are usually deposited on bonding surfaces as a viscous liquid through spin-on coating, and then cured at a moderate temperature (around 150°C) to form a solid bonding layer. These conventional polymers, however, go through a phase transition from a liquid (before curing) to a solid (after curing). Thus, they have problems, as bonding agents, with voids caused by the curing process, have difficulty in aligning fine features before curing, and cannot be easily spread uniformly on a wafer surface with tall structures or deep etched regions.

Of these polymers, BCB and parylene are discussed briefly since these are the two polymers that produce the least amount of outgassing and void formation. BCB is a spin-on liquid polymer and is

photodefinable, whereas Parylene is evaporated down as a dry layer over highly nonplanar surfaces. These are used as examples to show how polymer bonding can be done.

BCB is an epoxy-based polymer. It was primarily developed as a low dielectric constant material for planarization of ICs (Lan *et al.* 1997, Lee *et al.* 1997, Takahashi *et al.* 2000). When fully cured, BCB shows low volume shrinkage and high resistance to most wet chemicals (Folsom *et al.* 1999). Some of the properties of BCB are listed in **Table 4**. Void-free thermal compressive bonding by using this material was reported by Niklaus *et al.* (2000, 2001). BCB bonding strength is larger than other polymer-based materials (**Table 3**). Since the cured BCB is inert to most acids, bases, and solvents, it is an excellent bonding material for applications that require postbond wafer processing. BCB can be spun onto a wafer, exposed, and then developed to form specific patterns. After pattern definition, BCB can be partially cured to remove any residual solvent or directly bonded with a companion wafer by applying pressure and temperature. Compared to other bonding techniques, BCB bonding is a simpler process since it does not need any special setup. The cured BCB thickness can vary from ~1 μm to more than 10 μm depending on the spin speed and BCB-type used.

After patterning and precuring, the wafer coated with BCB is bonded to another wafer, and is then postbaked and cured to achieve the final strong bond between the two wafers. The bonding was performed under an applied pressure of 150 kPa at 250°C for 30 min, at which point BCB is more than 95% cured. The curing time increases exponentially in order to achieve 100% curing. One can achieve 95% curing within 5 min by increasing the baking temperature up to 300°C. The quality of BCB bonded wafers is excellent. When bonded wafers with 10-μm-wide and 6 μm thick BCB are bonded and then forced apart, it has been observed that more then 90% of the patterned BCB was transferred from the host wafer onto the companion wafer. The original pattern remained on the host wafer as well. This indicates that the BCB bond strength is sufficient to maintain structural integrity. The 10-μm-wide, 6-μm-thick BCB lines and 5-μm-wide channels formed by the surrounding BCB still retain their shapes after bonding. BCB can serve as the air gap spacer as well as the bonding medium between two wafers, as shown in **Figure 15** (Chou 2001). The final air gap is defined by the cured BCB thickness. In conventional MEMS fabrication, the air gap is usually formed by deposition of sacrificial layers, such as low-pressure chemical vapor deposition (LPCVD) polysilicon and silicon dioxide. These sacrificial layers are limited in thickness to a few microns and take a long time to deposit and etch. By using photosensitive BCB as a spacer, microstructures with air gap >10 μm can be fabricated using a standard photolithographic process. The air gap variation was <5% across the 4″ silicon wafer in this experiment. BCB bonding technique has several advantages, including: (a) low-temperature (<250°C) bonding and low-stress (<30 MPa) film, (b) uniform air gap formation (<5% variation), (c) easy processing for different thicknesses with high throughput, and (d) high electrical and chemical resistance. It can be used not only as the localized bonding medium at low temperatures, but also as the air gap spacer

between two structures with sufficient strength and uniformity.

Parylene (poly-*para*-xylylene), unlike conventional polymers, does not go through a liquid-phase transition; instead it is directly vapor-deposited from a solid powder. Thus, it can avoid problems associated with spinning of liquid materials, such as step coverage and outgassing. Parylene has not been widely used as a bonding agent, in spite of its widespread use in MEMS (Huang *et al.* 2004, Meng *et al.* 2000, Xu *et al.* 2003, Yang *et al.* 1999), until very recently (Kim and Najafi 2003, Noh and Hesketh 2000, Noh *et al.* 2004) for two main reasons. First, parylene does not form a strong covalent bond because it does not go through a curing process; it is deposited as a thin film through vapor deposition. Second, parylene is an inert film after deposition. Parylene is a high molecular weight, crystalline polymer, and consists of carbon backbones without any oxygen, nitrogen, or sulfur atom links. This crystalline carbon backbone film is naturally stable and highly resistant to chemical attacks. Thus, it does not allow permanent bonding or attachment to many surfaces. However, parylene is a thermoplastic polymer that becomes soft when it is heated and hard when it cools. Generally when a thermoplastic polymer is soft, portions of polymer chains can re-entangle with neighboring chains, thus forming a macroscopic bond (Ageoroges and Ye 2002, Smith 1993). In thermoplastic polymers, this phenomenon is reversible. It is believed that parylene undergoes this phenomenon.

In a recent paper, Noh *et al.* (2003, 2004) investigated wafer bonding using microwave heating of parylene on small (75 mm) wafers. His investigation mainly focused on the usability of microwave heating, the resultant uniformity, and the strength of parylene bonding. Kim and coworkers have done extensive characterization and testing of parylene-assisted wafer bonding (Kim and Najafi 2003, 2005, Noh *et al.* 2003). The bonding process starts by first preparing the wafers. Each of the two silicon wafers is coated with a thin (~0.381 μm) parylene layer, which serves as the glue layer. Each wafer is then cleaned using acetone and IPA, dried, and then bonded in a standard commercial bonder. Kim and coworkers demonstrated that wafers can be bonded using parylene; the optimized bonding conditions are a temperature of ~230°C, a vacuum of ~0.153 mbar, and a force of 800 N on a 100-mm wafer. It is noted that wafer bonding at 80°C (below the glass transition temperature) is almost too weak to be used. However, wafer bonding at temperatures above 130°C produces reasonable bond strength (>1.5 MPa) for MEMS applications. The measured bond strength versus bonding temperature is shown in **Figure 16** (Kim 2006, Kim and Najafi 2003, 2005).

Parylene bonding provides excellent qualities needed for many MEMS applications, as listed in **Table 3**. It produces reasonable bond strength above 3.60 MPa that is comparable to other polymer bonding methods. It maintains its bond strength

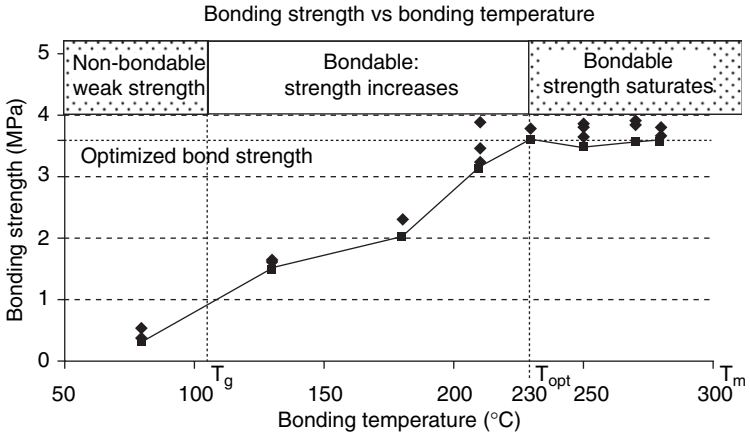

Figure 16 Measured bond strength versus bonding temperature for silicon wafers bonded using parylene. (Sources: Kim H, Najafi K 2003 Characterization of low-temperature wafer bonding using thin film parylene. *IEEE J. Microelectromech. Syst. (J. MEMS)* **14(6)**, 1347–55; Kim H, Najafi K 2005 Characterization of parylene-assisted wafer bonding: Long-term stability and influence of process chemicals. *Tech. Dig., 13th Int. Conf. Doctoral dissertation, University of Michigan.)

under a typical room environment for at least 2 years. The bond is stable for long periods of time and parylene is resistant to many of the ordinary chemicals used for semiconductor fabrication. Parylene bonding is free of voids because it does not go through curing process. Parylene layers can be patterned to form an arbitrary shape for bonding a specific area.

1.09.4.3 Other Bonding Techniques

As mentioned before, the bonding techniques discussed above are differentiated by the different mechanisms used to form the bond. All these bonding mechanisms utilize heat to initiate and complete the bonding process. Bonding is usually performed in a bond chamber where the entire wafer is heated in a controlled ambient under an applied load. Therefore, if wafers contain either devices or materials that cannot withstand the required bonding temperature for any specific bonding technology, then that bonding technology cannot be used. This indeed limits the types of materials and bonding technologies that can be used for that specific application. In order to overcome some of these limitations, different techniques for heating wafers have been developed, as discussed below.

To achieve wafer bonding, one typically needs to heat only the regions between the two wafers that are in contact (i.e., the bond regions). There is usually no need to heat the entire wafer. It is sometimes required that the bonding temperature be raised above 400°C to allow various other materials and bonding techniques be used. One such example involves glass frit bonding, which needs bonding temperatures in the 500–700°C range. This temperature is too high for many materials used in MEMS and ICs. In some applications, the temperature of the MEMS devices cannot be raised much higher than 50–100°C. This is often the case when the MEMS device incorporates materials such as polymers or biological coatings, which cannot withstand high temperatures. Therefore, one needs techniques where the temperature of the MEMS parts can be kept below 100°C, or even lower, and the temperature where the bond between the two wafers is formed can be raised above 500°C. To achieve this goal, several techniques have been developed and proposed, including bonding based on localized resistive heating, microwave heating, laser heating, localized chemical vapor deposition (CVD) and heating, ultrasonic bonding, inductive heating, and RF heating (Chang-Chien and Wise 2001, Cheng *et al.* 1998, 1999, 2000b, c, 2001a, b, 2002, He *et al.* 1999, Lin *et al.* 1998, Mitchell and Najafi 2006).

1.09.4.3.1 Localized resistive heating

A new technique for heating the bond regions between two wafers using on-chip resistors was reported by Cheng *et al.* (1998, 1999, 2000a, b, 2001a, b, 2002), He *et al.* (1999), and Lin *et al.* (1998). In this approach, a resistive heater, using standard materials like aluminum or polysilicon, is formed only in those areas where the wafers are to be bonded. Because silicon is a very good conductor, the heat generated by the resistive heater can be confined and localized to the bond area. In the sensitive device regions, the temperature is maintained at room temperature or slightly above by directing most of the heat away to a heat sink attached to the bottom of the device substrate. Simulations and experiments have demonstrated that the temperature gradient falls rapidly from a temperature of about 700°C to around 50°C over a distance of <100 μm from the location of the resistive heater. A vacuum package based on localized aluminum/silicon-to-glass solder bonding technique was reported earlier (Cheng *et al.* 2002). The heater is formed using a layer of polysilicon and is isolated from the wafer using deposited dielectrics. A layer of aluminum is deposited on top of the polysilicon resistor. A glass wafer with an etched cavity is brought into contact with the wafer containing the polysilicon heater, and the aluminum bonding layer and the resistor are heated to raise the temperature locally in the bond region. At a temperature of about 800°C, the glass and the aluminum form a solder that flows over the nonplanar surface. An excellent bond is achieved in the bond region. This approach is quite useful because it allows to maintain a low temperature in the region where the sensitive devices are and to maintain a high temperature where the bonding region is located. The high temperature not only improves the quality of the bond, but also allows various materials to be used in the bonding region and to have these materials flow at the bond temperature and conform to the topology on the substrate, which is often nonplanar.

A different approach to localized heating has been recently reported by Mitchell and coworkers (Mitchell and Najafi 2006). In this approach instead of forming on-chip resistors in between the two wafers, heat is supplied to the backside of one of the two wafers to be bonded and removed from the backside of the second wafer as illustrated in **Figure 17**. Because most of the heat is drawn towards the heat sink, the noncontacting

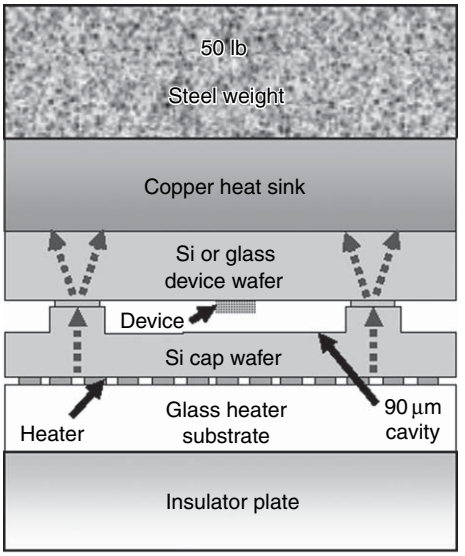

Figure 17 Cross-sectional view of the backside localized heating technique developed by Mitchell and coworkers One of the wafers is heated from the backside (in this figure it is called the silicon cap wafer), and the other wafer is cooled from its backside (this is called the silicon or glass device wafer). Heat is conducted through the bond regions (where the two wafers are in contact), thus heating these bond regions to a much higher temperature than the other noncontacting regions. (Source: Mitchell J, Najafi K 2006 Backside resistive localized heating for low temperature wafer-level bonding and packaging. *Tech. Dig., Solid-State Sensor, Actuator, and Microsystems*, Hilton Head Island, SC, USA, June 2006, pp. 352–5.)

regions are heated less than the bond regions. This method is attractive because it can be applied on a wide range of materials and at the wafer level without a need for on-chip resistors formed in between the two wafers. Using this technique, gold–silicon eutectic bonds were formed where the temperature of the bond regions were raised to about 400°C, and the sensitive device regions were heated to a temperature of only about 200°C.

1.09.4.3.2 Microwave, RF, and electromagnetic heating

Microwaves have long been used for heating various materials. Conductive layers absorb microwave energy and generate heat. This feature was first used by Budraa *et al.* (1999) to heat the bond region between two wafers to very high temperatures using microwave radiation. Microwave radiation selectively heats the metallic portion of the substrates. In addition microwave radiation (200 kHz–20 GHz) is transparent to a dielectric material that has a low dielectric constant, however energy is deposited in a skin depth (~1 pm) of a metal. This feature results in selective heating within the substrate. Heating of the silicon wafers is limited by the wafer material and is generally small for pure silicon. Budraa bonded silicon wafers with gold coatings for a MEMS packaging application by using microwave radiation in a single-mode cavity excited at 2.45 GHz. The experiment was performed in a high vacuum (~25 ptorr) to avoid the formation of plasma. The wafers were placed on top of each other without applying pressure inside a microwave transparent test tube. The quality of the bond was characterized by testing the hermeticity of a vacuum package formed using this bonding technology.

A variation of this microwave heating was used by Thompson *et al.* (2001, 2002) to heat and bond silicon wafers together. This work relies upon electromagnetic induction heating (EMIH), which uses electromagnetic radiation, ranging in frequency from a few megahertz to tens of gigahertz, to volumetrically heat silicon above 1000°C within a few seconds. Typical power requirements of silicon wafers of 75–100 mm in diameter fall between 900 and 1300 W. Note that in this work an intermediate layer need not be used. In order to get around the fact that silicon is transparent to electromagnetic radiation because of its small imaginary dielectric relaxation response to fields whose frequencies are below 100 GHz, Thompson took advantage of the ohmic response of silicon to an oscillating electromagnetic field; EMIH directly heats the silicon to temperatures at which the bonding can be achieved. This technique has successfully produced direct silicon wafer-to-wafer bonds without the use of an intermediate glue layer. Infrared images indicate void-free bonds that cannot be delaminated with knife-edge tests. In addition, four pairs of stacked wafers were bonded simultaneously in 5 min demonstrating the potential of multi-wafer bonds and high-throughput batch processing.

In yet another variation of microwave/RF heating, Bayrashev and Ziaie (2002) use RF radiation to heat a dielectric to achieve wafer bonding. RF dielectric heating uses a high-frequency electric field to send energy to an insulator placed between two metallic electrodes in a parallel plate capacitive configuration. Considerable energy can be imparted to dielectric molecules by agitating them as the field alternates each cycle. This energy appears as heat and since it is developed directly in the material, excellent uniformity and fast heating are possible. A

500-W, 14-MHz source was used to deliver RF power to the substrates. Two-inch diameter silicon wafers with 2- to 20-μm-thick polyimide or photoresist intermediate layers were successfully bonded (>95% bond area) in less than 7 min. The silicon substrate temperature remained below 280°C throughout the bonding process. The results of the pull tests indicate a bond strength of >1.5 MPa for fully cured substrates, which is greater than the strength of other low-temperature adhesive bonds. This method has several features. It is fast (<7 min bonding time), has a simple RF field configuration, is void-free, and the bond is stronger than that reported for adhesive bonds.

Finally, in yet another variation of the same basic concept, heating of a bonding layer, such as solder, using inductive heating was also reported by researchers (Cao *et al.* 2001, Yang *et al.* 2004). In this approach, a magnetic material is exposed to an electromagnetic field and is heated using the absorbed energy. The technique has been used for packaging of MEMS. In this approach an intermediate layer of a film that can absorb the electromagnetic field is needed. Yang *et al.* (2004) used this technique to bond a glass wafer to a silicon substrate using a nickel–cobalt layer and demonstrated that bond strength >18 MPa was measured. Both silicon–silicon and glass to silicon bonds were demonstrated.

1.09.4.3.3 Ultrasonic bonding

Ultrasonic wire bonding has been used extensively in the IC industry for bonding of conductive wires to pads on IC chips. The same basic technique has been used by Kim *et al.* (2002) and has been applied for attachment of a package die having a metal surface to a silicon substrate coated with another suitable metal layer. Ultrasonic bonding is a solid-phase welding process in which heat is generated by scrubbing two contacting surfaces during the bonding process, causing the materials to interdiffuse and bond together. The heat is insufficient to melt most metals and therefore melting temperatures and thermal conductivity of the materials are not decisive process factors. Ultrasonic vibration is usually generated at a frequency of about 60–80 kHz, and the force and pressure applied can be varied depending on the size of the bond ring. Bonds between aluminum–aluminum and indium–gold surfaces have been demonstrated (Yang *et al.* 2002). This technique is not easy to apply at the wafer level, and it has been mostly demonstrated for individual die or small area wafers.

1.09.4.3.4 Rapid thermal processing

A technology that is extensively used in the microelectronics industry is RTP. It is used for annealing and forming diffused junctions in ICs, among many other uses. In this approach, the wafer is rapidly, in the matter of a few seconds, heated to a high temperature and then cooled down. The limited exposure to these high temperatures is sufficient to achieve the desired objective of annealing or diffusion but not too long to damage the sensitive parts of the wafer. The same technique has been applied for wafer bonding and selective bonding in MEMS (Chiao and Lin, 2001, 2002). Surface-micromachined microresonators were sealed inside microcavities by an RTP aluminum-to-silicon nitride bonding. A glass wafer supporting 4-μm-thick aluminum rings was bonded to silicon wafer supporting a 0.4-μm silicon nitride layer using this technique. The assembled pair is loaded into an RTP chamber flushed with nitrogen gas, and then bonded within 10 s at 750°C. Due to the low thermal mass of the RTP system, the processing temperature rises from room temperature to 750°C and cools down to 350°C within 40 s. During the high-temperature bonding process, the molten aluminum reacts with silicon nitride, and a mechanically stable bond is formed at the aluminum–nitride interface. The measured aluminum-to-nitride bonding strength was found to be greater than the glass fracture toughness estimated at around 10 MPa. This technique has also been used for bonding other materials together (Chiao and Lin, 2001, 2002).

1.09.4.3.5 Laser heating

Lasers have long been used for welding, and have more recently been used for selective wafer bonding and welding of materials on wafers (Brown *et al.* 1999, Luo and Lin 2002, Luo *et al.* 2001, Mescheder *et al.* 2001, Sari *et al.* 2005, Stevenson 1988, Tao *et al.* 2004, Wild *et al.* 2001, Witte *et al.* 2002). The process is relatively straightforward. Two wafers with or without an intermediate layer are placed on top of one another and laser radiation is used to heat a selected region between the two wafers. One of the wafers or the material that is placed between the two wafers should be able to absorb the laser energy, and then be heated to a temperature where it melts and bonds with the materials surrounding it. Obviously, because of the high energy density of lasers, it is possible to quickly heat a selected region to very high temperatures and the literature cited demonstrates a number of different ways that this can be done. Laser welding and bonding are very attractive since the bond region

can be easily defined, and fast and localized heating can be easily achieved. The main drawback is that it is a serial process, although many emerging systems are capable of scanning large wafers for bonding. The display manufacturing industry uses this technology quite extensively for sealing and packaging of flat panel displays.

1.09.5 Summary and Conclusions

Wafer bonding has played a critical and extremely useful role in the development and successful commercialization of micromachined sensors and actuators. It is certain that it will continue to have an even more critical role in the development and the commercialization of future microsystems, ICs, nanoelectronics, and nano- and micromechanical systems. Its most important feature is that it allows the formation of complex microstructures and ICs through the precise and permanent attachment of multiple wafers, each of which can have other devices fabricated into it. Various wafer bonding technologies have been developed with each satisfying a different set of requirements and suitable for different applications. Because of this broad spectrum of applications and their specific requirements, it is difficult to compare these wafer bonding techniques. Nevertheless, Table 5 provides a summarized review and a comparison of wafer bonding technologies, and how they compare with respect to the set of desirable features that were presented in Section 1.09.1. Although many techniques have been developed and have matured, new technologies and improved understanding of the bonding mechanism of existing techniques are needed. Many of the existing technologies are constantly being pushed to reduce the bonding temperature or to improve the bonding quality and reduce cost. These efforts will continue and it is clear that we will see an expanding role for wafer bonding in many application areas.

Acknowledgments

The authors acknowledge the support of many organization and individuals who financially supported or participated in the development of some of the technologies reported here. The research results obtained at the University of Michigan were supported under various research grants funded by the US National Science Foundation (NSF), The National Institutes of Health (NIH), and the Defense Advanced Research Projects Agency (DARPA). The support of the faculty and the staff of the Solid-State Electronics Laboratory and the Michigan Nanofabrication Facility (MNF) at the University of Michigan is appreciated. Many former students and colleagues conducted the research that produced the results reported here. We especially thank Dr. T.K. Chou for his work on BCB bonding, Mr. Tzeno Galchev for his work on DBD plasma-activated bonding, Dr. Mehmet Dokmeci for his work on silicon–silicon bonding using evaporated

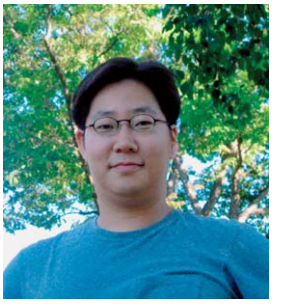
Biographies

Khalil Najafi received his BS, MS, and the Ph.D. degrees in 1980, 1981, and 1986, respectively, all in Electrical Engineering from the University of Michigan, Ann Arbor, MI. From 1986 to 1988 he was employed as a research fellow, from 1988 to 1990 as an assistant research scientist, from 1990 to 1993 as an assistant professor, from 1993 to 1998 as an associate professor, and since September 1998 as Professor in the Solid-State Electronics Laboratory, Department of Electrical Engineering and Computer Science, University of Michigan. His research interests include micromachining technologies, micromachined sensors, actuators, and MEMS; analog integrated circuits; implantable biomedical microsystems; micropackaging; and low-power wireless sensing/actuating systems. Dr. Najafi was awarded a National Science Foundation Young Investigator Award for the year 1992–1997, and has been active in the field of solid-state sensors and actuators for more than 20 years. He has been involved in several conferences and workshops dealing with microsensors, actuators, and microsystems, including the *International Conference on Solid-State Sensors and Actuators, The Hilton-Head Solid-State Sensors and Actuators Workshop* and *The IEEE/ASME Micro Electromechanical Systems (MEMS) Conference*. Dr. Najafi has served as the editor for several journals, including the *IEEE Transaction on Electron Devices*, *Journal of Solid-State Circuits*, *Transactions on Biomedical Engineering*, and is currently an associate editor for the *IEEE Journal of Micro Electromechanical Systems*, the *Journal of Micromechanics and Microengineering*, Institute of Physics Publishing, and an editor for the *Journal of Sensors and Materials*. He is a fellow of the IEEE and the AIBME.

Timothy J. Harpster received his BS degree in Electrical Engineering with a minor in Physics from the University of Dayton Ohio in 1998. He was the recipient of the University of Dayton Presidential scholarship and NAECON (National Aerospace and Electronics Conference) scholarship. During his undergraduate career, he interned at Intek Inc. where he participated in software development for the RheoVac® Diagnostic System, a real-time air in-leak measurement system for power plant condensers. He entered the University of Michigan in September 1998 to pursue his Ph.D. in Electrical Engineering with a major in Solid State Electronics and a minor in Circuits and Microsystems. He received his MS degree in May 2000 and his Ph.D. degree in December 2005 for his work on the development of passive wireless sensor technologies for packaging applications and glass silicon packaging technologies for implantable devices. Dr. Harpster is currently Director of Engineering at Intek Inc. in Westerville, OH. Intek is a manufacturing and research company that has established itself as a leader in low flow rate measurement instrumentation, a preferred supplier of unique aerospace payloads, the manufacturer of RheoVac air in-leak and condenser monitoring systems, and expert in steam surface condenser theory and design.



Hanseup Kim (IEEE S '00) received his BS degree in Electrical Engineering from the Seoul National University, Korea, in 1997, and the MS and Ph.D. degree in Electrical Engineering from the Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor, MA, in 2003 and 2006, respectively, where he is currently working as a postdoctoral research fellow. Since September 1999, he has been with the Center for Wireless Integrated MicroSystems (WIMS), University of Michigan, where he has been developing a high-performance polymer-based micropump with integrated microvalves for microfluidics applications including a high-speed micro gas chromatography. His research interests include microelectromechanical systems (MEMS), biomicrosystems, lab-on-a-chip, microfluidics, microsensors and actuators, micro/nanofabrication, and polymer technology development. He, with four other coauthors, was the recipient of the 2001 Best Paper and the 1st place award in the 38th Student Design Contest of Design Automation Conference (DAC 2001). Till date, he has authored and coauthored over 20 papers in refereed journals and

conferences, held one patent, and served as a technical reviewer for the *Journal of Microelectro-mechanical Systems*, *IEEE Transactions on Electron Devices (TED)*, and *Sensors and Actuators Journal (SNA)*.

Jay S. Mitchell was born in Madison, WI, in 1976. Jay received his BS and MS from Case Western Reserve University, Cleveland, OH, in 1999 and 2000, respectively, where he investigated the mechanical properties of silicon carbide for MEMS applications. In 2000 and 2001, he worked for Movaz Networks in the testing and design of micromirrors for telecommunications applications. In the fall of 2002, he began the Ph.D. program at the University of Michigan in mechanical engineering and is currently working on Au–Si eutectic vacuum packaging and localized heating methods for micropackaging. He also interned for Sandia National Laboratories in the summer of 2005 working in micropackaging.

Neil Welch was born in Jacksonville Beach, FL, in 1979. He received his BS in Electrical Engineering from Lehigh University in June 2001. During his time at Lehigh, he spent a summer at the Department of Energy's Princeton Plasma Physics Lab developing code to facilitate the visualization of scientific data. The following summer, he was part of the National Science Foundation (NSF) Research Experience for Undergraduates program at Lehigh's Sherman Fairchild Research Lab. At the lab, his work focused on reducing the number of oxide traps at the surface of a silicon carbide MOS capacitor. He enrolled at the University of Michigan in the fall of 2001 and received his master's degree in May 2003. In 2004, he was awarded the Outstanding Student Leadership Award for his efforts as part of the NSF Engineering Research Center for Wireless Integrated MicroSystems. He is currently pursuing his Ph.D. research into applications of solder for vacuum and hermetic packaging of MEMS. His other interests include miniature power sources and bioMEMS.

1.10 Electrodeposition

MEMS Microelectromechanical Systems

PMMA Polymethylmethacrylate, resist material used in X-ray lithography or LIGA

Wagner number, ***Wa*** Ratio of resistances in an electrochemical process that correlates to uniformity. Resistances may be due to the seed layer, charge transfer process, diffusion, or electrolyte conduction

1.10.1 General Principles

The electrodeposition of metals, alloys, and semiconductors has found broad use in the fabrication of microsystems and microelectromechanical systems (MEMS). While a large number of metals found in microsystems can be electroplated from aqueous electrolytes (Ni, Cu, Au, Pt, Fe, Pb, to name a few), a few metals cannot, notably Al, Ti, and pure W. Nickel and its high-strength alloys constitute some of the more useful materials available to microsystem fabrication by electrodeposition, owing to their use in forming mechanical and magnetic elements such as precision gears, latches, motors, and flexure spring arms (Malek and Saile 2004). Electroplating is a versatile technique spanning the range of coatings and thin films less than a micron to thick electroformed mechanical elements millimeters tall. Materials are deposited near ambient conditions without the need for expensive vacuum equipment. Deposition rates can be much faster than vapor deposition methods and film thicknesses can be as high as a millimeter or two. The essential elements of the process are the cathode, or the workpiece to be plated, an anode or counter electrode, and an electrolyte that possesses the metal ion in reducible form. Current is supplied to the workpiece, which for MEMS is often a flat substrate metallized by vapor deposition. This thin metal coating forms a conductive seed layer to which electrical contact is made. The seed layer can cover micropatterned films of insulator, as in the copper Damascene process for integrated circuit interconnects. Or, an insulating, patterned layer for through-resist plating can mask the seed layer. The latter approach is more often utilized for making freestanding parts, exemplified by the LIGA (lithographie, galvonoformung, abformtechnik, German acronym associated with the process of lithographically defining molds for electroforming) and X-ray lithographic methods.

In this chapter, some of the fundamentals of electrodeposition are reviewed first; there are numerous references that provide far more detail (Bard and Faulkner 2001, Dini 1993, Lowenheim 1995, Schlesinger and Paunovic 2000). In addition to kinetics, some general methods (including common issues) are detailed to give the MEMS practitioner a starting point for conducting an electrodeposition process. Some of the ramifications of plating through lithographically generated patterns are discussed. Although there is a rich literature and much recent progress has been made on the modeling and simulation of patterned electrodeposition, that topic is beyond the scope here. Instead, we cover some of the general principles and focus on the properties and processes of electrodeposits most relevant for MEMS. Finally, an assortment of materials, recipes, and applications are provided as a starting point for electrodeposition for MEMS, with emphasis on nickel and its alloys for application to micromechanical elements.

1.10.1.1 Kinetics

The rate at which a metal is deposited is related to the current density by Faraday's law, which states that the extent of an electrochemical reaction that occurs is proportional to the electrical charge passed. Each metal has an electrochemical equivalent Z, or the proportionality constant relating deposition rate to current density. For example, the growth rate can be expressed as follows:

$$\text{Rate}\left(\mu\text{m h}^{-1}\right) = 3.6 \times 10^4 \times \frac{Z \times \text{CE} \times \mathcal{J}}{\rho} \quad [1]$$

where CE is the current efficiency, $\mathcal{J}$ is the current density (in mA cm^{-2}), ρ is the density of the metal (in g cm^{-3}), and

$$Z = \frac{M}{nF} \quad [2]$$

where M is the molecular weight (in g mol^{-1}), n is the number of electrons involved, and F is Faraday's constant, 96 485 C mol^{-1}.

For the case of nickel electrodeposition Ni^{2+}, $n = 2$, $M = 58.71\,\text{g mol}^{-1}$, $Z = 3 \times 10^{-4}\,\text{g C}^{-1}$ and the linear growth rate ($\rho = 8.9\,\text{g cm}^{-3}$) at a current density of 10 mA cm^{-2} is 11.5 μm h^{-1}, assuming the CE is 95%, which is typical for Ni. The CE is the ratio of charge consumed toward the deposition reaction to the total charge consumed. Side reactions, such as the reduction of hydrogen, detract from the CE. Copper electrodeposition usually has nearly 100% CE with current densities up to 50 mA cm^{-2}. Nickel electrodeposition generally has 95–100% CE, but unlike copper, CE will drop at current densities lower than 3 mA cm^{-2} CE for gold electrodeposition can be as low as 50%, depending on the bath formulation.

The upper limit to the rate of metal deposition is determined by the mass transport, or diffusion, of the metal ion species to the cathode surface. In the case of

a planar surface with no convection or mixing of the electrolyte, the current decreases with time as metal ions are consumed near the vicinity of the electrode. For this case, the time-varying current density is described by the Cotrell equation,

$$j(t) = \frac{nFD^{1/2}C}{\pi^{1/2}t^{1/2}} \quad [3]$$

where D is the diffusion coefficient for the electroactive metal species and C is the concentration of the metal in the bulk solution.

Eventually, as the metal ions are consumed at the cathode surface, the deposition rate, or current density, becomes limited by the rate of diffusive flux of ions to the surface. When the length scale for diffusion, δ, is known, such as the height of a resist feature or for a rotating disk electrode, the limiting current can be described by

$$j_L = \frac{zFDC}{\delta} \quad [4]$$

For extreme cases of resist height (>100 μm) and plating rates, it has been shown that natural convection can be a significant component of the mass transport (Nilson and Griffiths 2003). Under these conditions, the limiting current can be larger than that expected by diffusion alone.

For a rotating disk electrode (the preferred tool of the electrochemist and the arrangement in many commercial electrodeposition tools), the diffusion layer thickness, δ, can be precisely described and the limiting current is described by the Levich equation,

$$j_{L,\,RDE} = \frac{0.62nFD^{2/3}\omega^{1/2}C}{v^{1/6}} \quad [5]$$

where ω is the angular frequency of rotation and v is the kinematic viscosity.

In some cases, it is preferable to control an electroplating process by the potential, rather than current. This can be beneficial if undesired side reactions are to be avoided or the plated area is quickly changing. The rates of electrochemical processes are strongly dependent on the potential, in fact exponential. The conventional approach to describing electrode kinetics in the absence of mass transfer limitations is the Butler–Volmer model:

$$j = j_0\left[\exp\left(\frac{-F\alpha\eta}{RT}\right) - \exp\left(\frac{(1-\alpha)F\eta}{RT}\right)\right] \quad [6]$$

where j_0 is the exchange current density, α is known as the transfer coefficient, and η is the overpotential or the difference between the applied potential and the equilibrium potential. The first term refers to the cathodic process and the second term refers to the anodic process. For irreversible electrochemical processes where the cathodic overpotential is large, the anodic component is negligible and the Butler–Volmer equation reduces to the Tafel equation:

$$\begin{aligned} \eta &= a + b\log j \\ a &= \frac{2.3RT}{\alpha F}\log j_0 \\ b &= -\frac{2.3RT}{\alpha F} \end{aligned} \quad [7]$$

A Tafel plot (log i versus η) is used to extract these kinetic parameters and glean insight toward the nature of the kinetic steps involved.

In describing the overpotential, the equilibrium potential E_{eq} is related to the concentration of the electroactive species by the Nernst equation, which for the reduction of a metal to its solid in an ideal solution is:

$$E_{eq} = E_0 + \frac{RT}{nF}\ln C \quad [8]$$

where E_0 is the standard potential.

1.10.1.2 Principles of Alloy Deposition

The performance (mechanical properties, corrosion resistance) of many electrodeposited materials can be greatly enhanced as a result of alloying. High-strength nickel can be made thermally stable with small amounts of manganese, a range of useful magnetic materials are possible with alloys of nickel and iron, and alloys of bismuth and tellurium possess superior thermoelectric properties. The principles of electrodepositing alloys and the broad range of alloys available are covered in several comprehensive references (Brenner 1963, Landolt 1994). A starting basis for understanding the relationship between electrolyte composition and resulting alloy content of the deposit is to consider the equilibrium potentials and relative concentrations of the metal ions. At first glance, metals whose equilibrium potentials fall close together can be codeposited to form an alloy. Alloy electrodeposition can be distinguished as normal codeposition when the resulting ratio of the metals in the alloy is that expected according to the equilibrium potentials and concentrations. Tin–lead alloys used in printed circuit boards as solderable coatings fall in this category (Jordan 2000). The equilibrium potentials are close (Pb = −0.126 V, Sn = −0.136 V) and the full range of

alloy composition is possible. Lead is a little more noble and will deposit slightly faster than tin, but for the most part the concentration of the electrolyte dictates the alloy content.

Metals whose equilibrium potentials differ significantly can still be made to codeposit by reducing the activity of the more noble metal. The classic example is Cu–Zn, where the equilibrium potentials are considerably different (Cu = +0.342, Zn = −0.762). In electrolytes of the simple salts, alloy deposition is impossible, as copper will deposit to the virtual exclusion of zinc. However, Cu–Zn alloys are readily plated using electrolytes where the copper species is complexed, typically as a cyanide.

Unfortunately, one of the most useful alloys for MEMS, Ni–Fe (and Ni–Co), falls in the category of anomalous codeposition. In this category of abnormal alloy electrodeposition, the less noble metal, iron, preferentially deposits and the alloy content does not prescribe to the usual equilibrium potential relationships (Ni = −0.257, Fe = −0.447). For this reason, the iron concentration in the bath is much lower than nickel and the process is highly sensitive to mass transport and mixing effects.

Another category of abnormal alloy deposition is induced codeposition, where one element is codeposited as a result of the catalytic activity or reduced overpotential of the alloy surface. Tungsten and molybdenum are examples of metals that can be electrodeposited as part of an alloy, but not as a pure metal, Ni–W being the example relevant to MEMS. Ni–W has many desirable properties including high hardness, improved corrosion and wear resistance, and thermal stability owing to the high melting point of tungsten. Historically, Ni–W has been difficult to process owing to the high temperatures (80–90°C) and high pH (8–11) required of the electrolyte. Recent work involving a sulfamate electrolyte has better enabled integration into a MEMS process flow (Slavcheva *et al.* 2005).

For the case of Ni–Mn (Ni = −0.257, Mn = −1.18), the manganese content is very low as expected, usually less than 1 wt.%. In fact, given the large difference in equilibrium potentials and the lower manganese concentrations in the electrolyte used (see **Table 2**), it is surprising that any manganese is codeposited. It has been argued that manganese is incorporated as a result of adsorption onto the nickel surface rather than a codeposition reaction (Atanassov and Schils 1999). This is consistent with the observed grain-refining effect that the manganese has on the resulting film.

1.10.1.3 Methods

Electroplating can be a simple laboratory exercise involving a beaker and a power supply or an elaborate operation with means for agitation, filtration, electric field shaping, temperature control, and multistep or pulsed current programs. As a matter of practicality, most industrial electroplating processes are galvanostatic, rather than potentiostatic. This obviates the need for a reference electrode and the variation in resistance that may occur as a result in subtle differences in cell configuration. The current may either be direct or pulsed. It is common practice for substrates to be immersed hot, that is with potential applied and current initiating immediately upon entry. This prevents any dissolution or deleterious oxidation of the seed by the electrolyte media.

1.10.1.3.1 Thickness uniformity

The most common issue confronted once the desired chemistry and metal properties are established is uniformity of the deposit across the plated area of the substrate. Although subsequent removal steps, such as polishing, can provide planarization, it is generally undesirable to have extreme variations in plating rate. The desired properties of the deposit, be they mechanical, electrical, or just cosmetic, vary with the current density and hence the deposition rate. An example of an extreme case, illustrated in **Figure 1**, demonstrates what can happen as deposition nonuniformity builds upon itself. If the plating surface is allowed to surpass the height of the mold or

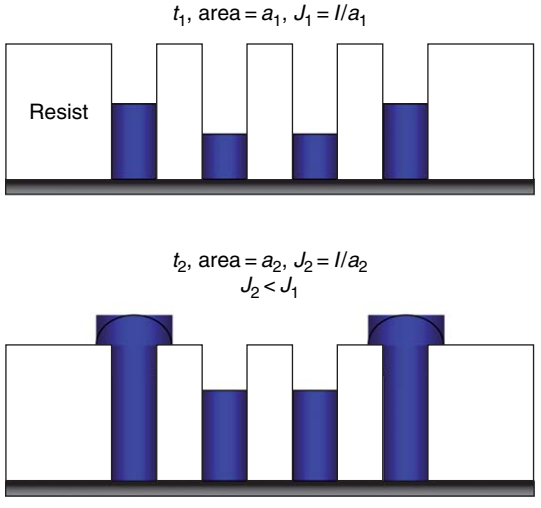

Figure 1 Overplating features increases surface area and reduces the overall current density, changing the properties of the deposit.

resist at any point, the plating area begins to increase and the current density drops, resulting in changing deposit properties for those features still filling. If the polarization resistance is low, the protruding overplated areas may attract a disproportionate amount of current and make it extremely difficult to fill the remaining underplated features.

There are several origins of nonuniformity, and there are usually several clever approaches that can be taken to address them. The first, described as the terminal effect results when the resistance of the metallization or seed layer is significant compared to other resistances such as conduction through the electrolyte or the charge-transfer process itself. Deposition rates are greater near the edges or points of the substrate where electrical contact is made. This can become an issue for large substrates and thin seed layers (such as copper Damascene plating on 300-mm-diameter substrates with sputtered copper seed layers <1000 Å thick). For most MEMS applications, a conductive metallization layer of a micron or so is sufficient to eliminate the problem. If not, the electrolyte can be made more resistive, for example, by reducing the sulfuric acid concentration in the case of copper plating. To describe the relative influence of these various resistances, a dimensionless Wagner number (Wa) is often employed

$$Wa = \frac{\mathrm{d}\eta/\mathrm{d}\mathcal{J}}{\rho_e L}$$

which in this case describes the relative influence of the polarization resistance, or the inherent resistance of the charge transfer reaction, to the electrical resistance of the electrolyte and ρ_e is the electrolyte resistivity, and L is a characteristic length for conduction. For $Wa \gg 1$, indicating that polarization resistance dominates, the current distribution is uniform and the secondary current distribution is said to predominate. For $Wa < 1$, the primary current distribution predominates, that is the current density is a result of the potential distribution of the cell.

In the cases where polarization resistance is relatively insignificant and the cell geometry dictates the potential field, numerous approaches have been used to improve the current density distribution. One way is to insert an insulating barrier at the cathode, or a cathode shield, to help shape the field lines and direct the current toward or away the center of the substrate. Another common approach is to add auxiliary features (known as a robber or current thief) at the edge of the substrate to absorb the nonuniformity intrinsic to any edge. Furthermore, sacrificial auxiliary features can be used to improve the area density, by provided isolated features of a pattern with neighboring areas. The size and placement of the auxiliary electrodes may vary as well: larger areas may be required at the substrate edge to direct current. Yet another approach is to provide multiple anodes, each with individual current or potential current to provide real time shaping of the current distribution. With even more complexity, the cathode itself can be divided into multiple current paths. Each approach has its own merits unique to the pattern and application, as well as level of complexity and as a result all are found in industrial practice.

1.10.1.3.2 Throwing power

Many of the early applications for patterned electrodeposition, particularly for through-hole plating of printed circuit board vias, were concerned with the ability to uniformly deposit within deep recesses. Electrolytes and conditions that could achieve this uniformity were deemed to have high throwing power. Hence the throwing power could be described as the ratio of the deposition rate at the furthermost point to the closest or top surface. In these cases, the conduction layer coating the walls of the vias provide a significant resistance. Organic additives that adsorb to the metal surface and increase the polarization increase the throwing power by reducing the impact of the electrolyte resistance, according to the relationships described above for the Wa. Other uniformity issues relevant to MEMS processing, including through thickness uniformity and variations associated with feature size, are covered in a following section.

1.10.1.3.3 Bubbles

With patterned substrates, particularly with thick resists (10–100 μm) and high aspect ratio structures, surface tension and wetting effects predominate. Generally, lithographically patterned substrates are dried in between processing steps and require wetting of the features to provide electrolyte to the conducting metal surface. Bubbles that become trapped within resist features during this initial wetting result in voids in the final metal, as the growing electroplating surface will envelope the bubble. Successful wetting is highly dependent on the geometry and aspect ratio of the features, in addition to the state of the metal seed layer and the hydrophobicity of the resist. If typical approaches such as rinsing or agitation are unsuccessful, extreme measures such as

evacuating the resist and immersing under vacuum can work for most cases. Bubbles can be formed as a result of incomplete wetting of the initially dry surface, or can be generated during plating as a result of side reactions like hydrogen reduction. Nickel electrodeposition, where the CE is usually less than 100%, can generate sufficient hydrogen to form bubbles. For this reason, the nickel electrolytes are either operated at elevated temperatures or contain a surfactant (sodium lauryl sulfate) to reduce the surface tension. Depending on the nature of the substrate, the initial stages of electroplating can be particularly prone to hydrogen generation. Initiating metal deposition onto the substrate may require an additional overpotential due to the fact that it is a different metal surface or that it possesses a thin oxide layer; the hydrogen overpotential itself may be reduced for the substrate metal, such as the case for nucleating nickel on copper.

1.10.1.3.4 Pulse plating

Certain situations in electroplating benefit from intermittently turning off the current (pulse plating) or intermittently reversing the current (pulse reverse plating) (Puippe and Leaman 1986). The net effect is to reduce the average current density. This allows temporarily depositing metal at high current densities that would become mass transport limited under DC conditions. The zero current portion of the pulse allows recovery of the metal concentration by diffusion. The pulsing frequency can vary from a few hundred megahertz (microsecond on/off times) to a several hertz (on/off times on the order of seconds). In general, the upper limit to the frequency is set by the capacitance of the electrical double layer. Pulse timing should be longer than the time required to charge or discharge this intrinsic electrode capacitance. As an estimate, for a typical double layer capacitance of $50\,\mu F\,cm^{-2}$, the charging time (in microseconds) is $17\,J^{-1}\,(A\,cm^{-2})$, and the discharge time is $120\,J^{-1}\,(A\,cm^{-2})$ (Puippe and Leaman 1986). The principal benefit most often associated with pulse plating is grain refinement. Electrodeposition is a crystallization process involving the dynamic competition between the nucleation of new crystals and the growth of existing ones. Higher overpotentials favor nucleation over growth. However, at sufficiently high overpotentials, or current densities, the metal ion concentration can be depleted in the vicinity of the cathode. Copper with fine grains and remarkably high strength has been made in this way with extreme values of the pulsing parameters (Lu *et al.* 2004). For other applications, pulsing is simply a means to overcome diffusion limitations, such as the filling of high aspect ratio alumina pores to create nanowires (Nielsch *et al.* 2000).

1.10.1.3.5 Multilevel microfabrication with electrodeposition

Electrodeposition can also be used to fabricate multiple level structures by combining a sacrificial metal with an electroplated pattern. **Figure 2** illustrates the concept, first demonstrated by Guckel and coworkers (Guckel 1993, Massoud-Ansari *et al.* 1996). A first

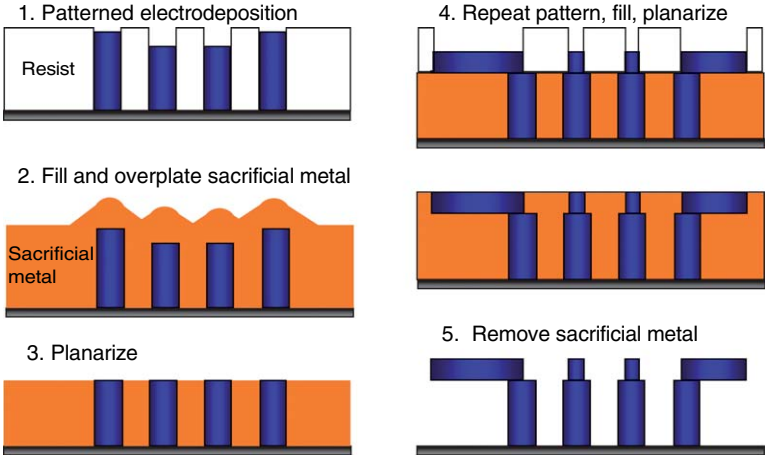

Figure 2 Multilevel structure fabrication by electrodeposition. Step 1: lithographically pattern resist on conductive substrate and electroplate structural metal. Step 2: remove resist and electroplate sacrificial metal such as copper to fill and cover structural elements. Step 3: planarize to desired thickness of the structural metal. Step 4: repeat steps 1–3, aligning to the previous level. Step 5: selectively etch the sacrificial metal to provide multilayer elements attached to the substrate.

metal, usually nickel, is electroplated through resist and the resist removed. A second metal covers the patterned metal deposit, by electrodeposition. The second metal such as silver or copper is one that can be etched selectively relative to the first. The sacrificial metal performs two functions. The first is to provide rigid support to the structures during planarization. The second function is to provide a conductive base to initiate electrodeposition of the subsequent level. This eliminates the restriction of plating on the structure exclusively and enables the creation more complicated by nearly 3D components.

1.10.1.4 Patterned Electrodeposition

The science and process sensitivities of electrodeposition through thin resist used to produce metallic conducting interconnects, packaging and contacts for the microelectronics industry have been much discussed (Dukovic 1994). In contrast, electrodeposition through thick resist for deep, high aspect ratio LIGA features has received relatively little attention (although we note that one study involving design rules for the LIGA electrodeposition step has recently become available (Drese 2004). In surveying the literature where electrodeposition through patterned photoresist is discussed, it is evident that the microelectronics industry has devoted a significant amount of experimental and modeling resources to understanding through-mask electrodeposition (more detailed reviews of these developments are available (Datta and Landolt 2000, Dukovic 1994). A central theme of the prior literature is the classification of three length scales over which electrochemical processes occur; the first, the workpiece scale, involves the distribution of current over the scale of the substrate or wafer; the second, pattern scale, involves the distribution of current between features defined in the insulating photoresist; the third, the feature scale, involves the distribution of current to and within an individual opening or feature in the resist. These three scales are depicted in **Figure 3** after DeBecker and West (West 1996). As will be discussed later, the principles governing the deposition of a metal structure or film having uniform thickness and properties over all these scales (usually desired for all electrodeposition processes) are largely the same, regardless of the final application. In terms of attaining uniformity across a substrate, the prior literature regarding the workpiece and pattern scales for electrodeposition

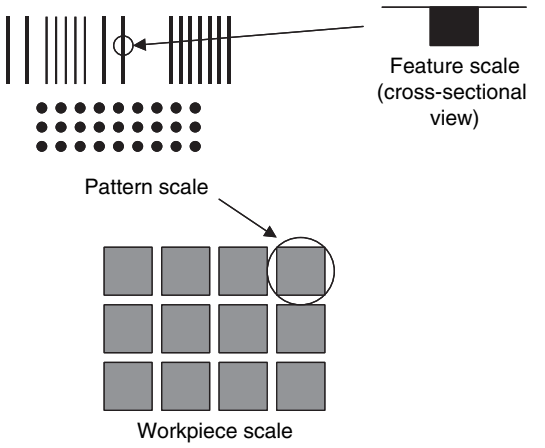

Figure 3 Schematic illustration of the workpiece, pattern, and feature scales, redrawn from a similar graphic from DeBecker and West. Groups of features are distributed across the substrate; these groups consist of a patterned array of features. The feature scale involves a single feature and its internal uniformity.

through thin resist is directly applicable to electrodeposition through thick resist.

The important difference regarding metal deposition through thin and thick resist comes when through-thickness uniformity is considered; as the electrodeposited metal films for microelectronics are usually only a few to several microns in thickness, appreciable through thickness variations in film structure do not usually occur as the thickness is so small. Moreover, any small microstructural deviation that may be present through the film thickness does not usually critically impact the function of the electrodeposited metal film in microelectronics. But in contrast to the thin films employed in microelectronics, large variations in deposit microstructure may occur over the hundreds of microns that comprise the through-mask electrodeposited thick films in LIGA. Because most of the issues in attaining uniformity across the substrate are similar to those in microelectronics, we will rather focus on a discussion on attaining through-thickness uniformity in structures electrodeposited through thick resist, a challenging aspect unique to LIGA. Besides differences in resist and metal thicknesses, another major difference between films electrodeposited for microelectronics and microsystem applications lies in the choice of materials. In microelectronics, the metal films are serving as conductors or contacts; hence, materials such as copper, gold, and lead–tin alloys (more recently lead-free alternatives are under development) have attractive physical properties

and are widely employed. In microsystems, the thick metal structures are typically serving as components in some mechanical device or as a replication mold; the mechanical properties are thus of most interest in these situations. Electrodeposited nickel has a long history of use as a structural material as its mechanical properties may be tailored by the use of alloying elements and electrolyte bath additives (both organic and inorganic) (Marti and Lanza 1969). Depending on deposition conditions and chemistries, Ni may be electrodeposited with low stress, making thick films possible. The generally good corrosion resistance of electrodeposited Ni also makes it attractive for mechanical applications in a wide variety of environments. The material properties of Ni and Ni alloys will be discussed in more detail later in the chapter. In comparing electrodeposition processes for thin and thick resists, we will keep in mind that the materials that are deposited into these lithographic molds may have very different deposition characteristics as well.

1.10.1.4.1 Workpiece and pattern scale effects

In prior treatments of through-mask electrodeposition, the first length scale often identified is the workpiece scale; this is usually the characteristic length of the substrate (or wafer) itself onto which resist defining the desired structures has been applied. Variations in the local current density typically occur over the workpiece scale. The cell geometry, the size of the substrate, and other deposition parameters dictate the uniformity across the substrate; the degree of this uniformity may be described by the Wagner number (*Wa*), a dimensionless parameter that has been discussed in more detail previously. Generally speaking, if no measures are taken to improve the current distribution across the wafer, regions close to the edge will have a locally higher current density than areas near the center of the substrate.

A few different approaches may be used to render the current distribution across the wafer more uniform. The appropriate placement of insulating shields with respect to the wafer may result in a more uniform current distribution. The use of auxiliary electrodes (also known as thief electrodes) in minimizing variations across the workpiece has been discussed previously (Mehdizadeh *et al.* 1990). For example, another cathode placed around the workpiece (as a type of surrounding frame) may improve the workpiece current distribution significantly. In industrial plating tools, all these aspects are carefully considered in optimizing the wafer scale uniformity. Obviously, as a large number of wafers are typically run under fixed conditions in the microelectronics industry, a fair amount of time and effort is spent in finding the optimal cell geometry and deposition conditions. These approaches for homogenizing the wafer scale uniformity are directly applicable to electrodeposition through thick resist in LIGA, and have in some cases been adopted.

The second length scale is referred to as the pattern scale. The relative amounts of exposed active metal and insulating photoresist may vary across the substrate due to the geometry and layout of the pattern defining the structures to be electrodeposited. Thus, the active area density varies depending on essentially the distribution of the insulating resist material. This leads to variations in the local current density (the deposition rate) depending on the local pattern geometry in the resist. Mehdizadeh *et al.* (1992) studied this problem for electrodeposition through photoresist having various pattern densities. West and coworkers considered the effect of patterning on multiple electrodes of disks and lines. These and other studies may be drawn upon in designing layouts where pattern scale effects are minimized. In our experience, LIGA pattern layouts that consist of an array of uniformly spaced features having similar dimensions are not commonly encountered; instead, patterns tend to consist of fine features (dense resist areas) located in close proximity to large, open areas of exposed seed metal (defining a wide, low aspect ratio feature). Thus, pattern scale effects must be managed on a fairly routine basis. Although it may not be possible to alter the particular part geometry and size (necessary for the device function), some discretion may be exercised in distributing the features in the resist defining the part geometry so as to mitigate pattern scale effects. Moreover, sacrificial features (openings in the resist) may be added to the pattern to break up areas that have long runs of uninterrupted insulating resist, resulting in a more uniform active area density distribution. This practice of inserting sacrificial moats or frames around features where dimensional fidelity is critical has been studied with regard to minimizing dimensional errors due to polymethylmethacrylate (PMMA) swelling and thermal expansion after immersion in the electroplating bath (Griffiths *et al.* 2004). It is somewhat fortuitous the same measures that aid in minimizing these dimensional errors in LIGA also may help in rendering the pattern scale current

distribution more uniform. Mehdizadeh *et al.* have discussed the possibility of carefully considering the wafer and pattern scale current distribution and arranging features in the resist across the workpiece so as to attain a more balanced current distribution. Even when detailed current distribution models are unavailable, past experience can be a useful guide in judiciously arranging the part layout to avoid uneven distributions of current at the pattern scale.

1.10.1.4.2 Feature scale effects

As mentioned previously, the similarity between microelectronics processing and LIGA through-mask electrodeposition diminishes as one moves from the workpiece and pattern to the feature scale. The principal reason for this is the large resist thicknesses typically employed for X-ray lithography. As pointed out by Dukovic, at the feature scale, the dimensions of the lithographic features are usually small enough (microns) that electrical field effects become less important, and the influence of the concentration field of the reacting species grows in determining the feature scale current distribution. Because mixing is limited inside the feature due to the presence of the surrounding resist material, the concentration of a reacting species may vary with position within the feature. Another aspect that must be considered for both thin and thick resists is that as deposition proceeds, the feature geometry changes as the deposited metal fills the feature. Generally speaking, obtaining good mixing inside lithographic features becomes more difficult with increasing resist thickness. When the electrodeposition reaction involves just a single metal cation, variations in its concentration inside the feature typically result in variations in the local rate of deposition and therefore deposit thickness (Mehdizadeh *et al.* 1993). The deposition characteristics of copper, gold, and tin alloys through relatively thin resists (less than 20 μm) for bump structures have been considered with attention to the thickness distribution of the deposit within a single feature (Hayashi *et al.* 2001, Kim and Ritzdorf 2003, Kondo *et al.* 1996, Watanabe *et al.* 1999). It is desirable that these bump structures have good as-plated uniformity for subsequent packaging processing. Another example of an important feature scale electrodeposition problem is the case of copper Damascene electrodeposition for copper interconnects. For this process, proprietary electrolyte bath additives and active feature sidewalls lead to more complicated feature filling behavior, despite the fact that only a single elemental species is being deposited. In the case of electrodeposition through thick resist for LIGA, the importance of the feature scale is not its influence on the local deposit thickness uniformity (the wafer is planarized after plating, removing thickness variations across the wafer at all scales). Rather, it is the more serious issue of poor mixing in the mold features themselves due to their small widths and large heights. This has broad implications with respect to the potential for variations in the concentrations of electrolyte species that may, in turn, impact the local deposit composition, morphology, and properties. For example, if additives or other metal species are present as alloying elements, profound changes may occur through the thickness owing to the constantly changing feature geometry that accompanies the metal growth. If the concentration of one of these species is close to zero at the feature bottom (e.g., due to its rapid incorporation into the deposit), large changes in the flux of this species will occur as the deposit grows and the diffusion length from the bulk electrolyte shortens. The resulting nonuniform deposit morphology or alloy composition may be unacceptable for some applications. The electrodeposition of the NiCo and NiMn systems and the resulting feature scale uniformity will be contrasted to demonstrate the importance of transport into LIGA features later in the chapter.

Interesting experiments involving the feature scale were carried out by Leyendecker *et al.* (1994). These authors studied the effect of thick photoresist on mass transport and on the pH within a LIGA feature using special electrodes. In the first series of experiments, a rotating disk electrode masked by an insulating patterned polymer layer of various thicknesses and feature sizes is employed to study a model redox reaction occurring under transport control. The aqueous electrolyte consists of 2 mM potassium ferro- and ferricyanide each in 1 M potassium chloride at 25°C. Results of their experiments are reproduced in **Figure 4**; although various geometries were investigated, they present results for a constant hole diameter of 200 μm and resist heights of 100, 200, and 500 μm (in addition to an unmasked electrode).

Another series of experiments relevant to the feature scale in LIGA involving transport limitations is reported (Griffiths *et al.* 1998). They used a commercial Ni sulfamate electrolyte to deposit Ni into features drilled into PMMA. A single piece of Cu foil attached to one side of the PMMA acted as the substrate, from which the deposited Ni structures

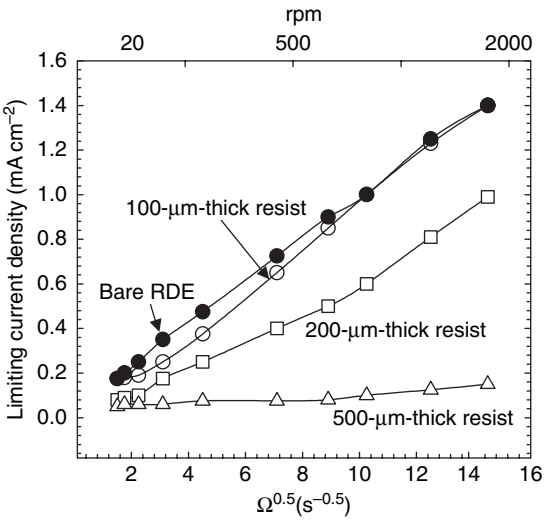

Figure 4 Limiting current densities for ferri–ferro cyanide redox couple on bare and patterned rotating disk electrodes adapted from Leyendecker *et al.* (1994). Feature hole diameter is 200 μm. The presence of the resist has a large effect on the transport of species to the feature bottom, even for an aspect ratio of one. Solid points are the bare rotating disk electrode, while the hollow points are electrodes patterned with resists of various thicknesses as indicated. (Source: Reprinted from *Electrochim. Acta*, **39**, Leyendecker K *et al*., New microelectrodes for the investigation of the electroforming of LIGA microstructures, 1139, Copyright (1994), with permission from Elsevier.)

could be removed for weighing in the determination of the CE. Current densities ranged from 1.1 to 108 mA cm^{-2} The drilled holes had diameters of 1.7, 3.2, and 6.4 mm and depths from 17 to 42 mm. They calculated the Sherwood number (the ratio between the measured current to the diffusion-limited current) for each case. The experimental results are surprising in that the Sherwood numbers are all between 10 and 100, indicating a much larger deposition current than expected based upon the diffusion-limited case.

The authors explain the unexpectedly high currents as resulting from enhanced transport of the reacting metal ion due to natural convection in the feature driven by its depletion at the substrate. This hypothesis is further supported by the fact that when the experimental cell was inverted, the measured currents were an order of magnitude less than with the deposition surface facing up. These authors go on to demonstrate by numerical modeling that flow across the top of the features cannot support the transport of the reacting metal ions at the observed rates, and that instead buoyancy-driven flows are probably important in allowing such high deposition rates. Nilson and Griffiths (2003) study natural convection in small features with respect to LIGA electrodeposition. They find that the relative importance of natural convection depends on the feature geometry and the inclination of the substrate. The authors conclude that some mixing from natural convection is expected to occur in features having aspect ratios less than 1.2, 6.6, and 37 for resist thicknesses of 0.1, 1.0, and 10 mm, respectively. Thus, natural convection becomes important for a wider range of feature aspect ratios as the resist thickness increases. Because resist thicknesses in microelectronics are usually only tens of microns or less, the importance of convective flow had not been widely discussed until electrodeposition into deep LIGA features was considered. It is interesting to contrast the findings of Leyendecker *et al.*, discussed at the beginning of this section, with those of Griffiths *et al.* In the former case, the insulating PMMA mask was shown to have strongly diminished mixing, resulting in lower transport rates of the reacting ions, while in the latter case, buoyancy-driven transport rates into deep high aspect ratio features higher than those expected from pure diffusion control were observed. Because Leyendecker *et al.* used a redox couple to measure transport rates through microstructured electrodes, they were not able to benefit from potential buoyancy-driven flows induced by the consumption of metal ions at the feature bottom.

Another series of studies focusing on feature scale uniformity in LIGA was carried out by Schwartz and coworkers (Leith and Schwartz 1999a). Leith *et al* considered the electrodeposition of NiFe at 23°C from sulfamate–chloride chemistries having various ratios of Ni to Fe electrolyte loadings. They pointed out that the plating characteristics of an electrolyte must be carefully considered before employing it for through-mask electrodeposition using thick resist. They found that electrolytes having less dissolved iron (e.g., 20:1 Ni^{2+}:Fe^{2+} as opposed to 10:1 and 5:1 also considered in their study) are less sensitive to mixing variations at relatively high current densities, suggesting that they would be more suitable for the electrodeposition of LIGA structures. Leith and Schwartz (1999b) also describe a cell designed to maximize workpiece and pattern scale uniformity, using the NiFe system (as it is a challenging system for uniformity) to demonstrate good uniformity across the wafer. The through thickness uniformity was not investigated in this study. In another article, Wang *et al.* (2002) used an electrolyte with a

10:l Ni^{2+}:Fe^{2+} loading (where the deposited NiFe alloy composition is more sensitive to mixing) to study convective–diffusion conditions during the through-mask deposition of LIGA structures. They term the approach process archaeology as the plated structure was planarized to half its deposited thickness for compositional analysis via energy-dispersive X-ray analysis. By observing in plan view the planarized structures, regions in the feature where locally high degrees of mixing occur could be easily identified as the Fe content as the alloy increases with mixing. In this case, the authors were using the transport-sensitive deposition kinetics of the Fe as a type of tracer tool to study the mixing within small cavities such as LIGA resist features. Another group of authors also considered the NiFe system to focus on the feature scale uniformity of through-mask deposited LIGA structures. Thommes *et al.* used a sulfate-based NiFe electrolyte at 50°C with a Ni^{2+}:Fe^{2+} ratio of about 12:1 to deposit NiFe structures at 5 mA cm^{-2} with good through-thickness uniformity. **Figure 5**, reproduced from their data, shows the compositional behavior of the deposition system using a rotating disk electrode. It is clear from **Figure 5** that for low current densities the electrode rotation rate does not influence the deposited alloy composition, suggesting that under these conditions the alloy composition is not greatly influenced by the amount of mixing. This relative insensitivity to mixing would appear promising for the feature scale uniformity of LIGA NiFe structures.

The suitability of the authors' deposition conditions for the electrodeposition of uniform high aspect ratio NiFe microstructures is evidenced by the through-thickness compositional data shown in **Figure 6**. For a resist thickness of 180 μm and a feature linewidth of 8 μm (aspect ratio 22.5), the authors obtain very good NiFe alloy uniformity throughout the entire structure thickness using a deposition current density of 5 mA cm^{-2}. Through-thickness uniformity suffers at higher deposition current densities. **Figure 6** also shows experimental results for deposition at 14 mA cm^{-2} using the same feature geometry. The Fe content increases through the deposit as the top PMMA surface is approached,

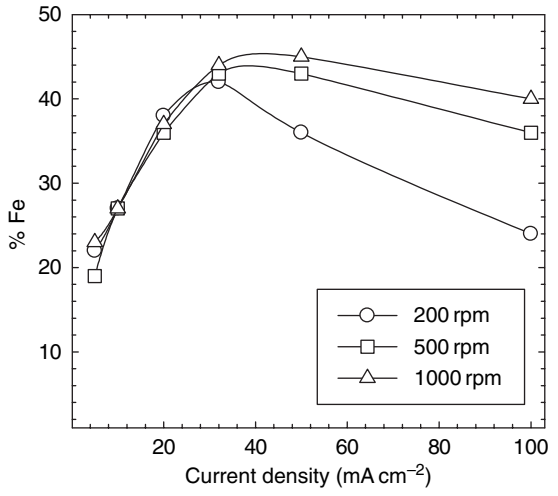

Figure 5 Electrodeposited NiFE alloy composition dependence on deposition conditions, for conditions given by and replotted from Thommes *et al.* (1994). The relative compositional insensitivity at low current densities suggests that the system may be a appropriate for the electrodeposition of uniform, high aspect ratio structures. (Source: Thommes A, Stark W, Leyendecker K, Bacher W, Liebscher H, Ilmenau C 1994 LIGA microstructures from a NiFe alloy: Preparation by electroforming and their magnetic properties. In: Romankiw L T, Herman D A Jr. (eds.) *Proc. 3rd Int. Symp. Magnetic Materials, Processes, and Devices PV 94–6*; reproduced with permission from the Electrochemical Society, Inc.)

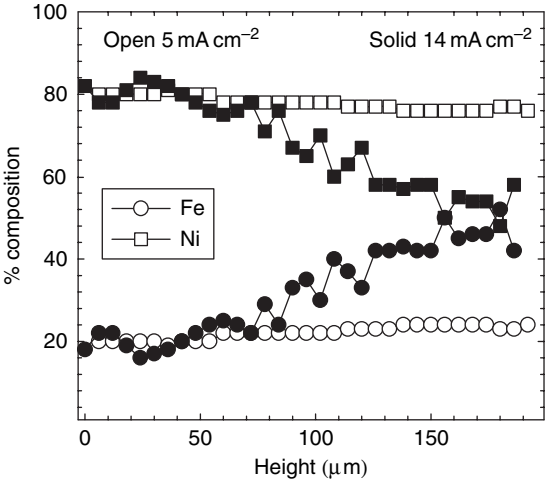

Figure 6 Electrodeposited NiFE alloy composition through-thickness uniformity replotted from Thommes *et al.* (1994). The structure width is 8 μm and its height is 180 μm. Open points are for deposition at 5 mA cm^{-2}, while the solid points are at 14 mA cm^{-2}. Deposition at the lower current density (where composition was shown to be less sensitive to mixing) leads to uniform alloy content through the structure thickness, as compared to 14 mA cm^{-2}. (Source: Thommes A, Stark W, Leyendecker K, Bacher W, Liebscher H, Ilmenau C 1994 LIGA microstructures from a NiFe alloy: Preparation by electroforming and their magnetic properties. In: Romankiw L T, Herman D A Jr. (eds.) *Proc. 3rd Int. Symp. Magnetic Materials, Processes, and Devices PV 94–6*; reproduced with permission from the Electrochemical Society, Inc.)

varying from about 20–50% across the thickness. Though not shown here, the authors filled cylindrical features with a diameter of 5 μm and a height of 90 μm depositing NiFe at 5 mA cm^{-2}. They show similarly good results as for the structure in **Figure 6** deposited at the same current density. The electrodeposition process outlined by Thommes *et al.* (1994) has been shown to be capable of producing high aspect ratio structures with good alloy through-thickness compositional uniformity. To the authors' knowledge, few other studies exist of alloy deposition through thick resist where the feature scale uniformity is considered in such detail.

An aspect that is likely important in explaining the good results obtained by these authors is the bath temperature; Brenner has discussed the fact that NiFe electrodeposition becomes less anomalous (and hence less transport sensitive) with increasing bath temperature. Andricacos and Romankiw (1993) also discuss the importance of bath temperature as well as other process variables on electrodeposited magnetic alloy composition. Given the limitations in obtaining good mixing in small LIGA features, it is not surprising that achieving good feature scale uniformity for anomalous deposition systems (such as NiFe) is challenging for geometries encountered in LIGA electrodeposition. New techniques are being employed for studying the electrodeposition reaction inside of small features like those fabricated by the LIGA process; for example, special microelectrodes and chronoamperometric methods have been developed to measure the local metal cation concentrations during alloy electrodeposition inside small cavities (Kuepper and Schultze 1997). In the study mentioned previously, concentration variations inside of a cavity where a NiCu alloy is being electrodeposited are investigated; they also observe the formation of a Ni hydroxide and nickel oxide at the deposition surface during electrodeposition of the NiCu alloy from a sulfate electrolyte with potassium nitrate as supporting electrolyte.

1.10.1.4.3 Summary: Uniformity at the workpiece, pattern, and feature scales in LIGA

The detailed study of Thommes *et al.* is a good example of the considerable effort required to develop an electrodeposition process capable of producing uniform structures at the feature scale for geometries encountered in LIGA electrodeposition. When mixing effects are important (as often the case in Ni alloy deposition), this is especially difficult. After some confidence in the feature scale uniformity is attained for a given chemistry and set of deposition conditions, the uniformity at the pattern and workpiece scales must still be addressed as well. This makes LIGA through-mask electrodeposition in some ways more challenging than electrodeposition through thin resist, as the feature scale adds literally another dimension to the problem of obtaining uniformity across multiple length scales. Considerable time and effort may be saved by first characterizing the electrodeposition kinetics and the importance of mass transport for an electrodeposition process before attempting to apply it to LIGA fabrication (especially in the case of an alloy system). If a good understanding of kinetics, transport, and alloy composition is in hand, electrolytes and deposition parameters suitable for deposition through thick resist may be chosen more prudently.

1.10.2 Properties of Electrodeposits

1.10.2.1 Internal Stress

For many electrodeposited metals, as-deposited internal stresses can be severe enough to deform the substrate or cause catastrophic detachment of the metal film. The severity of the effect depends on the metal, the electrodeposition process, the thickness, and the geometry of the plated structure. This stress is not to be confused with the stresses that originate from the substrate thermal expansion mismatch during subsequent elevated temperature processing (Keller *et al.* 1999). If the stress is tensile, the metal film will peel upward at corners and edges where discontinuities create a localized increase in force. If the stress is compressive, the film can buckle or blister. The degree of internal stress will limit the ultimate thickness of the plated film before it fails by either delamination from the substrate or cracks internally. For this reason, hard, stressed electrodeposits of Cr, Pt, and Rh are usually limited to a few microns. Copper and soft gold are relatively low stress as-deposited and can be plated hundreds of microns thick.

Several methods are available to measure the stress including the measurement of wafer or substrate bow by interferometry or capacitance, as well as *in situ* instruments like the spiral contractometer. In the bent strip method, the simplest technique for measuring stress, thin copper strips are coated with an insulating film on one side. As the thickness of the film builds on the copper surface, the strip deflects

according to the nature and magnitude of the internal stress. The amount of curvature depends on the properties of the deposit, the thickness, and the mechanical properties of the substrate. If the thickness of the substrate, t_s, is much thicker than the deposit, t_d, then the Stoney equation can be used to relate the radius of curvature, R, to the stress, σ:

$$\frac{Et_s^2}{6(1-v)t_d R}$$

where E and v are the Young's modulus and Poisson ratio of the substrate, respectively, and the substrate is initially flat (Stoney 1909).

Stress is a complicated function of all the plating parameters and is very much process dependent. For example, high-strength alloys of nickel with manganese iron or cobalt are highly stressed in tensile. High-strength nickel produced from organic grain refining agents is often stressed in compression. Varying the intrinsic stress through thickness has been used to intentionally induce curvature in gold electroplated beams and flexures (Chinthakindi *et al.* 2002).

1.10.2.2 Adhesion

For many multilayer processes encountered in MEMS and semiconductor processing, adhesion of the metal deposit to the substrate and pattern are critical to the success of the fabrication. Numerous forces can be applied to the metal interface that result in failure, including the internal stress of the deposit itself, stresses generated as a result of the coefficient of thermal expansion (CTE) mismatch during thermal processes, and stresses applied during the subsequent polishing of the metal such as that exerted by chemical–mechanical polishing (CMP) in the copper Damascene process or by grinding of excess deposit in the LIGA process.

Metals that readily form a native oxide, such as aluminum, or that form a chemically resistant oxide, such as nickel, prove to be difficult substrates for achieving good adhesion of electrodeposits. Standard methods are available and usually employ a series of acid treatments followed by a strike layer or a thin layer of metal generated in a specially adapted electrolyte. The Woods Nickel strike is such an example, consisting of 125 ml l^{-1} of HCl and 240 g l^{-1} of $NiCl_2$ operated at 50 mA cm^{-2} for a few minutes time (Lowenheim 1995).

While no universal method exists for determining an absolute value of adhesion, several methods are adequate for relative evaluations. Methods include the peel test, shear test, ring shear test (Dini 1993, Lowenheim 1995). The measurement of peel strength is readily adapted to thin films, but is highly dependent on strength and ductility of the metal film and requires large areas (Klingenmaier and Dobrash 1976). Other methods are purely qualitative, such as those to evaluate gold coatings: the coated components are subjected to elevated temperatures and the presence of blisters indicates poor adhesion. Instruments that measure the maximum shear force at failure provide a more quantitative measure of the adhesion. Thick-resist generated structures are plated onto a coating or substrate and provided the failure occurs at the intended interface, the adhesion can be described. The shortcoming of this approach is that the bulk strength of the substrate may be weaker than the interfacial strength, in which case only a minimum strength can be assigned.

1.10.2.2.1 Electroplating on aluminum

Aluminum is a notoriously difficult metal on which to electroplate, both for initiating metal film growth and for achieving sufficient adhesion. Despite this, successful methods have evolved and illustrate some of the principles of achieving adhesion of a electrodeposited film to its substrate. Aluminum is a common metal available to MEMS fabrication: it has low electrical resistivity, a self-passivating oxide, and it is easily patterned by wet etchants. Recently, aluminum thin films have been implemented as a substrate material in the X-ray lithographic LIGA process in order to provide better feature resolution and PMMA resist adhesion after exposure (Griffiths *et al.* 2005).

As with most electroplated metal adhesion issues, the critical factor is removal of a surface oxide layer. For aluminum, this native oxide can develop rather quickly. A established method is to use an intermediate layer of a displacement plated metal, such as zinc or tin. Employed in a caustic electrolyte to prevent oxide formation on the aluminum, the zinc or tin displaces the aluminum owing to their more noble electrochemical potential. Furthermore, optimal zinc films are obtained by a double immersion process whereby the first zinc layer is removed by a short nitric acid etch and the subsequent second zinc immersion has improved nucleation density and uniformity. A thin copper layer is often plated onto the zinc to provide a good base for subsequent metal deposition and to protect the zinc from more corrosive plating electrolytes.

Another common approach is to create a porous surface oxide by anodizing the aluminum. Recent use of the technique has focused on producing ordered arrays of directional nanopores. With more aggressive conditions such as stronger acids and higher temperatures, porosity is increased and it is this porosity that provides the physical interlocking for good adhesion. With respect to providing a base for electrodeposited metals, certain conditions for the anodization are preferred. Although sulfuric acid is common for producing hard anodic coatings, phosphoric acid anodized aluminum is optimal for electroplating due to the larger pores that are produced. Higher anodizing potentials also produce larger pores that correlate well with better adhesion. The alloy content of the aluminum also has an important role to play. It was found that aluminum with small amounts of copper and silicon (1% of each, a common alloy used for integrated circuits) greatly facilitated subsequent adhesion of electroplated copper onto the anodized surface (Griffiths *et al.* 2005).

1.10.2.3 Crystal Orientation and Microstructure

The polycrystalline nature of most electrodeposits render their properties highly sensitive to the nature of the microstructure, that is the size distribution of the individual crystals, or grains, their boundaries, and their lattice orientation. Many properties, including strength, wear resistance, corrosion resistance, etch rates, magnetic properties, are strongly dependent on the texture or crystal orientation of the electrodeposit, which in turn is dependent on all of the processing variables. For nickel electrodeposits, a fiber-oriented growth mode with a preferred orientation in the <110> direction is associated with high-strength deposits, and can be influenced by pH and current density (Amblard *et al.* 1979). The influence of the substrate is generally negligible once the deposit exceeds a thickness of a few microns (Dini 1993).

1.10.2.4 Mechanical Properties of Electrodeposits

As coatings, the mechanical properties of electrodeposits, particularly the strength and hardness, have been tailored to achieve high wear resistance. A wealth of historical mechanical properties and the respective electrodeposition processes are available (Safranek 1986). As the structural material in micromechanical elements, such as spring flexure arms, the electrodeposit needs to resist plastic or permanent deformation, and hence requires high strength. In addition, the mechanical properties pertinent to spring behavior, such as the stiffness or modulus, need to be precisely characterized. **Table 1** lists a range of strengths and modulii for various electrodeposited metals. These values are provided as an estimate: variation depending upon exact processing variables is expected. The most commonly used alloys for microsystem springs are those based on nickel, owing to the superior strength.

1.10.2.4.1 Tensile test

The traditional method for determining the strength and modulus of a metal is through a tensile test, in which a precisely shaped specimen is pulled in tension until failure. This produces the stress–strain curve for which the modulus, yield strength, ultimate tensile strength, and strain to failure can be determined. This approach can be applied to electrodeposits in one of two ways. The first is to electroplate a sheet of the desired electrodeposit to sufficient thickness, and then form the shape required through machining, stamping, or wire electrodischarge machining. The second approach is to lithographically define the tensile mold, provided

Table 1 Mechanical properties of common electrodeposited metals

	Modulus (GPa)	*Yield strength (MPa)*	*Vickers hardness*
Nickel, course grained	160	300–600	200–300
Nickel, organic additive refined	180	800–1200	400–600
Ni–1% Mn	190	600–1200	400–600
Ni–35% Co	200	600–1100	400–600
Gold	70	100	50–100
Gold – hard	70	200	150–200
Copper	11	300–400	50–200

the resist is thick enough (a few hundred micrometers is needed for a conventional tester). This latter approach captures the effects associated with feature scale transport, but suffers from long processing times and specialized lithography methods. Some specialized instruments have been developed specifically for thin-film tensile testing, but the approaches are not standard.

1.10.2.4.2 Hardness

Another gauge for the strength of an electrodeposited metal is its hardness, as determined by indenting a surface with a pyramidal diamond tip. For many metals, an excellent correlation between the yield strength and the hardness can be achieved. For a given load, the surface deforms plastically and the size of the remaining indentation is used to characterize the strength of the material. The resulting hardness number has been correlated to the flow stress, or yield strength, for numerous metals, although the exact relationship is unique for each material. A number of scales exist for the hardness, including Vickers, Knoop, Rockwell, and Brinell. The Vickers hardness is defined as

$$H = 1854\frac{P}{a^2}$$

where a is the length of the indent diagonal in microns and P is the load in grams-force. For thin films and coatings, a microhardness test is commonly used, where the applied load is small enough to reduce the indent size far below the thickness of the deposit. So for a 500 VHN_{25} nickel electrodeposit and a 25-g load, the indent diagonal is 9.6 μm, setting the minimum feature size for measurement around 40 μm. A requirement for the microhardness test is that the penetration depth is less than a third of the total depth of the material; otherwise, the substrate will influence the measurement. Furthermore, the surface being indented must be optically flat to provide an accurate measurement. The granularity of as-deposited films makes taking a reliable measurement without polishing difficult. As a result, samples must be carefully prepared to provide rigid backing, depth of material, and a smooth surface. Nevertheless, the technique is straightforward and commonly used to characterize electrodeposited metals.

1.10.2.4.3 Bulge test

Yet another technique for measuring these mechanical properties of thin films is the bulge test, in which the deflection of a membrane under pressure provides a measure of stress and strain, according to:

$$\sigma = \frac{2Pw^2}{bt}$$

where the stress is related to the pressure P, the width of the membrane w, the center deflection b, and the film thickness t (Xiang *et al.* 2002). And,

$$\varepsilon = \varepsilon_0 + \frac{b^2}{6w^2}$$

where ε is the strain and ε_0 the residual strain.

1.10.2.4.4 Origins of strength

It has been well documented that a principal source of strengthening in electrodeposits is the high concentration of grain boundaries, where the Hall–Petch relation correlates the strength to the grain size:

$$\sigma = \sigma_0 + Kd^{-1/2}$$

where σ can be the flow stress or microhardness and d is the grain diameter. Li and Ebrahimi (2003) have examined the Hall–Petch relation for a number of nanocrystalline nickel and nickel alloy electrodeposits.

1.10.2.5 Thermal Stability

For many microsystem applications, fabricated components will have an elevated temperature of operation or must retain their performance after being subjected to elevated temperatures. Unfortunately, for many electrolytic metals, the very nature of the deposit that renders it useful (fine grain size for high strength in the case of nickel, or fine grain size for bright films in the case of copper and gold) also produces a less stable microstructure. The higher density of grain boundaries and lattice defects provide a higher energy state of the metal, for which modest increases in temperature can activate modifications to the microstructure. In some cases, changes to the microstructure such as recrystallization and grain growth can cause the electrodeposit to lose its most desirable properties.

For Damascene copper interconnects however, recrystallization is desired in order to reduce the electrical resistivity and render the copper stable toward further high-temperature processing (Harper *et al.* 1999). Recrystallization manifests itself by an approximately 20% decrease in electrical

resistivity from the as-deposited state. Copper films prepared by electrodeposition are known to recrystallize easily at temperatures as low as room temperature. This self-annealing process is highly dependent on the deposition conditions (Perez-Prado and Vlassak 2002).

For nickel films, it is desired to preserve the fine-grained microstructure in order retain high-strength material. Pure nickel electrodeposits are thermally unstable, manifesting grain growth and texture evolution commencing near 300°C (Czerwinksi and Szpunar 2000). Thuvander *et al.* (2001) found the onset of grain growth for nanocrystalline electrodeposited Ni to be as low as 220°C; the onset for a Ni–Fe (50%) alloy was found to be near 400°C. For a Ni–Fe (20%) electrodeposit, Li and Ebrahimi (2003) found rapid grain growth to commence near 300°C, and the hardness falling by 50% with an annealing temperature of 400°C. Ni–W alloys have been shown to possess better thermal stability. Although the hardness was not characterized, Choi *et al.* (2003) demonstrated that a nanocrystalline electrodeposited Ni–W (20%) was microstructurally preserved up to 400°C, with good stability even at 700°C. Ni–Mn (1%) alloys have also demonstrated remarkable thermal stability, with high strengths and a fine-grained microstructure preserved with heat treatments up to 600°C (Talin *et al.* 2006).

1.10.3 Selected Metals and Applications

1.10.3.1 Nickel and Nickel Alloys for Mechanical Actuation

A number of electrodeposited nickel alloys have desirable mechanical properties with high strength and toughness and find use as structural materials in microsystem components like motors, gears, latches, nozzles, and flexure spring arms. While wrought nickel possess a yield strength around 300 MPa, the yield strength of electrodeposited nanocrystalline nickel and nickel alloys can exceed 1000 MPa. The small size of the as-deposited grains imparts strength according to the Hall–Petch relation. Nanocrystalline Ni, NiFe, NiCo, and NiMn can all have exceptionally high strengths. The deposition of alloys of NiFe (20% or 50% Fe) and NiCo (20% Co) are more susceptible to mass transport effects and can be difficult to control in high aspect ratio structures. Pure nanocrystalline nickel can have equally high strength if an organic grain-refining agent, such as saccharin, is used. While reducing the stress significantly, the use of these sulfur bearing agents results in sulfur inclusions in the metal that can lead to catastrophic embrittlement at temperatures near 300°C. Nickel alloys (NiFe, NiCo) can be as strong without the use of sulfur-bearing organics, but lose strength with temperature exposures larger than 300°C, as a result of grain growth. Electrodeposited NiMn alloys have been shown to have exceptional thermal stability, in addition to high strength.

Resist-patterned electrodeposited nickel has found use as a spring material in flexure elements for forming mechanically compliant electrical contacts. Individual spring components, millimeters thick, have been electroformed using a LIGA process (Goods *et al.* 2004). The electrical contact spring was electroformed with nickel manganese first and then coated with gold after release to provide electrical conduction and corrosion resistance.

Another recent application of resist-patterned electrodeposited nickel is in the fabrication of arrays of microminiature springs for making electrical contact to the bond pads of integrated circuits during testing. As the size of the chips decrease and the number of electrical connections increase, the requirements for the probe cards used during electrical test exceed conventional fabrication methods. MEMS fabrication is uniquely suited to provide the reduced size and pitch of electrical contact springs needed for advanced probe cards (Itoh *et al.* 2003, Kataoka *et al.* 2003, Kim *et al.* 2004). Higher strength nickel alloys afforded by electrodeposition, allow for the design of smaller, more tightly packed springs with the contact forces needed to make reliable connection. The electrical test can be at elevated temperatures for accelerated reliability prediction that demands a strong, thermally stable nickel material. Repeated and aggressive cycling of the springs requires an electrodeposit strong enough to resist deformation. **Figure 7**, taken from Kataoka *et al.*, illustrates one concept for the creation of cantilever-based nickel contact probes fabricated through lithography and electrodeposition.

In addition to microsystem components, electrodeposited nickel finds use as the tool material for hot embossing and injection molding of plastics for microfluidics, optical recording media (Czerwinksi and Szpunar 2000), replication of nanostructured surfaces (Lee and Kwon 2006), and nanoimprint lithography (Park *et al.* 2004). Electrolytes for the

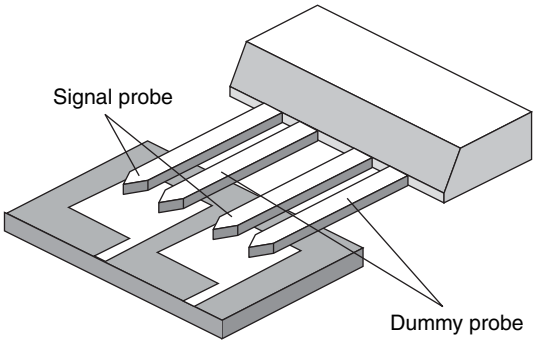

Figure 7 Example of nickel-plated microelectromechanical systems (MEMS) cantilever for use as an electrical test probe. (Source: Reprinted from *Sens. Actuators*, **103**, Kataoka K *et al*., Electroplating Ni micro-cantilevers for low contact-force IC probing, 116–21, Copyright (2003), with permission from Elsevier.)

electrodeposition of nickel are based on nickel sulfate (the Watts bath) or nickel sulfamate.

$$Ni^{2+} + 2e^- \rightarrow Ni_{(s)}$$

Some amount of chloride is present to assist dissolution of the nickel anode, but specially formulated nickel anodes possessing sulfur will sufficiently release nickel without the chloride. **Table 2** lists a common formulation for a sulfamate electrolyte, which is used for high-speed electroforming owing to the reduced stress and slightly higher concentrations of nickel available. Typically, a concentrate of nickel as nickel sulfamate (24 oz gal^{-1} or 180 g l^{-1}), available from a number of commercial vendors, is diluted to the desired concentration.

Table 3 lists a representative formulation for a Watts nickel electrolyte with saccharin as an organic brightner to reduce stress and refine the grain size. Sulfamate electrolytes can be used in conjunction with these additives as well, and the resulting deposits are lustrous, smooth, low stresses, and high strength. The downside to these addition agents, as mentioned previously, is the incorporation of sulfur into the nickel deposit.

A range of temperatures is feasible for nickel electroplating, but usually falls within 32–60°C.

Saccharin (g l^{-1})	1
Sodium lauryl sulfate (g l^{-1})	0.2
pH	4
Temperature (°C)	40
J (mA cm^{-2})	15
Anode	Ni–S

The low end of the temperature range is dictated by the boric acid, a critical component to both types of electrolytes. Boric acid, in the range 30–40 g l^{-1}, is believed to act as a buffer to mitigate the local rise in pH associated with hydrogen formation. The amount of boric acid is close to the solubility limit, and temperatures below 32°C should be employed with caution. A wetting agent or surfactant such as sodium lauryl sulfate is also desirable to inhibit pitting that can result when hydrogen clings to the growing surface. A low surface tension, which can also be accomplished with higher temperatures, is especially critical for plating in patterned resists where feature walls can pin bubbles within the feature.

While nickel sulfamate-derived electrodeposits are stronger than most other metals and easily integrated due to low stresses, some applications require a thermally stable alloy with high strength and resistance to embrittlement. The trade-off is that these alloys (Ni–Fe, Ni–Co, and Ni–Mn) are highly stressed as-deposited with more complicated processes. An extensive literature exists for the electrodeposition of magnetic Ni–Fe and Ni–Co alloys, so the processes are only briefly described here. **Table 4** provides the electrolyte used in Leith and Schwartz (1999a) as an example of Ni–Fe deposition in high aspect ratio structures. The high stresses encountered required the saccharin stress-reducing additive, rendering the deposit susceptible

to embrittlement. Furthermore, the alloy composition was sensitive to the extent of mass transfer, a difficulty for Ni–Fe and Ni–Co alloys.

A high-strength nickel alloy developed to avoid these issues with mass transport and electrolyte sensitivity is Ni–Mn, where the Mn content is low, less than 1% (Kelly *et al.* 2003). Uniform alloy content through the thickness of high aspect ratio molds demonstrates the reduced sensitivity to mass transport with respect to the codepositing element. The electrolyte is based on sulfamate and pulse plating is used to alleviate some of the tensile stress. The low temperatures employed dictate caution with extended use of the electrolyte (Goods *et al.* 2006) (**Table 5**).

1.10.3.2 Copper for RF MEMS and Electrical Interconnects

Copper finds use primarily as an electrical conductor. Thin deposits on the order of a micron are used in the Damascene process for copper interconnects. For other microsystems, thick deposits have been used to construct elements for radio frequency (RF) MEMS, such as transmission lines (Wu *et al.* 2003), wave guides, filters (Park *et al.* 2000), and switches (Amaya *et al.* 2004). The thick deposits afforded by electrodeposition are particularly useful for high-power microwave applications (Choi and Yoon 2004).

The most common electrolytes are based on copper sulfate and sulfuric acid near room temperature. Bright coatings are obtained through the use of addition agents that refine the grain size and level the surface morphology. The electrolytes used in Damascene interconnects possess multiple organic additives to induce super-filling or bottom-up feature deposition, resulting in the void-free deposition in features with aspect ratios greater than one. These and other organic additives may not be suitable for the thick deposits desired in MEMS applications, owing to the unstable microstructure that results. **Table 6** lists a typical copper electrolyte formulation, where pulse plating can be used to refine grains and reduce stress without the use of additives.

1.10.3.3 Gold

Gold finds use as both a corrosion-resistant coating and an electrical conductor. Through-resist plating of gold has been extensively used in microelectronics, particularly for packaging. Lithographically patterned gold also finds use in the fabrication of X-ray masks for the LIGA process.

Early electrolytes were based on cyanide complexes (Green *et al.* 2003, Morrissey 1993) of the gold, which were generally incompatible with photoresists. Formulations common to microelectronics and MEMS consist of sulfite-based chemistries (Horkans and Romankiw 1977). **Table 7** gives a representative formulation based on Green *et al.*

1.10.3.4 Thermoelectric Thin-Film Microdevices: Bi_2Te_3

In addition to materials with enhanced mechanical properties, semiconductors like CdTe for photovoltaics and Bi_2Te_3 alloys for thermoelectric energy conversion or Peltier cooling are readily electrodeposited and incorporated into microsystem fabrication schemes (Snyder *et al.* 2003). A number of MEMS-based thermoelectric device designs and fabrication schemes have emerged recently (Bottner 2005, Bottner *et al.* 2004,

Table 7 Gold, sulfite

Da Silva and Kaviany 2005). These devices are targeted at various cooling applications, such as the site-specific cooling of hot spots on microprocessors or optoelectronic components, as well as energy conversion applications such as remote power sources for sensors. The efficiency for which a thermoelectric material can convert heat into electricity or pump heat from a source is related to the materials intrinsic material properties by a figure of merit, z. This figure of merit is a strong function of temperature and as a thermoelectric material, bismuth telluride and its doped alloys have some of the highest figures of merit near room temperature. Electrodeposition is an attractive route for synthesizing the material as the technique affords thicker films for taller elements. Taller thermoelectric elements are crucial to increasing the thermal resistance in order to increase the temperature gradient and improve conversion efficiencies. A number of studies have examined the process–property relationships for this material (Magri *et al.* 1996, Martin-Gonzalez *et al.* 2002, Tittes *et al.* 2003). Moreover, electrodeposition has been shown to create the preferred crystal orientation with the highest figure of merit. The properties of Bi_2Te_3 are highly anisotropic, with a figure of merit for energy conversion nearly two times larger in along the preferred crystal axis. However, much like the high-strength nickel alloys Ni–Fe and Ni–Co, the electrical performance is highly sensitive to the alloy composition and process control is tantamount. By varying deposition conditions, investigators were able to achieve both n- and p-type semiconductor material, depending on the relative excess of one of the elements (Takahashi *et al.* 1994). Exacerbating the issue is the fact that the elements are in low concentrations (of the order of 10 mM) due to their low solubility, even in the 1 M nitric acid electrolyte commonly used. The overall reaction in the acid electrolyte is:

$$3HTeO_2^+ + 2Bi_3^+ + 18e^- + 9H \rightarrow Bi_2Te_3(s) + 6H_2O$$

Electrodeposition is also the key to the synthesis of many of the nanostructured thermoelectric materials. By using the template synthesis method in nanoporous alumina, nanowires of thermoelectric materials are electrodeposited and the properties improved over bulk materials (Borca-Tasciuc *et al.* 2004). A clever integration of such a nanostructured thermoelectric material into a MEMS device has been demonstrated (Wang *et al.* 2005). The promise for improved materials and novel applications promise to make this an important contribution to MEMS by electrodeposition.

1.11 LIGA

Ulrike Wallrabe and Jan Korvink, Department of Microsystems Engineering-IMTEK, University of Freiburg, Freiburg, Germany

Jürgen Mohr, Institute for Microstructure Technology, Karlsruhe, Germany

1.11.1 Introduction

The LIGA process was first developed at the Forschungszentrum Karlsruhe GmbH in Germany towards the end of the 1970s. The process was required as part of the so-called nozzle separation process required for uranium isotopes (Becker *et al.* 1982, 1986), which needed inexpensive yet very small slotted separation nozzles. Once in place, it was soon recognized that the process could also accurately produce other high aspect ratio microstructures, and nowadays it is employed worldwide by a number of other research institutes and, increasingly, by industries.

The strength of LIGA lies in its aspect ratio, as it combines lateral resolution at the micrometer range and lower level with heights up to the millimeter range. The sidewalls have unprecedented verticality, yet lateral shapes can be freely formed. Another attractive feature is the alternative it offers to silicon-based microstructures, and indeed the designer can choose among polymers, metals, and ceramics, but of course, structuring can also be performed on top of a silicon substrate.

In essence, the process follows the steps outlined by its acronym: lithography is performed with highly parallel synchrotron radiation (X-rays), and after a developing step, metal structures are grown in the cavities via galvanic forming (or electroplating) upon which the polymer mold is stripped away. In the last step, the metal structures can be replicated by using a replication technology such as embossing, known in German as Abformung.

Since its invention, many interesting variants and improvements to the process have emerged, but its advantage is certainly the highly collimated and energetic beam of X-rays of a synchrotron that penetrate, with only marginal scattering, through hundreds of micrometers of polymer resist and thereby pattern it with exceptionally sharp-edged, smooth vertical sidewalls.

With the advent of the ultraviolet (UV)-sensitive resist family SU-8, the LIGA concept has been extended to UV lithography, thereby avoiding the need for a synchrotron source. Although the process cannot achieve the same qualities as traditional LIGA, it is growing in popularity and is known under the names UV–LIGA and poor man's LIGA. The fabrication of microstructures by the LIGA process is schematically represented in **Figures 1–4**.

In the first step of the process, also known as deep X-ray lithography (DXL), synchrotron radiation with a wavelength spectrum of 0.2–0.6 nm is used to transfer the pattern of an X-ray mask into a layer of resist. The resist, several hundreds of micrometers thick, is usually made of polymethylmethacrylate (PMMA, better known as Plexiglass). Its high contrast to radiation is

Figure 1 X-ray lithography with a thick resist film using an X-ray mask. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

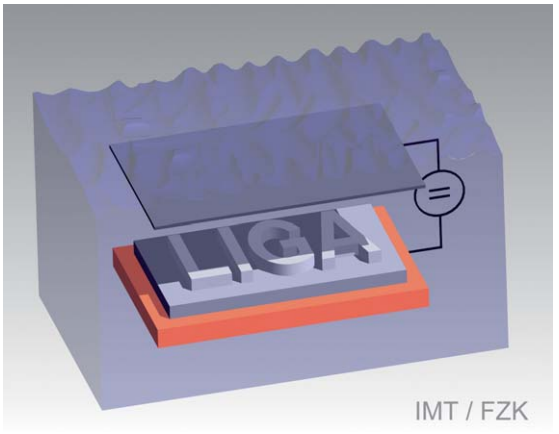

Figure 2 Electrodeposition of metal in a resist template. Typical metals are Ni, Au, Cu, or NiFe. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

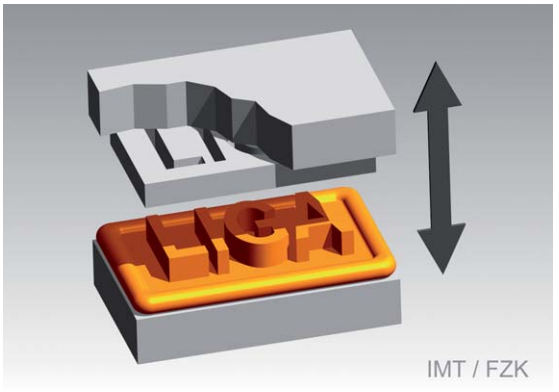

Figure 3 Molding (here hot embossing) of a polymer using a metallic molding tool. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

known from electron beam lithography. Nowadays, chemically strengthened X-ray-sensitive resists (Schenk *et al.* 1997) as well as the epoxy-based resist material, SU-8, are also used in the LIGA process.

The X-ray radiation that passes the mask is absorbed into the resist and causes a localized chemical or structural modification of the polymer chains. In PMMA, the localized molecular weight decreases due to scission of individual polymer chains. By using molecular-weight-dependent developer solvents, exposed regions of polymer can be selectively dissolved, leaving the desired cavities in the resist material. It is possible to create metal geometries complementary in structure to the cavities by

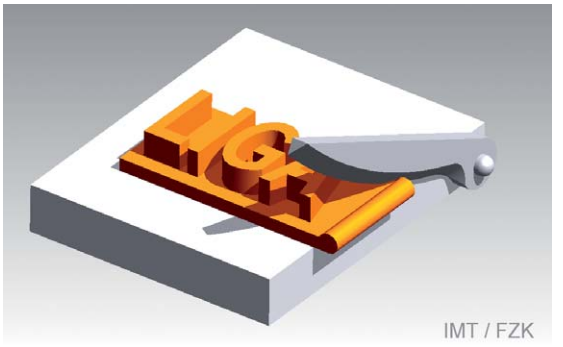

Figure 4 Postprocessing of molded component, here dicing. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

electroplating within the cavities. An electrically connected base plate has only those regions exposed that correspond to the dissolved resist, and hence the metal, either copper, nickel, or gold, will be selectively electrodeposited. Once the remaining resist has been removed, the remaining metal part can either end up as the final part or it can be used as a tool, a mold insert, for subsequent mass production by embossing or injection molding. In the latter case, the electrodeposition step is continued until the metal part has grown a thick metallic layer above the resist surface. This continuous and solid base plate strengthens the fragile microstructures underneath.

The mold insert allows the high-quality manufacture of numerous plastic copies of the microstructure by injection molding, reaction injection molding, or hot embossing (see **Figure 3**). Replication techniques extend the materials palette to numerous other thermoplasts, e.g., polyoxymethylene (POM), polyether ether ketone (PEEK), polyvinylidene fluoride (PVDF), polysulfone (PSU), and polycarbonate (PC). These molded parts can either be the end product or again be used for an intermediate step. As end products, they can be filled with metal through electrodeposition, and as intermediate forms, they may become lost templates during the fabrication of, for example, ceramic microstructures.

The key characteristics of the LIGA process are as follows:

- Structure heights of up to 3 mm, depending on design
- Freedom in lateral shape
- Smallest achievable lateral dimension of a structural detail down to 200 nm

- Highest achievable aspect ratio of freestanding structures is 50, and of supported structures is 500
- Surface roughness of sidewalls is less than 20 nm
- A broad range of materials for the final structures:
  Polymers: PMMA, POM, PSU, PEEK, PVDF, PC, liquid-crystal polymer (LCP), polyamide (PA), and polyethylene (PE)
  Metals: Ni, Cu, Au, NiFe, NiP
  Ceramics: lead zirconium titanate (PZT), $Pb(Mg_{1/3}Nb_{2/3})O_3$–$PbTiO_3$ (PMNT), Al_2O_3, ZrO_2

The long LIGA process chain is the reminiscent of semiconductor manufacturing. Thus, in order to make the LIGA process available as a competing manufacturing technology, the individual process steps have to be stable and achieve a high yield. A major effort in development was therefore directed toward establishing the so-called standard processes based on the better-characterized PMMA resist. Other professional equipments that were developed included X-ray scanners, megasonic development tanks, and electroplating facilities.

The ensuing and detailed description of the LIGA technology is presented in two sections. The first part is concerned with the process itself, whereas the second part provides an overview of typical applications that can be achieved with the technology. Because lithography is the most critical process step and X-ray lithography places strong constraints on the employed masks, it is explained in somewhat more detail than the other processing steps. The applications will focus on optical and mechanical devices that range from industrially commercialized products all the way to components that are still under investigation at either the research or the development level.

1.11.2 The LIGA Technology

1.11.2.1 Generation of X-rays

The resolution in lithography is directly dependent on the wavelength of light used. Optical lithography made an unexpected progress by the repeated development of new exposure equipment that already works in the far UV region. Even smaller wavelengths in the range from 0.2 to 2 nm are provided, for example, by a synchrotron. A synchrotron is a storage ring for relativistic electrons, which emit characteristic X-rays while accelerated on a circular path. In the case of synchrotron radiation, the X-rays are extremely parallel, which allows for the exposure of very thick resists behind the mask without loosing the required accuracy. In addition, they are highly energetic and very powerful, i.e., the quantum flux is high, which guaranties for sufficient penetration depth at still moderate exposure times.

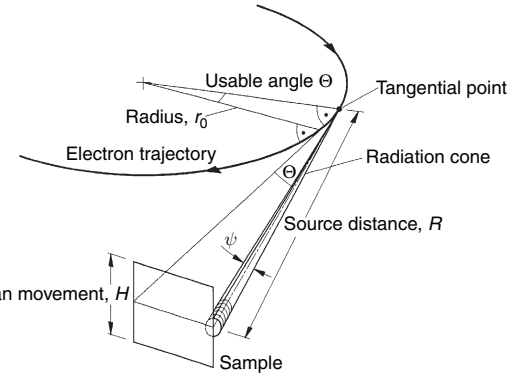

Figure 5 Principle of the generation of synchrotron radiation.

Figure 5 shows schematically the generation of synchrotron radiation. A large number of free electrons run in an electron storage ring at a highly relativistic energy, that is, almost at the speed of light, on a circular path with a fix annular frequency. Due to the strong centrifugal acceleration that the electrons suffer they emit an electromagnetic radiation along the whole circumference of the storage ring.

The radiation is extremely collimated in vertical direction, and it is emitted in tangential direction from the electron's path of flight. The opening angle ψ of the beam is dependent on the electron energy E, and is typically on the order of 1 mrad.

$$\Psi = \frac{m_e c^2}{E} \qquad [1]$$

The radiation power P and the characteristic wavelength λ_c are also strongly dependent on the energy, i.e., with the fourth and third power on the radius R of the ring and of the electron current I, respectively.

$$P = 88.5 \times \frac{E^4 I}{R} \qquad [2]$$

$$\lambda_c = 5.99 \times \frac{R}{E^3} \qquad [3]$$

The emitted power as a function of wavelength is plotted in Figure 6 for several electron energies. The electron current was chosen to be $I = 0.1$ A, and the radius of the ring $R = 10$ m. The characteristic wavelength is also given. It is defined in a way that the

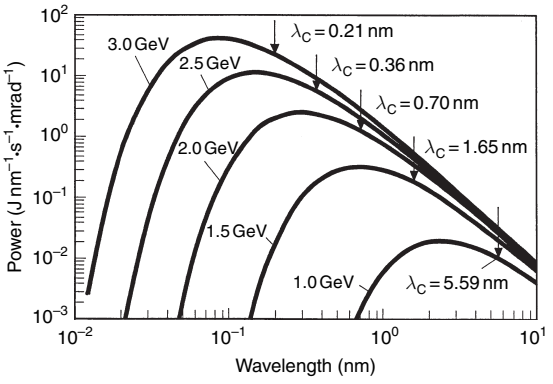

Figure 6 Emitted synchrotron radiation power as a function of wavelength for various energies of the stored electrons.

integrated radiation power above and below λ_c is equal. The wavelength with the maximum radiation power, however, is different from λ_c by a factor of 0.650.

Different from the basic sketch of a synchrotron featured above, a real synchrotron is not a circle but a polygonal-like shape. The bending radius of the electron flight path is defined by dipole magnets that are arranged regularly along the storage ring. In this case, the synchrotron radiation is generated only at the dipole magnets; hence, the steel pipes that guide the X-rays toward the exposure chamber, the so-called beamlines, are flanged to the ring in a tangential orientation only here. Between the dipole magnets, that is, in the straight ring sections where no centrifugal force acts on the electrons, crosswise arranged quadrupole magnets are placed for refocusing the electron beam, which otherwise tends to spread because of electrostatic repulsion. Additional sextupole magnets provide an energy refocusing, as the electrons suffer energy loss due to the emitted radiation on the one hand and due to scattering at residual gas molecules on the other hand. In order to keep the scattering losses to a minimum, the whole synchrotron is evacuated to vacuum, which is of the order of 2×10^{-9} mbar. **Figure 7** shows a schematic top view of the synchrotron ANKA in Karlsruhe, Germany. The polygonal shape, the star-shaped wall of concrete that surrounds the ring in order to protect the environment against the X-rays and the tangential beamlines, which are also shielded by concrete walls, can be seen. The electrons are generated and preaccelerated in the injector, which is positioned in the center of the ring. Here, the electrons are generated by a hot cathode and are brought to an energy of 500 MeV by a microtron or by a linear accelerator. From there, they are injected into the ring and accelerated to their final speed by a kicker magnet.

For using synchrotron radiation for lithographic purposes, an exposure chamber is flanged to the beamline. The mechanical separation of the vacuum in the ring and an air or helium atmosphere in the exposure chamber is done by a vacuum proof but X-ray transparent vacuum shielding. Typically this is a beryllium metal sheet that combines mechanical stability with minimum X-ray absorbance (see Section 1.11.2.2.2). **Figure 8** shows a basic X-ray lithography setup. The X-rays from the beamline enter the exposure chamber through the vacuum shielding. Due to the fact that the X-ray beam is so well collimated (it spans vertically 1 cm at a distance of 10 m to the ring), the substrates need to be scanned through the beam to ensure

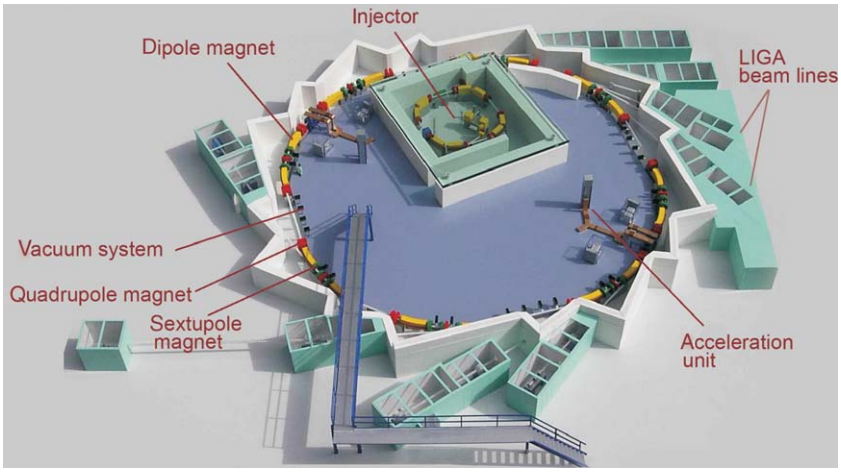

Figure 7 Top view of the synchrotron ANKA in Karlsruhe, Germany. On the left side there are three beamlines for LIGA applications.

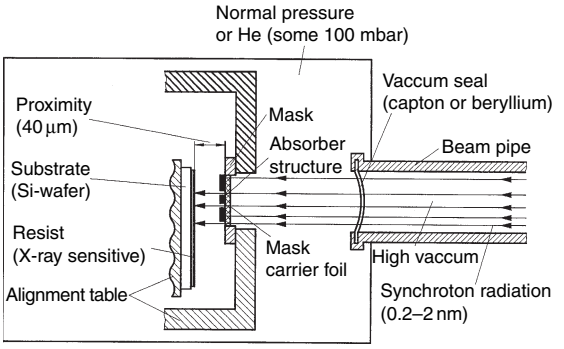

Figure 8 Schematic drawing of an X-ray lithography setup for shadow projection with beamline, mask holder, and scanner table for the substrate.

Figure 9 Professional scanner from Jenoptik Company, Germany: the mask is fixed to the scanner table in the rear side and the substrate on the front plate.

sufficiently large exposure areas. Hence, the exposure chamber features a substrate holder and a mask holder for the X-ray mask on a movable scanner table. Between the mask and the substrate remains a proximity gap of several tens of micrometers to protect the fragile membrane mask (see Section 1.11.2.2.2) from the damage. **Figure 9** shows a professional scanner from Jenoptik Company, Germany, from the user's view. The mask is mounted onto the back plate and the substrate onto the front plate.

A pure shadow projection of the X-rays through a suitable shadow mask is recommended as X-ray optics are very expensive and available only to a limited extent. In addition, as the synchrotron radiation is so highly parallel and highly energetic, it may penetrate into an X-ray-sensitive resist by hundreds of micrometers without the risk of dramatic structural losses and size deviations. This finally gives rise to the uniqueness of X-ray lithography, namely of DXL; it allows the patterning of very thick resists with extremely high resolution and very smooth sidewalls.

1.11.2.2 X-ray Masks

A mask suitable for the LIGA process consists of an X-ray absorber, a carrier foil or a substrate for the absorbers, and the frame of the mask (Bacher *et al.* 1991). In contrast to masks for optical lithography, the absorbers for high-energetic X-rays need to be quite thick, whereas the carrier is typically very thin to ensure sufficient transparency. These requirements call for a specific mask fabrication process.

1.11.2.2.1 X-ray opaque absorbers

The pattern that is to be transferred in a thick X-ray-sensitive resist is given by the pattern of the absorber. While in optical lithography using UV light, an approximately 0.1-µm-thick chromium layer on the mask is already sufficient, the absorber in X-ray lithography must consist of a material with a high absorbance for X-ray radiation in the wavelength region used. Materials, such as gold, tantalum, or tungsten, that have a high atomic weight and therefore a high absorption coefficient are considered. Mostly gold is used due to its ability of electroplating deposition. Tantalum and tungsten find few applications and are structured by reactive ion etch processes.

The retention capability of X-ray radiation is given not only by the absorption coefficient $\alpha_{Au}(\lambda)$ but also by the thickness d_{Au} of the layer. The transmission of a layer is given by the following equation:

$$T_{Au}(\lambda) = \exp(-\alpha_{Au}(\lambda) d_{Au}) \quad [4]$$

The minimum thickness of the gold absorber depends on the characteristic wavelength of the synchrotron radiation, and it increases with decreasing wavelength and increasing resist thickness. As a rule of thumb, 20 µm of gold can be considered as an appropriate average.

Because the gold absorbers are made by electroplating, they are deposited on a negative form of a resist template, which is somewhat higher than the absorber thickness, i.e., 30–40 µm. With the exception of structuring with synchrotron radiation itself, there is no existing process that guarantees the required precision on the one hand and that can grant for the structuring of resist layer thicknesses of several tens of micrometers and a precision in the submicrometer region, on the other hand. Therefore, such a mask has to be fabricated in two steps. First, an initial

X-ray mask with an absorber thickness of only 3 μm is produced, a so-called intermediate mask. The pattern of the intermediate mask is then transferred by X-ray lithography in an approximately 30-μm-thick resist layer, which after development serves as a template for 20-μm gold electrodeposition to form a second mask. The mask produced in this way is called the process mask. The synchrotron radiation is linked to almost no structure loss in this copy step because of the high parallelism and the small wavelengths.

In total, the mask production in the LIGA process comprises the following process steps:

- Manufacture of a carrier substrate for the intermediate mask
- Structuring the resist layer of the intermediate mask
- Electroplating of the absorber structure with gold
- Copying the intermediate mask to a process mask by the first LIGA-like process

1.11.2.2.2 X-ray transparent carriers for absorbers

The absorber structures have to be fabricated on a suitable carrier (Schomburg *et al.* 1991). In optical lithography approximately 2-mm-thick polished glass or quartz substrates are used. However, in X-ray lithography glass of this thickness is not transparent enough to the relevant X-rays. Hence, the carrier must not only have a low absorption coefficient, but also be thin enough to ensure sufficient transparency. Therefore, materials with low atomic weight, for example, beryllium, carbon (diamond), silicon and its compounds, plastics, or metals with low atomic number are considered as carrier materials. Additional requirements on the optimum material are mechanical rigidity, dimensional stability, and – very important – resistance against X-ray radiation. All these limit the use of plastics. Therefore, earlier, thin metal foils have been used as the carrier material in the LIGA process. Only in that way was it possible to realize a large area of a freely strained carrier (e.g., 25 mm × 65 mm) with low stress. Among the metals, beryllium shows an ideal transmission (**Figure 10** shows the absorption coefficient *vice versa*) even at a thickness of several hundreds of micrometers. The transparency is still high in the useful wavelength region. However, because of high toxicity (dust from beryllium and its oxides can cause lung cancer), the handling and mechanical treatment of beryllium is difficult. As a consequence, beryllium substrates are delivered only by very few companies, and they are quite expensive (>1 k€ per 4″ substrate). Nevertheless, in the past years beryllium gained more and more interest because it guarantees very low mask distortions generated by thermal load during the X-ray exposure, and they are mechanically stable due to their mentionable thickness.

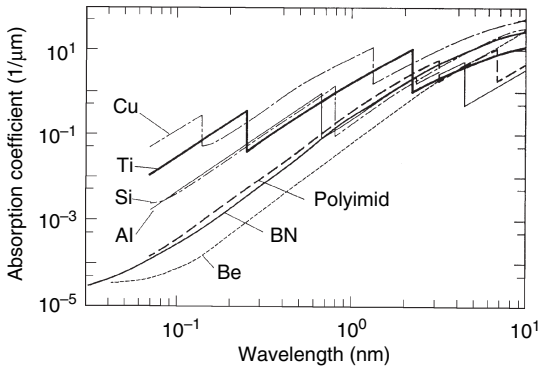

Figure 10 Absorption coefficient of diverse low-absorbance materials, which are, in principle, suitable carriers for absorber structures.

Titanium is an often-used alternative to beryllium as a carrier layer. Because of the high absorption coefficients of titanium compared to beryllium, the membrane thickness must be considerably smaller and should only be several micrometers; a typical value is 3μm. The thin carrier foils are stretched across a frame to give the necessary mechanical robustness to the mask and to ease the handling during fabrication or alignment.

1.11.2.2.3 Fabrication of an intermediate mask

1.11.2.2.3.(i) Fabrication of the carrier membrane For the fabrication of a 3-μm-thick titanium membrane, first a layer of carbon is sputtered onto a silicon wafer. During sputtering, a ring-shaped aperture covers the outer edge of the wafer so that no carbon is deposited at the periphery. Substrate temperature and other coating parameters are adjusted in such a way that the carbon adheres poorly to the wafer. Then, a titanium layer of 2- to 3-μm thickness is sputtered on top of the carbon layer. This layer exhibits good adhesion to the substrate in the outermost periphery of the wafer, while that on the carbon layer is applied only relatively loosely. After the patterning of the mask, a rigid frame from Invar (a metal alloy with very low thermal expansion coefficient) is glued onto the inner part of the titanium layer (**Figure 11**). After

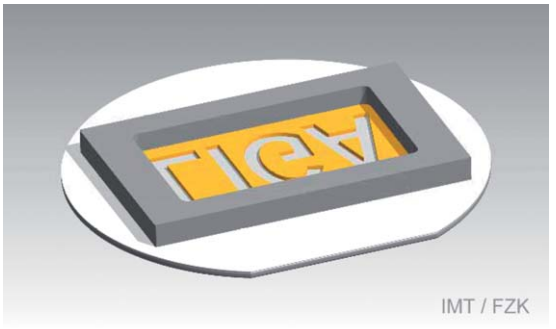

Figure 11 Electroplated mask pattern in gold with mask frame glued onto the substrate.

Figure 12 Release of the titanium membrane from substrate.

hardening the glue, the frame together with the titanium membrane can be lifted off the support by gently bending the silicon wafer resulting in a carrier membrane with excellent surface finishing, which is freely suspended onto a frame (**Figure 12**).

1.11.2.2.3.(ii) Patterning of the resist Depending on the requirements that the microstructures must fulfill, different processes can be utilized for the patterning of intermediate masks. For structures that do not necessarily call for the highest precision, the X-ray intermediate mask can be produced by an optical copy of a conventional chromium–quartz mask in an approximately 3-µm-thick photosensitive resist. The most perpendicular sidewalls can be attained by optimizing the baking process and the exposure and development conditions so that structures with a slope angle of about 88° are possible (Schulz *et al.* 1996). The minimum achievable lateral dimensions are about 2 µm because of the unavoidable effect of diffraction in optical lithography and

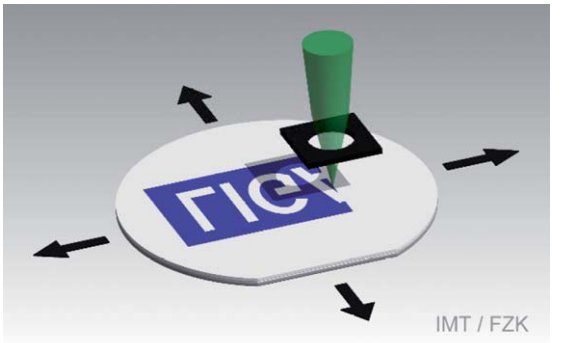

Figure 13 Writing of the master pattern with an electron beam writer. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

due to the resist thickness of 3 µm. Apart from that, rounding of edges is unavoidable. The structural loss, that is, a decrease in the structural width of about 0.5 µm, can be controlled by a corresponding size compensation on the chromium mask.

For high-precision requirements, electron beam lithography is recommended as indicated in **Figure 13**. For this purpose, an electron-sensitive resist of about 3 µm thick is spun onto the wafer with the titanium layer. An electron beam writer with high acceleration voltage (e.g., 100 keV) is suitable for direct structuring of an approximately 3-µm-thick resist layer (Hein *et al.* 1992). The 100-keV acceleration voltage ensures the required steepness of the sidewalls because the electron lobe that results from scattered electrons in the material is shifted into the substrate. PMMA is used as the resist because it provides a very high resolution in electron beam lithography, however at the prize of a low sensitivity, which results in long writing times. The 3-µm-thick PMMA layers are produced by spin coating twice with a very homogeneous thickness, whereby an annealing step is carried out after each coating in order to reduce internal cracking and avoid stress cracking. In case of less demands on the precision, negative diazo-based resist materials are also available representing a compromise between resolution and writing time.

In order to attain precision in the submicrometer range, the pattern is divided in a fine region, which contains the border, and in a coarse inner region. The fine region of a width of 1 µm, for example, is exposed to a small beam diameter (0.02–0.05 µm). For the coarse region, a considerably larger beam

diameter of up to 0.5 µm is sufficient. Thus, the border can be structured with high precision and at the same time the total writing time is considerably reduced, as the writing time per surface unit for the coarse region is about a factor of 50 smaller than it is for the fine region. This procedure results in a smallest line and space structure of about 1 µm, limited by the proximity effect. The dimensions of the structure details, however, are between 0.1 and 0.2 µm.

1.11.2.2.3.(iii) Electroplating of gold The electroplating of microstructures is as an essential process step of the LIGA process (see Section 1.11.2.7). As for the fabrication of both intermediate mask and process masks, electroplating of gold is required (Maner *et al.* 1988). Typically, in the macroscopic world, cyanide electrolytes are used. However, the cyanide electrolytes do have some disadvantages; above all the toxicity, but they also attack the resist and produce rough surfaces. By using suitable sulfite gold electrolytes instead, fine-grained depositions with smoother surfaces can be achieved.

The essential requirements of gold electroplating of the absorbers are as follows:

- The absorber structure must adhere well to the carrier material, as the cross-sectional area of the absorber structure often amounts to only a few square micrometers.
- The deposition should be carried out with the least amount of stress as possible in order to provide good adhesion of the absorber to the carrier after resist stripping and to avoid mask distortions.
- The thickness of the deposited layer must show a high uniformity, both in the microscopic as well as in the macroscopic range so that a uniform and the greatest possible X-ray contrast results.
- Also, pattern details of the resist structure in the submicrometer range must be copied by electroplating.

As titanium belong to the materials that are difficult for electrodeposition of other metals, either suitable intermediate layers or a chemical pretreatment is necessary. For example, a wet chemical oxidation of the surface has proven to be a suitable method (Mohr *et al.* 1988). It increases not only the adhesion of the resist, but also the adhesion of the gold absorbers. In order to ensure a uniform initiation of the electroplating, a gold starting layer of about 10 nm thick is sputtered onto this titanium oxide layer.

1.11.2.2.4 Fabrication of a process mask The process mask is produced by transferring the pattern of the intermediate mask into a relatively thick resist layer using synchrotron radiation (**Figure 14**). PMMA of 30–40 µm thickness is used as a resist material, which is applied to the mask carrier by direct polymerization (see Section 1.11.2.3.1). For the process mask, besides the titanium membranes, the above-mentioned beryllium substrates can also be used as a carrier. They are produced by fine mechanical processing of metal sheets with a currently limited thickness of 500 µm. This metal sheet is inactivated on both sides by a silicon nitride layer in order to avoid corrosion during utilization. A polyvinylidene (PVD)-deposited gold layer is used as the electroplating starting layer. This may cause problems in resist adhesion, which have to be overcome by initial adhesion promoters. If titanium is used for the process mask, the same fabrication sequence as for the intermediate mask can be used for the membrane.

As the X-ray lithography is a pure shadow projection of the absorber structure, the process mask features an exactly negative image of the intermediate mask after development and electroplating of gold. Even the lateral roughness of the absorber structures of the intermediate mask, which is only on the order of 20 nm, is completely transferred to the process mask. Because the X-ray contrast of the intermediate mask with an absorber thickness of only 3 µm is limited, the wavelength of the synchrotron radiation must be considerably larger compared to structuring of resists with a thickness of several hundreds of micrometers. Sufficient contrast between the illuminated and nonilluminated areas can be achieved only by using softer

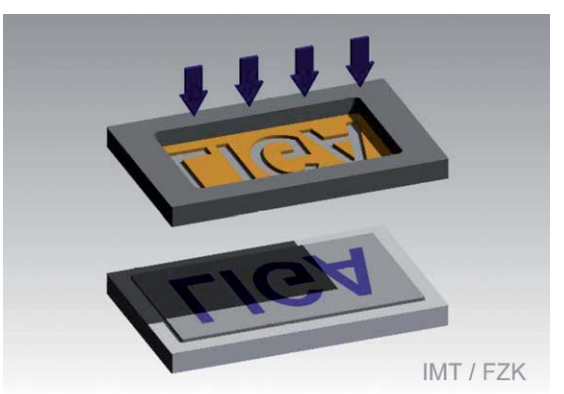

Figure 14 Copy of intermediate mask to thick resist layer for process mask using X-ray lithography.

X-rays. A fully manufactured process mask is shown in Figure 15 for a titanium membrane and in Figure 16 for a beryllium substrate, respectively.

1.11.2.2.5 Alignment marks in X-ray process masks

If microstructures that lie accurately aligned on top of previously structured auxiliary layers are to be produced by X-ray lithography then the process mask must be adjusted relative to these auxiliary layers before the X-ray exposure. This can be done not only with the help of alignment marks that are part of the X-ray mask layout on the one hand, but also by the prepatterned auxiliary layer on the other hand. Because titanium or beryllium mask membranes are not optically transparent, perforations are locally

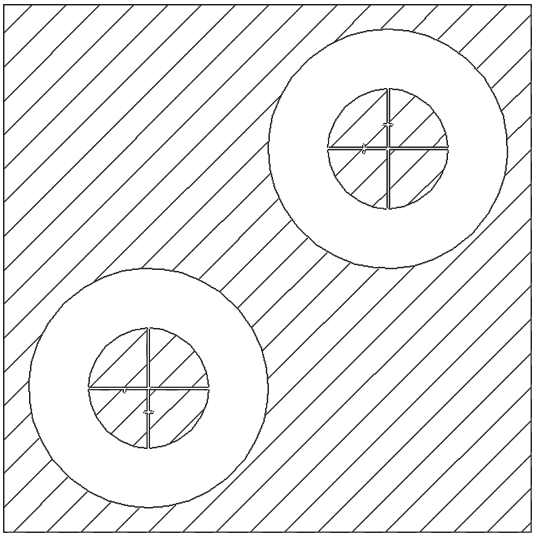

Figure 17 Alignment marks on X-ray process mask.

etched in the mask membrane through which the alignment marks can be observed. In order to etch little holes into the membrane, the entire mask is covered with a photoresist. It is opened at the positions of the alignment marks by optical lithography and wet etching. In the case of titanium, undercut etching of the photosensitive coating plays a subordinate role due to the thin membrane and hence the short etching times. In contrast, with thick beryllium masks, the entire membrane cannot be entirely etched through, as this would lead to a strong undercut due to isotropic etching. For these reasons, mechanical cavities must be introduced into the beryllium before etching.

The alignment marks, typically thin- and long-legged crosses, on the X-ray mask are produced simultaneously with the other absorber structures. Therefore, they are precisely positioned relative to the other structures. The crosses are surrounded by a broad ring, which is also electroplated in gold and which helps to prevent undercutting and thus defines the final dimensions of the etched hole. Figure 17 shows a typical layout of the alignment marks. The four quarter sections within the rings are opened by etching and are viewed through the mask membrane with a microscope. For the alignment marks on the substrate, a respective pattern shown in Figure 18 is recommended. The arrows help the user to move the mask in the correct direction in case the starting position is so bad that the cross on the substrate is out of sight when observed through the mask hole. The alignment accuracy obtained with this procedure is on the order of 3 μm.

1.11.2.3 X-ray Resists

1.11.2.3.1 Production of thick resist layers

The resist layers used in microelectronics rarely exceed thicknesses of 1 μm and are usually polymers that can be dissolved to the desired viscosity with a solvent. By spin-coating the resist solution onto a substrate, the solvent is partially centrifuged off leaving a homogeneous resist layer on the substrate. The thickness of the layer can be precisely controlled by the speed of rotation.

Spin coating is, however, not suitable for thick resist layers on the order of a few hundred micrometers, as required for the LIGA process. Spin-coated layers produce only loosely intertwined polymer strands and produce large internal stresses for increasing layer thickness. During development, stresses cause nonuniform penetration of the developer solution and stress-driven cracking of the polymer material. Hence, thick resist layers are directly polymerized onto a base plate (Mohr *et al.* 1988) or alternatively, a polymer plate is glued or welded to a base plate. PMMA is almost exclusively used as the resist material.

For the direct polymerization process, the starting material is a viscous cast resin that consists of the low-viscosity monomer methylmethacrylate (MMA) and a solid fraction that is dissolved in it. After the addition of a polymerization starter, e.g., peroxide, the MMA polymerizes to PMMA, but only if the temperature is raised or through the addition of a room temperature initiator such as aniline. The molecular structures of MMA and PMMA are shown in Figure 19.

The solid additions to PMMA are not affected by the polymerization through secondary effects. The resulting molecular weight is strongly dependent on the concentration of the initiators and starters and the prevailing reaction conditions. The polymerization results in a typically bimodal molecular weight distribution. Internal stresses are reduced by subjecting the sample to a thermal tempering cycle.

In order to attach an existing polymer plate to a substrate, two variants are typically followed. In the first variant, a thin layer of the cast resin monomer is applied as a 10-μm-thick adhesion layer directly onto the base plate. The PMMA substrate is pressed directly onto this layer, and the assembly is hardened at room temperature as described before. In the second variant, a thin monomer layer is spin-coated onto the base plate. The monomer contains adhesion elements so that the application of pressure and temperature to the assembly results in the formation of a bond forming between the PMMA substrate and the base plate (Skrobis *et al.* 1995).

It is imperative that, subsequent to the lithography step that includes both irradiation and development, the finest high aspect ratio structures still sufficiently adhere to the base plate. In addition, as electroplating almost always follows lithography, the exposed adhesion layer on the substrate must guarantee uniform initiation of electroplating on the base plate. In addition, as X-ray lithography can result in the generation of

photoelectrons, the effective cross section must be very small, a requirement that is fulfilled by a material of low atomic number. In order to fulfill these requirements, a compromise is taken in the form of a sputtered titanium layer, which is subsequently oxidized in a wet chemical bath. Upon oxidization, a microporous layer is achieved, which in turn results in a microtoothing of the interface between the base plate and the substrate. To further strengthen the bond, an adhesive is added to the resin. The adhesives are typically siloxanes, which form an oxygen-bridging bond with the oxidized surface (Boerio and Williams 1981). It is also possible to use copper, nickel, or gold as adhesives and electroplating initiation layers, but none have the high adhesive strength associated with titanium. For gold, the adhesion strength can be improved by the addition of thiophenols. If the resulting microstructure is the polymer itself, then carbon is also well suited as a adhesion layer (El-Kholi *et al.* 2000). Though its adhesion strength exceeds that of titanium, it is not suitable as an electroplating initiator.

1.11.2.3.2 Beam-induced reactions and development of resists

Upon exposing a resist to radiation, its polymer chains are cracked resulting in a lower molecular weight distribution (Schnabel 1978). From **Figure 20** it can be deduced for PMMA that by increasing the dosage of radiation to high levels, it is possible to transform the molecular weight from an initial $650\,000\,\mathrm{g\,mol^{-1}}$ to a minimum that lies between 2500 and $3000\,\mathrm{g\,mol^{-1}}$.

The scission of the main chain of the polymer is initiated by the electronic excitement of the molecule's bonds. The X-ray photons reach the polymer with energies in the kiloelectron volt range and are absorbed by individual atoms via the photoeffect along the polymer chain. In turn, they release high-energy photoelectrons and Auger electrons. In this way, energy is progressively transferred to other molecules or molecular building blocks, and secondary electrons are generated. This excitation chain continues until only thermal energy remains in the form of ionized and excited molecules and thermal electrons.

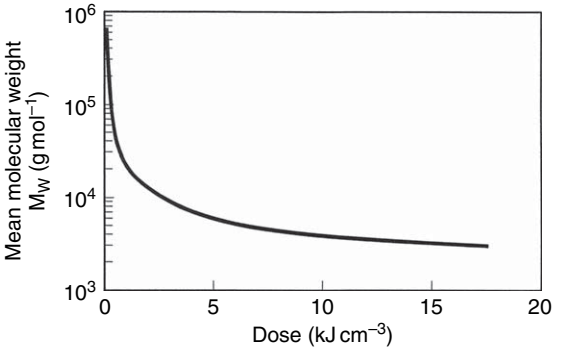

Figure 20 Decrease in molecular weight upon X-ray exposure. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

For PMMA, the excitation results in a cleavage of the first side chain. As a result, a radical ester group and a radical carbon atom are available in the main chain of the polymer. The radical carbon atom initiates scission of the chain and results in both a radical and a saturated piece via a double bond with the free carbon atom (Schnabel 1981, Schnabel and Sotobayashi 1983). The result is therefore a short stable chain and two radicals, namely the radical polymer chain and the radical ester chain, which in turn are free to react with each other or with other radicals in the mixture in order to form stable molecules. Further postscission processes exist, namely electron or energy transfers to other molecules. Chains are also known to persist in a metastable excited state.

At higher radiation doses, not only chain scission but also cross-linking of PMMA is observed. At the same time, the molecular weight increases because chemical bonds are formed between different main chains of the polymer. Clearly, chain scission and cross-linking have opposite influences on the molecular weight distribution, even though the influence of the scission mostly dominates the cross-linking; nevertheless, it explains the limiting lower value of molecular weight achievable, as shown in **Figure 20**.

1.11.2.4 X-ray Lithography

During X-ray lithography, synchrotron radiation transfers a mask pattern to a millimeter-thick resist layer. The exposed resist material undergoes chemical modification. The degree of this modification depends on the X-ray sensitivity of the material and on the energy of the absorbed radiation. The quality of the transfer process and hence of the achievable structure geometries depends on the degree of parallelism of the radiation, the degree of radiation smearing on the absorber edges, and on the spectral range of photoelectrons produced in the resist layer.

Furthermore, secondary effects must be considered. These include fluorescence electrons produced in the mask membrane and photoelectrons that are released in the substrate. It is also important to take into account deformation of the mask due to thermal expansion of the mask membrane.

1.11.2.4.1 Requirements on the absorbed radiation dosage

PMMA is distinguished as a resist by its high contrast, i.e., by its excellent image reproducibility (Greeneich 1975). However, its resistance to radiation damage results in the need for fairly high radiation dosages in order to achieve a significant reduction in molecular weight. Before radiation, the molecular weight distribution of PMMA is typified by **Figure 21(a)**. The bimodal distribution has an average molecular weight of 600 000 (El-Kholi *et al.* 1993). Now, at 38 °C, only 50% of the molecules with weight up to 20 000 g mol^{-1} are dissolved. Because the nonradiated PMMA has only a small fraction of its molecules in this weight range, it remains relatively unaffected by the developer.

For PMMA, a radiation dose of 4 kJ cm^{-3} results in a monomodal weight distribution of 5700 g mol^{-1} (**Figure 21(b)**). Because the weight distribution lies well within the 50% dissolution range of the developer, the radiation dose is sufficient for material removal. At lower dosage levels, dissolution is insufficient and residues remain; hence 4 kJ cm^{-3} represents the lower dosage limit for PMMA. Mechanical measures such as stirring or ultrasonic agitation during developing can somewhat lower this limit.

At a radiation dose of 20 kJ cm^{-3}, the average weight distribution is around 2800 g mol^{-1} as shown in **Figure 21(c)**. All the reduced PMMA are relatively quickly dissolved by the developer. Higher dosages should, however, be avoided, as they lead to intrinsic damage such as the formation of bubbles, which, in turn, would hinder the formation of defect-free microstructures.

Thus, in order to process defect-free microstructures with complete resist removal, it is essential that the deposited radiation dosage lies between 4 and 20 kJ cm^{-3}. The dosage may therefore vary by at most a factor of 5. Now we can proceed to deduce the wavelength of the radiation. From **Figure 22** we plot, for monochromatic X-ray radiation and as a function of wavelength, the depth in PMMA at which the absorbed dose has dropped by a factor of 5. For example, for structures with a 500 µm depth, it follows that the X-ray wavelength may not exceed 0.25 nm.

Because the synchrotron radiation has a fairly wide spectral distribution, any long-wavelength components that are not yet absorbed by the X-ray window of the beam tube should be additionally filtered out using an appropriate preabsorber. **Figure 23** demonstrates how, to what extent, and where synchrotron radiation is absorbed for a typical

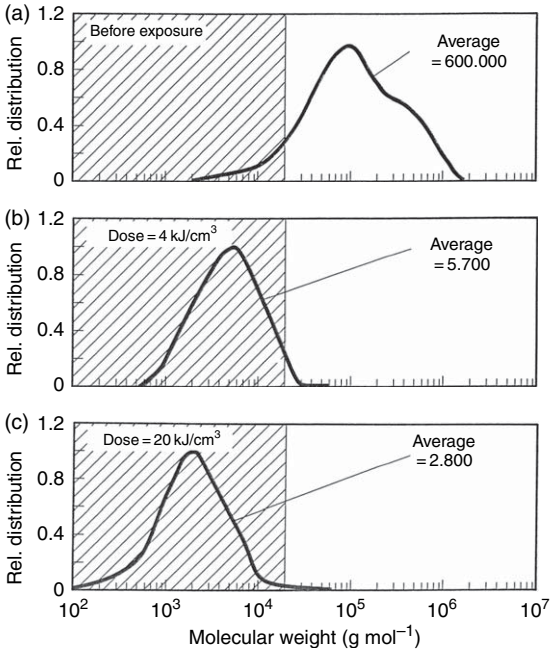

Figure 21 Distribution of molecular weight of polymethylmethacrylate (PMMA) before and after exposure at radiation dose of 4 and 20 kJ cm^{-3}, respectively. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

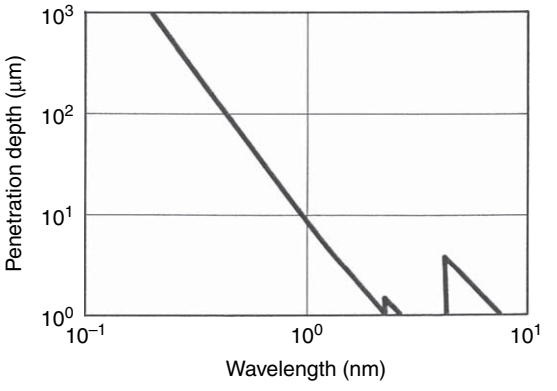

Figure 22 Influence of the X-ray wavelength on the penetration depth in polymethylmethacrylate (PMMA) for the case that the absorbed dose has dropped by a factor of 5. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

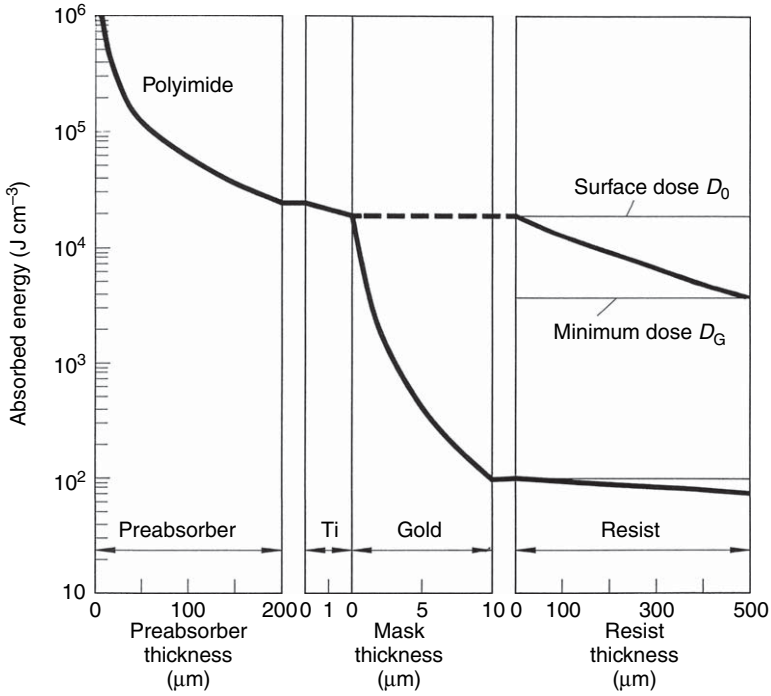

Figure 23 Absorbed energy of a 500-μm-thick polymethylmethacrylate (PMMA) layer with a mask having gold absorbers of 10-μm thickness and with a 200-μm-thick Kapton (polyimide) membrane as preabsorber. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

microstructure experiment. The curve is typical for the electron stretcher and accelerator (ELSA), the electron stretcher ring, with a characteristic wavelength of 0.5 nm, situated in Bonn, Germany. Here the experimental conditions, especially for the irradiation time and for the choice of preabsorber, are selected so that the underside of a 500-μm-thick resist layer obtains the minimum dose of $D_G = 4\,\mathrm{kJ\,cm^{-3}}$, yet the dose does not exceed $D_O = 20\,\mathrm{kJ/cm^{-3}}$ on the upper surface. For the upper limit, the long-wavelength component of the incoming radiation is filtered out through a 200-μm-thick preabsorber. It is usually made of Kapton (polyimide), but beryllium or other materials are also appropriate. The key feature is that the material should show a high contrast between soft and hard radiation, with the soft radiation being absorbed.

In order to ensure that resist areas that correspond to shadow regions of the mask are not attacked by the developer, the deposited doses should not exceed the damage dose limit of $D_s = 100\,\mathrm{J\,cm^{-3}}$. This places a minimum contrast limitation on the mask of 200. In order to achieve this high value, the thickness of the mask's gold absorber should be at least 10 μm. For other radiation choices, it may be that mask gold layers should be even thicker. It is imperative to note that the spectrum should be optimized with respect to the radiation source and the resist type and thickness.

1.11.2.5 Development

In order to achieve a predictable production process, the regions of low molecular weight must be selectively soluble in a suitable developer. Furthermore, the specificity of dissolution must be very high, as unexposed polymer at the surface of the substrate will be exposed to the developer for long periods of time as the development process progresses. In addition, a swelling of the polymer during development is not allowed, as this will lead to stress crack formation and propagation.

A measure for the qualification of a good developer is the contrast γ, which should be as high as possible. At the dose D_c the resist will be completely dissoluted, whereas at D_i it will still not be attacked.

$$\gamma = \frac{1}{\log \frac{D_c}{D_i}} \qquad [5]$$

In addition, the development rate is, of course, material-dependent, i.e., from the molecular weight

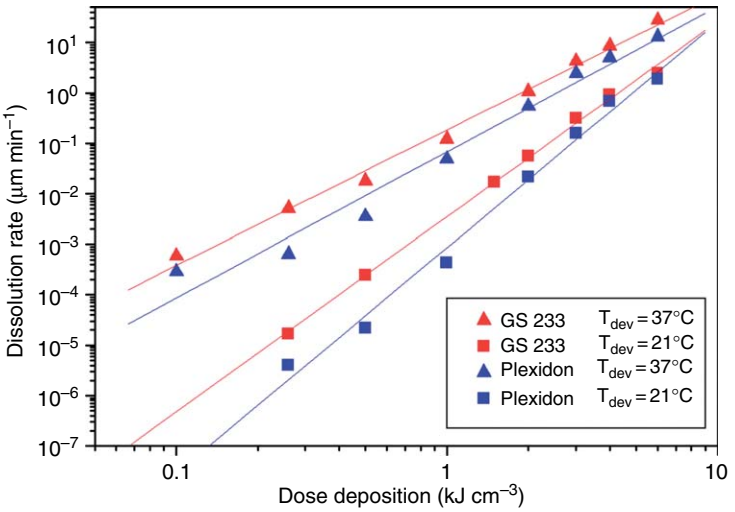

Figure 24 Developer dissolution of two different commercial polymethylmethacrylate (PMMA) brands as a function of the exposure dose.

and the development rate of the unexposed material, and it is crucially dependent on the temperature of the developer.

A developer that satisfies these requirements, suitable for PMMA X-ray lithography, is a mixture of ethylene glycol–monobutyl ether, monoethanolamine, tetrahydro-1,4-oxazine, and water (Ehrfeld *et al.* 1988). The dissolution rate as a function of the deposited dose in the PMMA is shown in **Figure 24**. Two different commercial PMMA types were investigated and the solubility was measured at 37 °C and at room temperature (Achenbach *et al.* 2000).

As expected, the dissolution rate increases with the deposited dose and with the temperature. At lower temperatures, the contrast (in **Figure 24** the slope of the straight line) of the developer increases, i.e., it becomes more selective. The two chosen PMMA brands differ in molecular weight: the Plexidon is cross-linked, whereas the GS233 is not, i.e., it features a lower molecular weight. Consequently, the dissolution rate of the GS233 is larger than that of the Plexidon.

1.11.2.6 Quality of LIGA Structures

One of the outstanding features of the LIGA process is its ability to produce high aspect ratio structures whose sidewalls show vanishing deviation from the vertical and therefore possess constant quality over the entire height of the structure and over all lateral dimensions. **Figure 25** shows a 400-µm-high test structure produced by X-ray lithography. Its width was measured optically as a function of height, and shows a deviation from the perpendicular of only 40 nm per 100 µm height (Mohr *et al.* 1988).

The factors that contribute to this variation are the inclination produced by the scan movements of the substrate through the beam; low selectivity of the developer and direct physical effects brought about by the X-ray radiation (Becker *et al.* 1984); and effects resulting from the construction of masks and samples. The different sources of error are now considered in detail.

1.11.2.6.1 Fresnel diffraction, photoelectrons

Figure 26 shows the effect of Fresnel diffraction at an absorber edge, as well as the influence of photoelectrons produced in the resist. Furthermore, the effect of the divergence of synchrotron radiation is shown.

When an incident light beam is partially shadowed by an edge, then all points along the edge have to be treated as light sources for circularly diffuse light waves. These waves in turn interfere with each other (the Huygens' principle) and lead to the phenomenon of diffraction, i.e., a local variation in light intensity. The variation at a point is a function of the position of the point relative to the edge, the wavelength of the light, and the lateral distance of the point of analysis. As a result of diffraction, instead of a sharp shadow, we obtain regions of lower intensity in the unmasked area and regions of higher intensity in the masked regions. The effect is especially pronounced for monochromatic radiation,

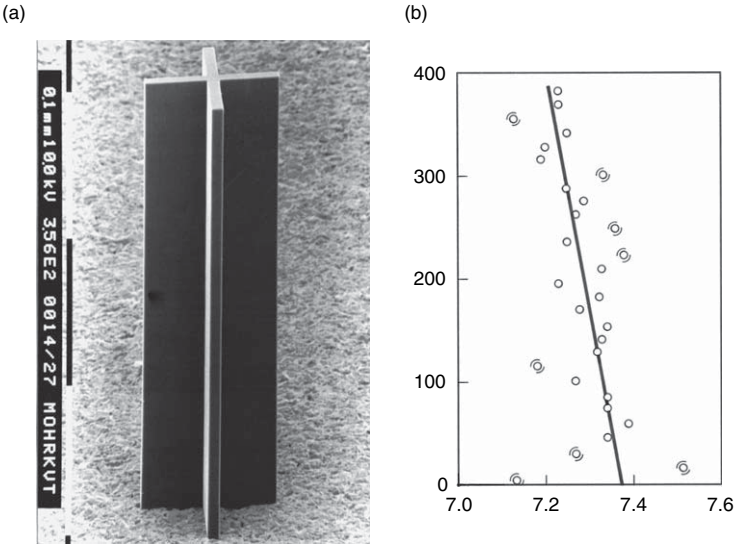

Figure 25 (a) Scanning electron microscope (SEM) picture of the 400-μm-high test structure and (b) measured linewidth in dependence of vertical position. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

where the extinction conditions (path length difference of $\lambda/2$) are exactly met. Now, for polychromatic radiation, the entire spectrum must always be considered at every point. Because the exact conditions for extinction only corresponds to exactly one wavelength at each point, the resultant influence of diffraction is relatively small. The ideal shadow limit due to Fresnel diffraction can be calculated and is found to vary linearly with wavelength. In the wavelength region of interest, i.e., between 0.1 and 1.0 nm, this results in an uncertainty of only 0.1 μm as shown in **Figure 27**, which is calculated for a resist thickness of 500 μm.

Within the resist, the X-ray photons release photoelectrons and Auger electrons. Their reaction with the resist material is the cause of the desired chemical modifications of the resist material. The electrons impact with the molecules of the resist,

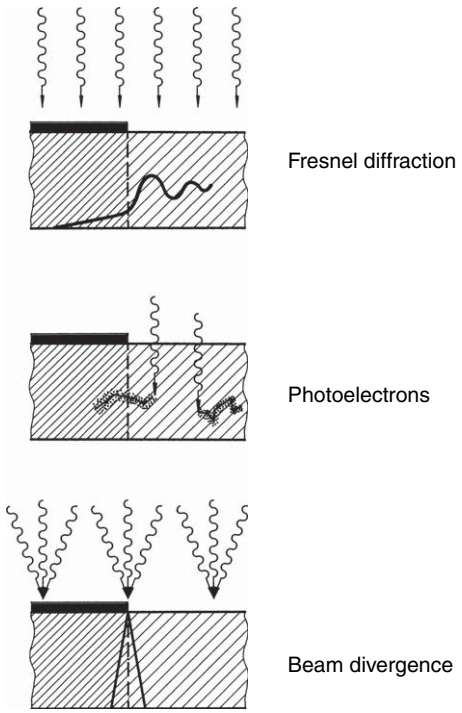

Figure 26 Effects that limit the lateral resolution of X-ray lithography. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

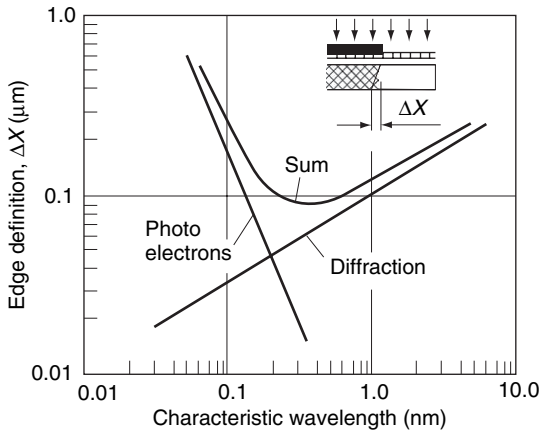

Figure 27 Total error related to Fresnel diffraction and photoelectrons. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

thereby losing some of their energy. Due to their initial energy, they potentially have infinite range so that they can end up in unexposed regions of the resist and thereby reduce the sharpness of the image. The effective range of the electrons varies quadratically with their energy, so this effect increases with the shorter wavelengths of synchrotron radiation (see also **Figure 27**). Again, at the wavelengths of interest, the uncertainty lies around 0.1 μm. The observed error is of course a superposition of both effects and is presented as the sum of both in **Figure 27**. The minimum error is obtained with a wavelength of around 0.3 nm.

1.11.2.6.2 Divergence of radiation

The synchrotron radiation does not propagate perfectly parallel. Its finite divergence has two sources. First, there is a natural divergence due to the finite electron energy of the beam and the second source of divergence is due to oscillations of the electron orbits about the ideal reference orbit, also known as betatron orbits (Koch 1987). Neglecting the betatron orbits, an ideal current filament results in an opening angle that depends on the radiation wavelength. The angle decreases with increasing electron energy.

The divergence due to the betatron oscillation is strongly dependent on the specific details of the synchrotron, as well as position of the tangential point of the electronic orbit. Typical divergence values lie between 0.1 and 1 mrad in the horizontal and vertical directions. Now, in order to analyze the influence of beam divergence on the resulting micropart precision, we need to consider the source points in the electron orbit, which are approximately 10 m removed from the substrate. In addition, we need to consider that the sample is scanned across the beam in the vertical direction. In this way, every point is exposed to a multitude of beam angles. Hence, the vertical edges experience the full effect of beam divergence.

This contrasts strongly with the horizontal direction, where the local divergence at worst leads to a slight inclination of the structure with respect to the perpendicular. At a distance of 10 m from the electron orbit, the maximum rotation from the vertical of a 100-μm-wide structure is expected to be about 0.01 mrad, which of course can be neglected.

1.11.2.6.3 Inclination of the absorber walls to the beam

A relative inclination of the absorber walls with respect to the beam can occur in two ways. First of all, the normal of the mask and sample, which should lie parallel to the photon beam, can only be adjusted to this value to be within a finite tolerance. Second, the mask absorber walls may themselves not be perfectly perpendicular. For example, for masks produced by optical lithography, the angle of the sidewalls can be in the region of 85°.

The dose deposition under a strongly sloped absorber varies considerably. This can be used to an advantage when producing high aspect ratio conical structures, as we can achieve a lateral variation of 0.4 μm over a height of 500 μm.

1.11.2.6.4 Fluorescence radiation from the mask membrane

The absorption spectra of most materials are characterized by edges at which the absorption coefficient increases stepwise with increased radiation energy (*cf.* **Figure 10**). Such increases arise because the incoming photons are energetic enough to excite electrons from the inner K or L shells to the continuum. When such excited states recombine, fluorescence radiation is released proportional to the energy difference of the level. This radiation is generated in the mask membrane and propagates isotropically and of course can also be directed under the absorber, damaging the resist in unwanted areas. In practice, this is noticed after development as a rounding of edges of the resist and, in case of long exposure times, also in an attack of the remaining PMMA structures.

The effect will be especially pronounced when the increase of the absorption coefficient lies in a wavelength region, which overlaps with the primary synchrotron spectrum used for lithography. This is in fact the case for titanium, which is mostly employed for the mask membrane and whose absorption edge lies at 0.497 nm. In the example shown in **Figure 28**, a 1-mm-height structure, irradiated with a titanium mask, shows a rounding radius of 150 μm. The effect is very much reduced to about 2 μm when using a beryllium membrane, as it does not possess absorption edges in the wavelength region of interest (Pantenburg and Mohr 1995).

1.11.2.6.5 Production of secondary electrons from the adhesion and electroplating initiating layer

As discussed in detail earlier, the resist is mounted upon a metallic substrate, usually titanium or gold. The substrate has a considerably enhanced absorption coefficient when compared with the resist

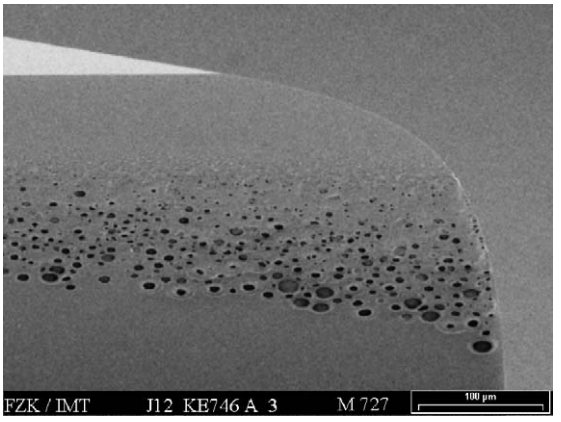

Figure 28 Typical structural loss due to fluorescence radiation on a 1-mm-thick PMMA structure after an exposure through a titanium process mask. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

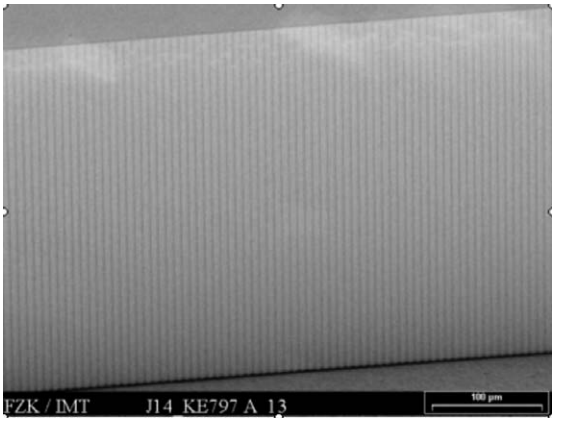

Figure 29 Microprecision component type A, grating of a microspectrometer. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

material. As a result, the effective cross section for secondary electron generation is greatly increased at the interface between the substrate and the resist. Such electrons greatly contribute to resist damage at this interface. Whereas this is useful in areas that are exposed; it has a detrimental effect on masked areas, as the adhesive bond between the resist and the substrate is thereby damaged. Two remedies exist. First, it is wise to raise the thickness of the absorber above the minimum value discussed previously. Second, the fraction of high-energy photons can be reduced by employing special X-ray mirrors.

1.11.2.6.6 Achievable aspect ratios

An important quality measure is the aspect ratio of structures, usually the height of a structure (or feature) versus the smallest achievable lateral dimension. Table 1 provides some examples of the aspect ratios that have been achieved. We distinguish between fairly large type A structures (millimeter to centimeter) that have fine details (nanometer to micrometer), for example, in case of spectrometers, and stand-alone type B microstructure components with lateral dimensions in the micrometer range as in most other cases. The table is illustrated by examples shown in Figures 29–31.

1.11.2.7 Electroforming of LIGA Structures

X-ray lithography produces plastic microstructures directly as end product, and for micro-optical components made of PMMA this makes sense. In many cases, however, metallic parts are required, and for these the formed resist cavities are filled with metal by electroforming. For example, in order to produce high volumes of plastic microparts economically using any of the replication techniques listed in Section 1.11.2.8, robust and shape-retaining metallic mold inserts are required. Galvanic deposition after X-ray lithography is well suited to this purpose. In addition, electroforming is also an important step in producing the gold absorption masks needed for quality X-ray lithography.

Masks are predominantly electroplated in gold, whereas microstructures are typically formed from nickel. Copper plating has not nearly played the same role in LIGA operations. For special needs, alloys are also produced. For example, for high hardness structures, a nickel–cobalt bath is used and for magnetic cores, a nickel–iron bath is employed.

1.11.2.7.1 Galvanic deposition of nickel for the production of microstructures

For the galvanic production of nickel microstructures, as required for mold inserts, a nickel sulfamate electrolyte is employed. It typically contains 75–90 $g\,l^{-1}$ of nickel in the form of nickel sulfamate, 40 $g\,l^{-1}$ of boric acid as a buffer, and approximately 4 $g\,l^{-1}$ of an anion-active wetting agent. The pH of the bath is between 3.6 and 4, and the bath is operated at a temperature between 50 °C and 60 °C.

Electroplating begins on the exposed substrate areas of a lithographically structured resist–substrate sandwich. The substrate is generally covered by an oxidized titanium adhesion layer. The layer is the result of a compromise between a good resist bonding interface and an ideal seeding layer for electroplating. Recent findings recommend the use of solid gold or copper as a seeding layer, but adhesion onto these layers is not good enough.

Titanium is oxidized under the influence of a hydrogen peroxide solution, which forms a ~40-nm-thick nonstoichiometric oxide layer, considerably different from the naturally occurring oxide layer that is only 3 nm thick. It is experimentally observed that the oxide layer shows excellent adhesion to PMMA and is sufficiently conductive to allow electroplating to initiate. The titanium surface is microscopically rough and contains microchannels in which the resist molecules can anchor itself. As a result, both the metal and plastic regions adhere excellently to the substrate (Bacher *et al.* 1992).

In order to attain the highest possible rate of film growth, a relatively high nickel concentration is used in the electrolyte bath. Through this choice, structures with small cross sections are filled at a rate comparable to those with larger cross sections. The alternative would be to use leveling agents. This technique is, however, strongly geometry-dependent, as metal ion concentration levels must exactly match the particular transport situation as dictated by local feature layout, and hence avoided.

The height uniformity of structures of different cross section depends strongly on the electrolyte flow conditions also (Bade *et al.* 1996). Material transport differences are minimized if the electroplating current density is kept small when compared to that dictated by the diffusion-limited flow thickness. As a result, diffusion of ions only takes place as material transport and convective effects are minimized. This is fulfilled for a Reynolds number less than or equal to 2.

Electroplating should proceed in a uniform manner that ensures that uniformity in thickness and quality is achieved not only across the micrometer dimensions of a few microstructures, but also across the entire substrate surface of a few centimeters diameter. A major cause for inhomogeneity in electroplating is a nonuniform current field distribution across the substrate. One way to compensate for

the nonuniform distribution is to use electrical field blends made of dielectric material between the substrate and electrodes.

An anion-active wetting agent present in the electrolyte supports the penetration of electrolyte into the deep and narrow channels of the PMMA resist so that electroplating initiates uniformly across the metallic base plate. Typically, the influence of the wetting agent on the value of the surface tension of the electrolyte saturates at higher concentrations of agent. The optimum value of wetting agent concentration was determined by measuring the contact angle between the PMMA and the electrolyte. For nickel sulfamate electrolytes at 50 °C, an optimum concentration of 0.5% was determined. At this dosage level, the surface tension drops from the original 75 to 25 mN m^{-1}. The contact angle drops from about 75° to approximately 5° after 10 min of wetting time, which is considered sufficient for the purpose. Penetration is additionally supported by evacuating the microstructure plate.

Galvanic deposition of nickel is typically carried out in the range of 1–10 A dm^{-2}, which results in a film growth speed of 12–120 µm h^{-1}. The current density determines the amount of intrinsic film stress, which should be kept below 20 MPa. If a higher stress occurs, large area structures will bend in response and could even detach from the base plate during plating.

Inner stresses typically vary across the thickness of the deposited film (Harsch *et al.* 1988). **Figure 32** illustrates the influence of layer thickness and current density on internal stresses. With increasing current density, the internal film stress changes from compressive to tensile. In this example, it was possible to deposit stress-free layers with thickness above 50 µm by using 5 A dm^{-3}. The concentration of the wetting agent also has an influence on the level of film stress.

When using nickel sulfamate electrolytes, the internal stresses of deposited films can be also controlled through the temperature of the bath. Higher temperatures result in lower internal stresses. It should be noted, however, that high electrolyte temperatures lead to large evaporation rates and hence reduced exposure times of the electrolyte.

The level of the current density also influences the Vickers hardness value of the resulting structure. **Figure 33** shows that lower deposition current densities result in harder metal parts. For example, the peak hardness of 350 Vickers was achieved at a current density of 1 A dm^{-3}. At higher current densities, the hardness first drops rapidly, then more gradually falls away until reaching a measured value of 200.

The hardness variation is due to the simultaneous deposition of hydrogen, which increases with increased current density. One side effect is that released hydrogen bubbles can settle on the metal structure, thereby screening the surface from the electrolyte and forming pores in the structure. These pores show up only when the electrolyte contains impurities, which in turn serve as nucleation sites for bubble formation. Impurities can be dust from the environment, anode deposits, nickel hydroxide, components of the wetting agent and its

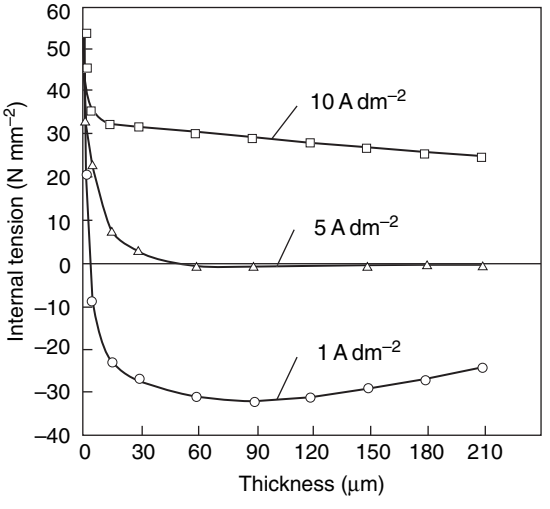

Figure 32 Intrinsic stress on electroplated nickel layer as a function of the layer thickness for different current densities. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

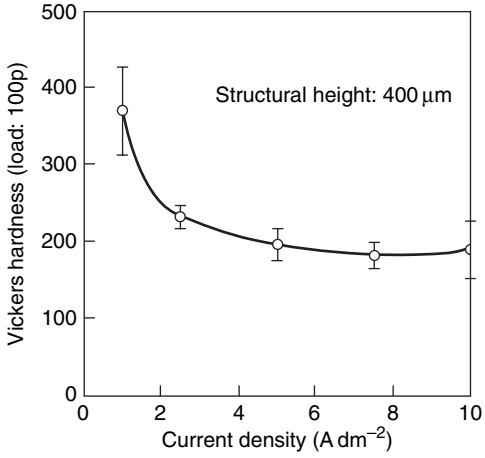

Figure 33 Vickers hardness of electroplated nickel layer as a function of the current density. (Source: Menz W, Mohr J, Paul O 2001 Microsystem Technology, Wiley-VCH.)

decomposition products, and other solid particles. Solid impurities should be continuously removed from the electrolyte through proper circulation through a filter of 0.2 μm pore size.

Defects are caused by an organic decomposition product of the wetting agent in the electrolyte during the course of the electroplating process. By exceeding a critical concentration, an increase in pore formation is observed. The organic impurities are eliminated from the electrolyte via active carbon purification. This has to be carried out regularly, with intervals dependent on the bath load. In addition, over a period of about 14 days, no defects were observed in the electroplated samples while plating with current densities between 1 and 10 A dm^{-3}. However, after this period, the defect rate increases drastically. At this point, the bath is actively carbon purified, which also completely removes the wetting agent. After the addition of fresh wetting agent, the bath is available again for defect-free plating.

Based on the operating parameters presented above, it is possible to completely fill narrow and deep channels in the resist with high-quality metal via electroforming. Surface features of the plastic mold, which lie in the submicrometer range, are copied with high precision. **Figure 34** shows a nickel honeycomb structure that was electroformed as detailed above. The height of the structure is 180 μm, with wall thicknesses of 8 μm. The small nonuniformities visible in the structure are already present in the mask in the form of ridges. As can be seen from the illustration, the resulting top surface of the structure is smooth. The smoothness depends strongly on the roughness of the substrate and the thickness of the deposited layer. In general, for layers above 100 μm we can expect a roughness (R_a) of the top surface at a value somewhat below 1 μm. If required, the roughness can be removed mechanically via polishing, lapping, or milling.

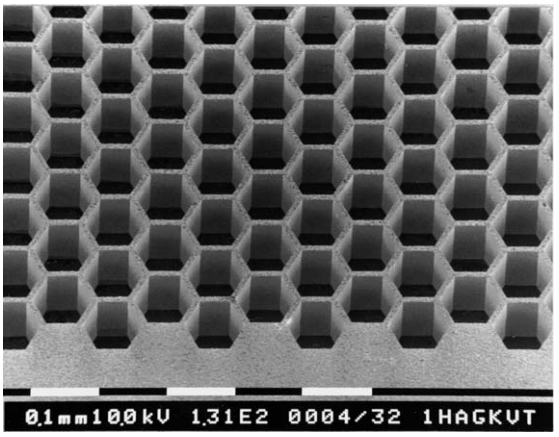

Figure 34 Honeycomb structure electroplated in nickel; the wall thickness is 8 μm, the height of the structure is 180 μm.

1.11.2.7.2 Electrodeposition of further metals and alloys

In principle, LIGA can be used to produce microstructures from any metal or alloy that can be electrodeposited. However, for process reliability, a number of electrolyte requirements need to be fulfilled, including those on microscatterability, wetting, inner stress of the resulting deposited thin film, and the level of gas formation during deposition. Only a few metals can meet these requirements.

Apart from X-ray masks, gold microstructures of several hundreds of micrometers in height have been successfully microstructured. Whereas either cyanide or sulfite gold electrolytes can be used, the sulfitic baths show several advantages as discussed above.

Copper can be plated as microstructures from either sulfamate or fluoroborate electrolytes. Sulfamate electrolytes yield ductile and practically stress-free level layers with high current yield. Organic bath additives are required, though. Because they are difficult to detect, it complicates their regulation in the bath and hence makes the process difficult to control. In addition, copper sulfamate baths are sensitive to impurities. Fluroborate baths also result in high current yield and low film stress, yet do not require any additives and are far less sensitive to impurities. Fluoroborate baths are, however, highly corrosive and the deposited layers are softer on the order of 120 Vickers. When used in conjunction with reactive substrates, a precopper plating layer is necessary. Both baths have been used to successfully produce LIGA microstructures.

Various investigators have produced LIGA structures from metal alloys. A nickel–cobalt alloy was successfully plated from a modified nickel sulfamate electrolyte (Eicher *et al.* 1992). Because the metal obtained is much harder than pure nickel, it is of interest for the manufacturing of mold inserts. Nickel–iron alloys such as permalloy, a mixture containing 80% nickel by weight, are weakly magnetic and feature both a high saturation field strength and a low coercive field strength. These

characteristics are important for the manufacturing of electromagnet cores and hence feature in the design of microactuators.

It is particularly difficult to homogeneously deposit the alloy into microstructures with specified constituents from the appropriate electrolytes. Spatially varying parameters such as the bath temperature and the current density directly influence the local composition of the film. The iron deposition is controlled by diffusion at high current densities. This can lead to iron depletion at diffusion boundary layers and hence to a reduction of iron in the deposited alloy. At lower current densities, the material composition is not influenced by material transport, as ions are replenished sufficiently fast. Nevertheless, the diffusion layer thickness has a strong influence on the material transport, which leads to problems in high aspect ratio cavities, where the diffusion layer thickness can easily reach the same value as the structure's height. Hence, current densities are quite a bit lower than those used for single metal deposition, in the range of only a few amperes per square centimeter (Thommes *et al.* 1995). As a rule of thumb, the highest aspect ratio cavity in a structure will provide the limit on the applicable current density. Based on this rule, uniform composition nickel/iron microstructures have been produced with greatly varying aspect ratio.

The measured magnetic properties of galvanically grown permalloy thin films are comparable to those measured from fused alloys, with the magnetic saturation of 1.1 T being only 5% below the bulk material's value. The difference is accounted for by the mixed crystal structure of the micropart. Whereas the 80–20 alloy showed no difference in properties when measured parallel to and perpendicular to the growth direction, this was not the case for pure nickel and the 50–50 alloy. Anisotropies can be avoided by recrystallization through tempering of the sample. The magnetic saturation can be increased further to about 1.4 T by increasing the iron content to 55%. Beyond this concentration, the saturation drops again. The reason for this change is the transition from face-centered cubic awaruite to body-centered cubic kamacite (Abel *et al.* 1996).

1.11.2.8 Molding

Molding, finally, is the cost-effective process part of the LIGA technology. Molding stands for the innumerous replication of a work and cost-intensive master template whose fabrication starts with the X-ray mask and ends with an electroplated mold insert. This section describes the mold insert fabrication, and then reports very briefly on the applied molding procedures. A detailed description of the fabrication of LIGA mold inserts can be found in (Guttmann *et al.* 2005).

1.11.2.8.1 Mold insert fabrication

Ten-millimeter-thick copper substrates are used instead of silicon or ceramic wafers for the production of LIGA mold inserts. This is a tribute to the electroplating process, which in case of a mold insert does not stop before the metal reaches the upper rim of the PMMA. In order to obtain a rigid and stable metal block with the microstructure incorporated inside, one allows the metal to overgrow the complete PMMA until it forms a closed layer on top of the substrate. The metal is grown to a thickness of at least 5 mm in total. Because of the internal stress that cannot be completely avoided, the metal block tends to bend, and the substrate follows accordingly. The thick copper substrate helps to keep this bending to a minimum. In addition, to reduce the internal stress, the current density has to be kept low even if the metal exceeds the PMMA and has already overgrown the critical structures. Typically, nickel is used for the mold insert, but nickel alloys are also becoming more and more attractive because of better mechanical behavior. **Figure 35** shows such an overgrown nickel block on a copper substrate.

In order to give the mold insert its final shape, the outer contour is defined by wire erosion, as can be seen from **Figure 36**. The first cut planarizes the rear side of the nickel block. Then a step profile is cut into the side of the nickel block. This step profile is

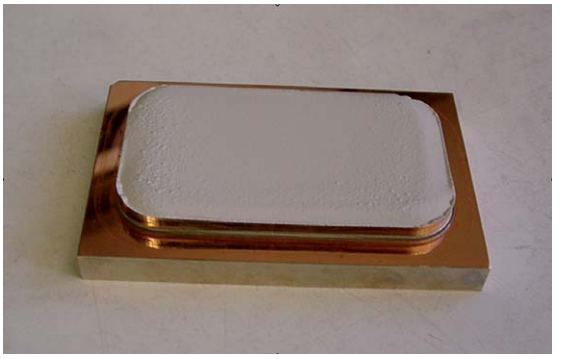

Figure 35 Photograph of a copper substrate with electroplated nickel block on top of it. The polymethylmethacrylate (PMMA) microstructures are completed covered with metal.

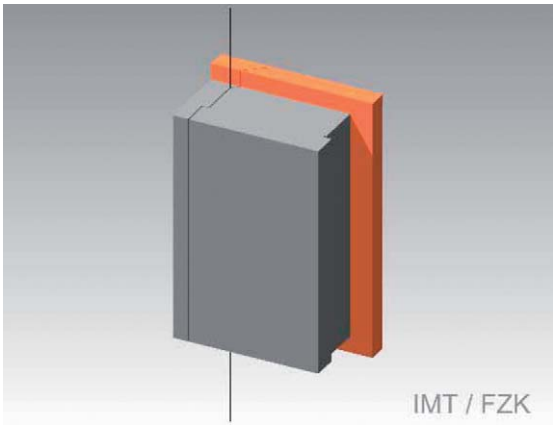

Figure 36 Finishing the outer contour of mold insert by wire erosion.

mandatory for the fixation of the mold insert in a molding machine. Finally, to release the nickel block from the substrate the wire cuts in parallel to the substrate in a depth of 200 µm through the copper. The residual copper layer can be easily wet etched without attacking the nickel.

The surface quality of the front side of the mold corresponds to the surface quality of the original substrate. No surface finishing is needed in the case of sufficient surface quality of the substrate. For optical applications, however, before the removal of the resist, it is possible to process the front of the matrix to the required roughness by milling, lapping, or polishing. After resist stripping, the mold insert features the original PMMA pattern as hollow cavities that can be filled again and again with any polymer that is suitable for replication. **Figure 37** shows an example of a mold insert for the fabrication of microspectrometers (see Section .11.3.2.5).

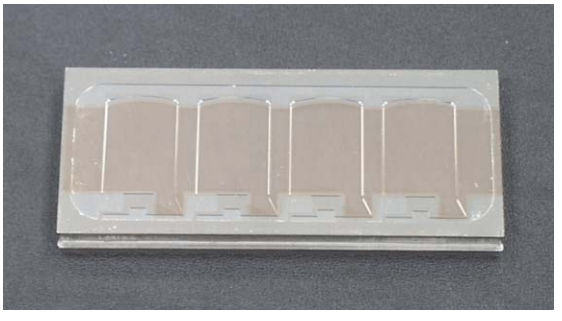

Figure 37 Mold insert featuring the hollow cavities of a microspectrometer pattern.

1.11.2.8.2 Plastic molding in the LIGA process

The mold inserts can be used for reaction and injection molding as well as for hot embossing. They can easily withstand temperatures up to 150 °C and pressures of up to 10 MPa. Even after thousands of molding cycles, the microstructures do not show obvious wear or degradation. Nevertheless, the replication of LIGA microstructures provides some specific challenges that are related especially to the high aspect ratio of the structures. First, the complete filling of the insert with the polymer is a critical process. To fill even the smallest structure details in the depth of the mold, which could be in dimension of submicrometers, the polymer must have a high filling ability, which means a low viscosity. Also during the cooling phase, lunkers and cavities can be formed, which cannot be compensated for later on. Even more difficult is the demolding procedure. On mold release, any tilt of the insert must be avoided, i.e., the mold release should be carried out extremely parallel so that the microstructure will not be deformed or damaged. Finally, measures must be taken to avoid or counteract volume changes due to the shrinkage of the plastic on hardening with process control.

1.11.2.9 Process Variations

In order to cover the widest possible spectrum of applications, the standard LIGA process is extended by numerous process variations. The most important of these are discussed in the following sections. Others will be listed and referenced to.

1.11.2.9.1 Sacrificial layer technology

Micromechanical sensors or actuators often require stationary microstructure parts that remain fixed to substrate in direct neighborhood to moveable microstructures that need to be released from it. In many cases, the movable and the stationary microstructures are mechanically linked so that they form one piece, which makes mounting of separate parts impossible. In addition, many devices need an electromechanical function, i.e., especially the stationary parts have to be electrically connected. These constraints apply to, for example, acceleration sensors, gyrometers, linear actuators, resonators, and similar structures.

In order to overcome these limitations, a sacrificial layer technique that allows for electrical connection on the one hand and partial release of the microstructures from the substrate on the other

hand was developed (Mohr *et al.* 1990) and first applied to LIGA acceleration sensors (Strohrmann *et al.* 1994), microturbines (Himmelhaus *et al.* 1992), and electrostatic motors (Wallrabe *et al.* 1994). **Figures 38–40** explain the process idea. The process starts on an electrically nonconducting substrate, e.g., on a silicon wafer equipped with an isolation layer or on an alumina ceramic substrate. A multifunctional chromium–gold layer is evaporated onto the substrate; during the process it ensures adhesion of the resist and electroplated metal to the substrate, and it serves as a starting layer for the electrodeposition process. Later, it provides electrical connection for the final stationary microstructures. To ensure electrical insulation of the microstructures from each other, the chromium–gold layer is structured by optical lithography and wet etching processes forming contact pads and conductive lines.

In a second step, titanium is sputtered onto the substrate and is also patterned by optical lithography and wet etching. It plays the role of the sacrificial layer, which has to remain underneath the movable structures during the process, and which will be sacrificed at the end in order to release the structures from the substrate.

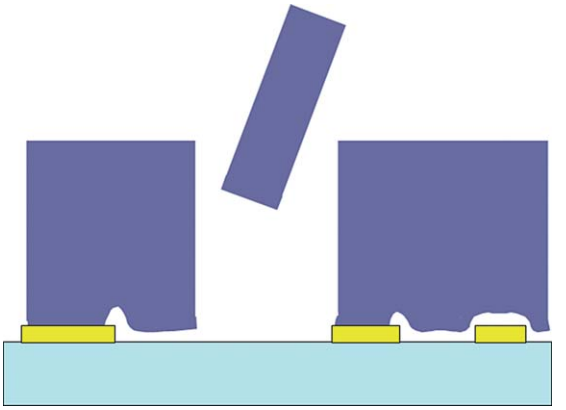

Figure 40 Filling of developed structures with metal and selective etching of titanium in order to release structures from substrate. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

Titanium (Kunz *et al.* 2000) has proven to be a suitable sacrificial layer because it fulfills the following requirements:

- Good adhesion of the resist used in X-ray lithography
- Good initiation and good adhesion of the subsequent electroplating
- Good selective etchability without attacking the other used materials (Cr, Au, Ni, Cu, Al_2O_3, Si)
- Fast underetching underneath structures with large areas

The titanium layer should be thick enough so that the movable structures have a sufficiently large distance to the substrate and are not clamped by etchant residues or impurities. With increasing thickness, however, the precision of patterning with wet etching decreases. A titanium thickness of 3–5 μm is a good compromise between these opposing requirements.

The two masks, the copper–gold and the titanium, that are used subsequently for the optical lithography of the two layers have to ensure an overlap of the etched patterns in order to provide an electrical shortcut among all structures on the substrate for the electroplating during the following LIGA process (**Figure 38**). For X-ray lithography, the substrate is covered in a typical manner with the PMMA. The exposure is performed well aligned to the prepatterned metal layers (**Figure 39**) with the help of

alignment marks on the substrate and on the X-ray mask as described earlier (see Section 1.11.2.2.5).

After electroplating and stripping, the titanium sacrificial layer is selectively etched using hydrofluoric acid, which is shown to be particularly suitable. By undercutting the microstructures that were placed on top of the titanium, they are released from the substrate and become freely movable, while the other parts of the metallic microstructure above the copper–gold layer remain well anchored on the substrate (**Figure 40**). After dicing by laser cutting from the rear side, the electrical connection is made by wire bonding on the prepatterned layer by bond pads and conducting lines.

1.11.2.9.2 Three-dimensional structuring

In principle, the standard LIGA process, whereby the structuring is carried out by a shadow projection, allows only the production of structures with a constant structure height and perpendicular walls. However, many structures require a variation in geometry in the third dimension. This can be achieved in simple forms by the structuring of different levels (Müller *et al.* 1996, Wallrabe *et al.* 2002) (stepped structures), by tilting of masks and substrates relative to the X-ray beam (Feiertag *et al.* 1997) (inclined structures), by careful exposure and melting processes (Göttert *et al.* 1995) (structures with spherical surfaces), or by effective use of secondary radiation (Göttert *et al.* 1995) (conical structures). All these processes are not be described here in detail, and we refer to the mentioned literature.

Another approach for the fabrication of almost fully 3D LIGA structures was pursued at the Ritsumeikan University, Kusatsu, Japan (Tabata *et al.* 2002). During the X-ray exposure, the mask can be moved relative to the substrate in the horizontal and vertical directions, the substrate can be rotated and tilted toward the synchrotron beam, and even a multimask process can be run. The multi-degree-of-freedom X-ray scanner is schematically shown in **Figure 41**.

By combining the exposure features in a clever way, not only inclined structures can be produced but also gray-tone lithography can be performed, resulting in microstructures that have nonconstant lateral dimensions across their thickness. Upon movement of the mask a continuous lateral dose profile can be deposited in the resists in contrast to a stepwise profile as was assumed in this chapter so far. The result becomes clear from **Figure 42**. A simple line pattern can lead to purely inclined lines when the mask and the substrate are just tilted during the exposure. Combined with a lateral mask movement, the dose deposition and the penetration depth

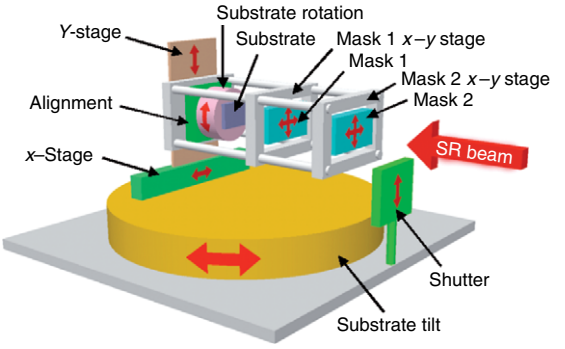

Figure 41 Multi-degree-of-freedom X-ray scanner. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

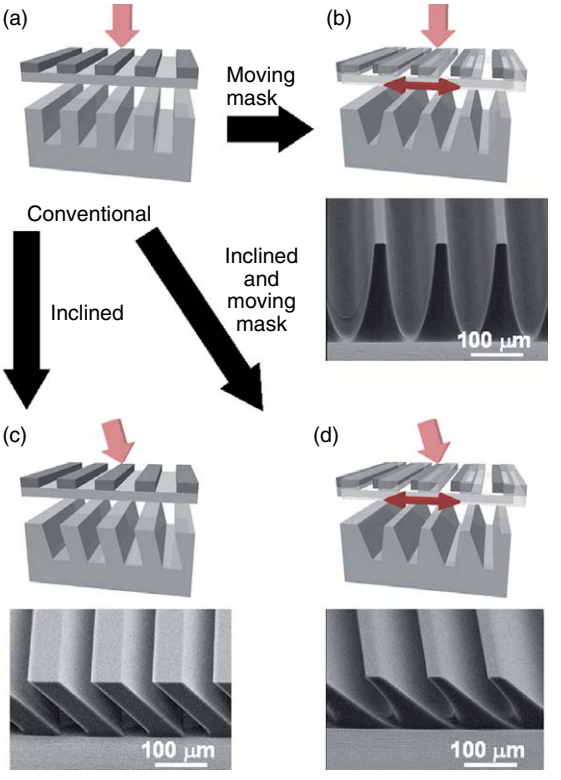

Figure 42 Principle of X-ray gray-tone lithography: upon moving the mask above the resist a continuous dose profile can be deposited. vary across the line pattern. After development, this results in a linewidth, which is smaller at the top than at the bottom and which, in addition, is tilted versus the normal axis.

Due to the inhomogeneous X-ray dose deposition in the resist, special care must be taken with the dose profile and the development of the structures. For a better understanding of the process, dedicated simulation tools have been developed that allow an accurate prediction of the process parameters and the feature geometry (Hafizovic *et al.* 2003). **Figure 43** shows as an example of a predicted resist profile at different stages of its development. The exposure was done in two simple steps. First, the overall rectangle was exposed with a dose, which is not sufficient for complete development. Second, only the center part was exposed for a second time. The developed profile does not simply show two levels with vertical sidewalls at the edges but with distinct slopes at the border. These slopes are related to a decreasing development rate with a decreasing deposited dose in the depth from the first exposure.

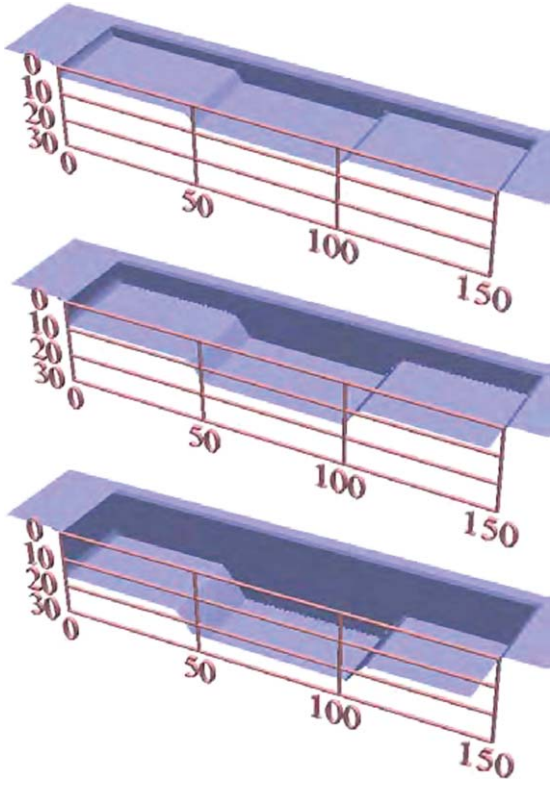

Figure 43 Resist profile at three different development times after a two-step exposure: *x*- and *y*-axes both represent dimensions in micrometers.

1.11.3 LIGA Technology Applications

1.11.3.1 Fields of Application

LIGA structures are typically from polymer or from metal. The commonly used polymer is PMMA because it can be patterned directly by X-ray lithography, and it is also very well suited for molding. Because PMMA also has a very good optical transparency in the visible light range, it is a perfect material – and LIGA a perfect technology – for applications in micro-optics. On the other hand, microstructures from metal are electrically conductive and therefore useful for actuators, as, for example, for electrostatic actuators, but more than that for electromagnetic actuators because soft magnetic FeNi alloys can be easily deposited by electroplating. In addition, metallic microstructures provide a good mechanical stability and can be used for most classical mechanical applications such as for gear tracks. Hence, this part of the chapter that reports on the applications of LIGA technology has four subsections: the first subsection covers the field of micro-optics made from polymer, which are either patterned by direct lithography or by molding. The second subsection describes some optical MEMS (MOEMS) that are made from metal because they incorporate electromechanical actuators, the third subsection gives an overview on mechanical applications also made from metal for stability reasons, and the fourth subsection reports on other applications that do not fit to the three previous subsections.

1.11.3.2 Optical Applications Made from Polymer

Striving for cost reduction through higher integration and on-going miniaturization, there are two basic technological approaches for micro-optical systems: a fully integrated fabrication sequence and a more modular approach. The choice as to which is best suited is a question of the available processes and of the respective yield, of the number of pieces to be fabricated, and most of all of the complexity of the system and the variety of the integrated functions (Ruzzu *et al.* 2003, Wallrabe and Mohr 2003). In the case of lower production numbers, and for the combination of several functional components, a modular design and fabrication are often the better choice. The processes are easier and safer, and one can work with pretested components that help to enhance the yield. This is exactly a case of designing

and manufacturing where LIGA perfectly matches the requirements. Therefore, many of the applications described in this subsection concentrate on micro-optical systems for telecommunication and sensors, which follow the modular approach, or at least a partially modular approach.

A micro-optical system is defined to be modular if its diverse functions are not fabricated in one common fully integrated fabrication sequence and/or if they are not integrated on one and the same substrate. In this section, they typically consist of a micro-optical bench that not only integrates some optical functions but also features alignment aids for other functional components. Examples for pure optical functions are light transfer, refraction and diffraction, imaging, filtering, beam splitting, or image superposition. Electrical or optoelectrical functions can be light generation, light detection or analysis, electronic circuitry, or current/voltage supply to optoelectrical components.

In the following, we start with the description of some elementary optical components such as cylindrical lenses, X-ray lenses, and multifiber connectors. We then introduce the principle of optical bench using a heterodyne receiver as an example. Afterward, we describe the LIGA spectrometer and a distance sensor.

1.11.3.2.1 Cylindrical lenses

Lenses are among the most elementary optical elements. In the macroscopic world, they are made of glass as well as of transparent polymer, in many cases of PMMA. Hence, lenses seem as if they could be easily miniaturized and manufactured by means of LIGA technology. This is true to a limited extent. Like all microstructure technologies, LIGA is a 2D process. Normally, the third dimension is simply the height or the thickness of the structures, whereas geometrical variations in the third dimension are normally restricted to a few different level heights. Only the moving mask technology of the Ritsumeikan University (Tabata *et al.* 2002) (see Section 1.11.2.9.2) allows for fairly free shapes in the third dimension. As a consequence, spherical lenses, as they are common in classical optics, cannot be fabricated. Cylindrical lenses, however, are very well suited for LIGA fabrication, especially for direct X-ray lithography. Because cylindrical lenses can focus the light only in one direction, which results in a focal line instead of a focal spot, it is necessary to combine two of them crosswise. The focal width can be easily determined by the lens radius, of course depending on the refractive index of the PMMA, which is around 1.5.

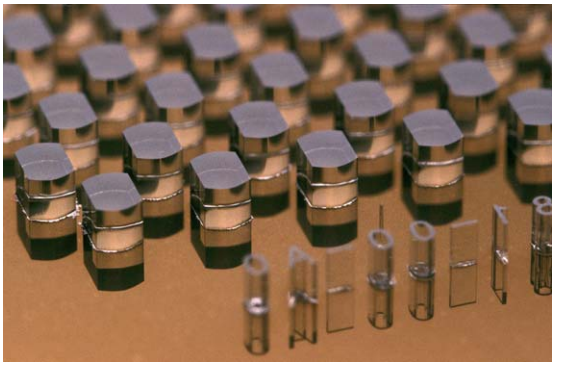

Figure 44 Array of cylindrical lenses with a focal length of approximately 10 mm. The polymethylmethacrylate (PMMA) thickness is 750 μm. The mirror image of the lenses is reflected from the substrate. An identification number together with its mirror image can be seen in the front part.

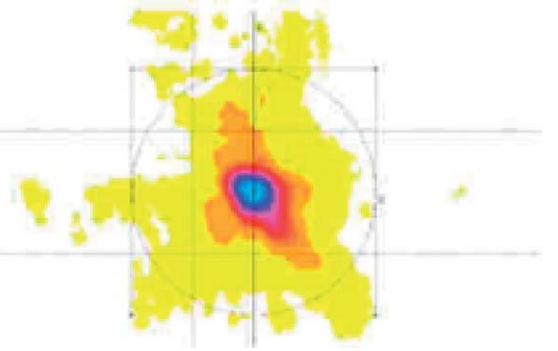

Figure 45 Spot of a horizontally oriented cylindrical lens crosses with a vertical focusing mirror; the full-width at half-maximum is 20 μm.

A photograph of a lens array that was patterned on a silicon substrate in 750-μm-thick PMMA layer by X-ray lithography is shown in **Figure 44**. The substrate is covered by an oxidized titanium layer, which serves as an adhesion layer for the PMMA and also as a sacrificial layer in order to release the lenses from the substrate. **Figure 45** shows a spot intensity distribution from such a single cylindrical lens combined with a focusing mirror (*cf.* Section 1.11.3.2.6). The center of the spot is fairly circular, and the full-width at half-maximum (FWHM) is about 20 μm. The focal length of the lens is 25 mm and the surface roughness is on the order of 20 nm.

Of course, lens arrays as shown in **Figure 44** can also be nicely replicated by molding. However, releasing them from the substrate directly after

X-ray lithography is much easier than after molding. In the first case, sacrificial layer etching is a straightforward and easy to perform process because no residual PMMA layer prevents the etchant to get in contact with the sacrificial layer. Molding such a lens array, however, always results in a residual polymer layer underneath the lenses, which connects the lenses at their bottom side. This residual layer has to be either dry-etched, which would attack the optical lens surface too and is therefore not recommended, or mechanically removed by back side polishing. Another advantage of sacrificial layer etching after pure X-ray lithography is the fact that one may stop etching shortly before the complete release of the lenses from the substrate. In this case, the lenses remain slightly attached to the substrate but maintains their position and, even more important, their orientation. This is of tremendous help for the subsequent lens assembly in any optical system because knowing the orientation enables the assembling person or the assembling machine to touch the lens where it is not risky, i.e., where it has no optically important surface. Hence, if one finally summarizes the effort to obtain individual high-quality lenses, the choice of using direct X-ray lithography and abandoning molding is often the better option.

1.11.3.2.2 Ultra-high X-ray lenses in SU-8

A very new optical application for LIGA cylindrical lenses arises from the development and fabrication of X-ray lenses. Research in X-ray optics is triggered by a large number of potential applications ranging from space-based X-ray telescopes and focusing or imaging systems for synchrotron radiation analysis to medical imaging. A recent approach, first proposed (Tomie 1996) and demonstrated (Snigirev *et al.* 1996) in the 1990s, is the application of lenses for X-rays. Such lenses function as their counterparts for the visible spectral range by refraction of electromagnetic radiation. For X-rays, however, materials have refractive indices of slightly less than 1, typically 0.99999. This small difference between air and materials is generally exploited for total reflection of X-rays at mirror surfaces when irradiated under small glancing angles. X-ray lenses are based on the fact that air (or vacuum) is the medium with a higher refractive index than the surrounding matter. A hole in a piece of metal therefore acts as a cylindrical lens (Snigirev *et al.* 1996). However, the hole shows a very large focal length due to the small differences in refractive indices. For achieving useful focal lengths with X-ray lenses, many individual lenses are arranged along the optical axis.

Modified LIGA techniques are employed to produce X-ray lenses with superior performance (Nazmov *et al.* 2004a). The lithographic process allows for producing several different lens systems in parallel, e.g., for different wavelength ranges and/or focal lengths. The lateral geometries can be chosen absolutely free for optimization of optical properties and correction of aberrations.

Two materials have been evaluated for the matrix in which the air lenses are embedded: SU-8 epoxy for lower photon energies at 5–50 keV (Nazmov *et al.* 2004b) and electroplated nickel for higher energies >40 keV (Nazmov *et al.* 2005). A major breakthrough for X-ray lenses was the use of negative tone SU-8 resist that can be patterned to high accuracy with DXL. The cross-linked areas are rather stable upon further irradiation. Hence, they can be directly used for X-ray lenses even when exposed to high-intensity X-ray beams.

Various different lens designs (**Figure 46**), for linear as well as double focusing, have been tested

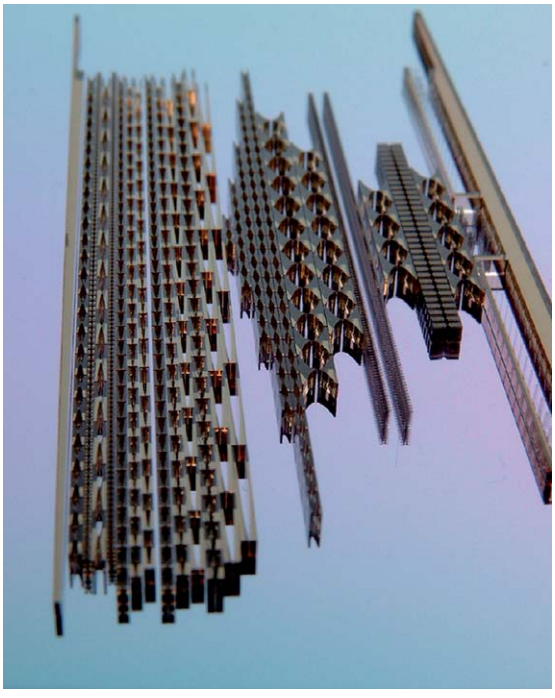

Figure 46 Twenty X-ray lens systems: the optical axis is along the individual rods. Lens details are displayed in the inset. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

at various synchrotron radiation facilities and the results have been compared to theoretical calculations. For the European Synchrotron Radiation Facility (ESRF) in Grenoble, dimensions of the focal spot are as small as 300–900 nm limited only by the demagnified X-ray source size, by diffraction, and by fabrication inaccuracies. **Figure 47** shows the respective lens system. The lenses are tilted with respect to the surface. A second lens system following this is tilted to the other side. By such an arrangement, a point focus can be achieved rather than a line focus. The gain in intensity as compared to a pinhole with the same dimensions was found to be approximately 5000.

1.11.3.2.3 Multifiber connectors

A device between a simple optical component and an optical bench is a multifiber connector that allows the parallel coupling of 16 optical fibers (Wallrabe *et al.* 2002). It consists of two plastic pieces out of PMMA: one for the alignment of fibers and guide pins with five rows of highly precise alignment structures and the other for their fixation and protection. Elastic ripples in the sidewalls of the alignment structures facilitate fiber and pin insertion, as can be seen in **Figure 48**, and make the connector insensitive to variations in fiber diameter and dust. The gap between the alignment structures decreases successively from the last row to the first row facing the opposite connector. This enables a very straightforward passive alignment and assembly of the fibers, without the need for micropositioning. Because the gap at the front face is 2 µm smaller than the fiber diameter, the fibers are softly clamped between the alignment structures, thus allowing an easy handling during the on-going assembly. UV curing adhesive is filled into the device through a hole in the cover piece and spreads into the coupler by capillary forces alone. The possibility of using fast UV-induced curing glue instead of epoxy resin that requires longer processing times in an oven is a positive trade-off of the fact that the couplers are made from transparent polymer. Finally, the front face is polished. The pins of both connectors to be coupled are inserted into a similar precise coupling adaptor as shown in **Figure 49**. If the pins damage their respective holes in the adaptor, e.g., due to frequent

reconnection, the adaptor can be replaced easily, whereas the fibers and connectors can be maintained in their assembled form.

For single-mode fibers, the coupling losses are in the range between 1 and 2 dB, on an average at 1.5 dB, and for multimode fibers the reach is 0.5 dB, as can be seen from **Figure 50**. The solid symbols indicate the best connection between the two connectors that was observed from a set of 50 connectors. The connectors are fabricated by means of plastic microinjection molding from PMMA or PC. The tool was fabricated by LIGA technology in combination with microprecision engineering as described in detail in (Wallrabe *et al.* 2002). The connectors are commercialized under the name RibCon® by Spinner Company (www.spinner.de).

1.11.3.2.4 Heterodyne receiver

The optical heterodyne receiver is a perfect demonstrator example for the optical bench approach because it combines various optical and optoelectrical functions. The heterodyne receiver works like a radio for light; hence, it is a wavelength filter for telecommunication. The needed functions are light input, beam collimation, beam splitting, polarization splitting, and finally detection by photodiodes. These totally different tasks call for a modular approach in order to avoid complex, difficult, and expensive processes. **Figure 51** shows the setup of a heterodyne receiver. In this case, two incoming light beams need to be split and superimposed (Ziegler *et al.* 1999). The signal beam and the beam from a local reference laser are coupled into the system using monomode fibers. The light is collimated by ball lenses and then split into the two polarization states. Upon reaching the next optical surface, the beam of each polarization state is again split by 50% and is simultaneously superimposed with the respective beam from the opposite light source. Each of the four final superimposed beams is detected by a photodiode. The system consists of a ceramic chip on which exclusive alignment structures out of polymer are patterned using direct X-ray lithography. The fibers, the ball lenses, the prisms for the polarization beam splitters and 50/50 beam splitters, and the diodes are separately manufactured components. All these additional components are assembled in a fully passive manner on the chip. They are simply pushed toward the alignment structures and subsequently fixed by UV curing glue. The electrical connection of the diodes is achieved through gold tracks, which are

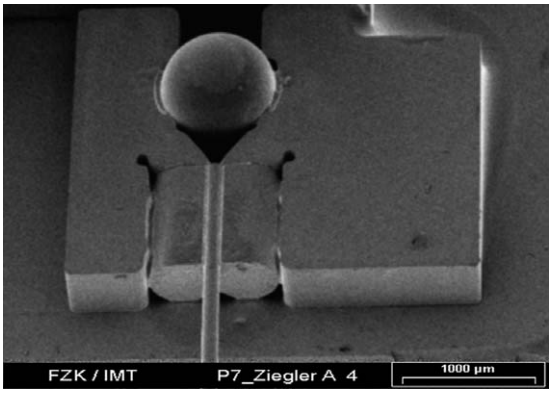

Figure 52 Scanning electron microscope (SEM) of an optical fiber on top of a fiber alignment mount in front of a ball lens; the parts are assembled into the LIGA positioning structures. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

prepatterned on the substrate by optical lithography and wet etching.

Another quite often-used concept is the fixation of the optical fibers. As the altitude of the optical axis is defined by the radius of the ball lens (here 450 µm), the fiber with a diameter of only 125 µm needs to be levered to the same height. This is done by a fiber mount, as shown in **Figure 52**. The fiber mounts are also LIGA devices; however, they were fabricated on a separate substrate with a suitable resist thickness (1 mm) in a vertical orientation, in analogy to the cylindrical lenses that was explained before. Afterward, the fiber mounts are released from the substrate by sacrificial layer etching, and they are assembled in a flipped orientation, i.e., with the axis parallel to the substrate.

From the superposed intensity pattern that was depicted with a camera at the position of one of the diodes, it follows that the assembly accuracy in all directions is on the order of 1 µm across the substrate of size 1 cm^2. This very good result proves the efficiency of the modular approach on the one hand and of the ease of passive assembly on the other hand.

1.11.3.2.5 Spectrometer

The LIGA-made microstructures of the heterodyne receiver have a purely mechanical function because they are used for alignment. In many other cases, they may also have a very distinct optical function, as, for example, in microspectrometers, one of which is illustrated in **Figure 53**. The LIGA spectrometer

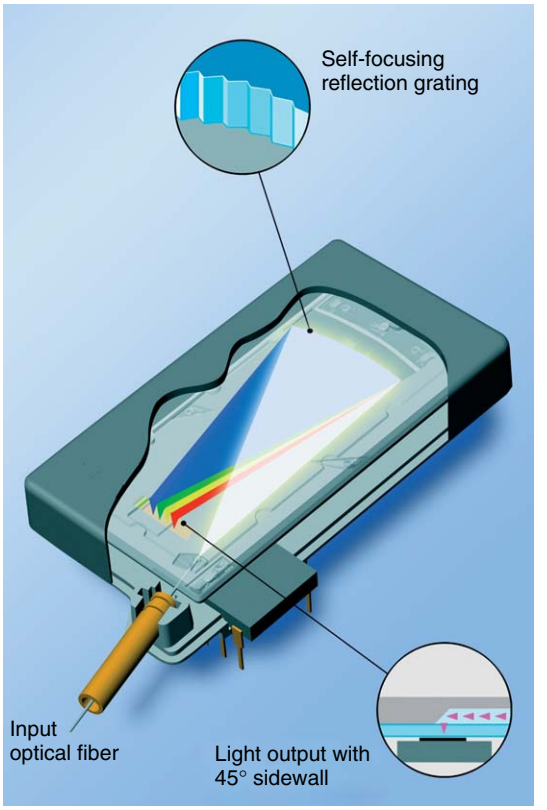

Figure 53 Principle of microspectrometer for visible light: the device is molded in polymethylmethacrylate (PMMA) or polycarbonate (PC) and coated with reflective layers.

was developed for visible and infrared light. The light is coupled into the device by an optical multimode fiber. In a former design, the light was guided using total internal reflection in a three-layer polymer waveguide with adapted refractive indices. Today's design features a hollow waveguide with reflective coating on the top and the bottom surface (Krippner *et al.* 2000). The in-coupled light spreads into the free space of the spectrometer toward a reflecting and self-focusing grating, which diffracts the light and thus separates it spatially into its constituent wavelengths. The grating is typically blazed to the first- or second-order refraction, which means that the simply reflected part of the light will also be reflected to the respective angle, thus enhancing the light intensity there tremendously. In addition, for the self-focusing, the grating is arranged on a Rowland circle, as becomes clear from **Figure 54**. This allows the light to be focused at least horizontally in order to strike just a minimum number of pixels on a photodiode array that is aligned on top of the waveguide. In order to deflect the light out of

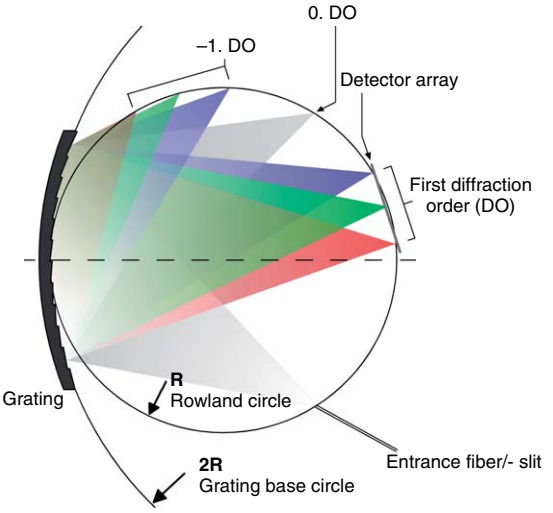

Figure 54 Arrangement of the grating on a Rowland circle leading to a horizontal self-focusing of the light.

Figure 55 BiliChek system for the detection of bilirubin (a jaundice indicator) in newborn babies. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

plane toward the diode array a 45°, mirror is patterned at the focal line. The overall size of a visible light spectrometer is about 20 mm × 13 mm, i.e., it is fairly large. The grating constant, however, is only 1.5 µm with a depth of the teeth of only 0.2 µm. In the case of infrared spectrometers, the grating constant and the overall size increase correspondingly. The spectral resolution is greater than 10 nm for visible light and greater than 15 nm at a wavelength of 1.7 µm. The spectral accuracy is 2 nm and the signal-to-noise ratio greater than 5000.

The spectrometer is produced by hot embossing or injection molding in PMMA or in PC using a nickel or an iron–nickel molding tool. After the molding step, a gold layer is sputtered onto the polymer components in order to make the optical surfaces reflective. The photodiode array and some electronics are assembled upside down on top of the spectrometer. A variety of different spectrometer designs for different application purposes are produced in volume by the company Böhringer Ingelheim microParts (www.boehringer-ingelheim.de/produkte/mikrosystemtechnik/Microtechnology/index.jsp). These modules form the key components of portable measurement systems for various applications. Three examples are given here: the BiliChek system (http://bilichek.respironics.com/), which is an instrument for the noninvasive measurement of the bilirubin concentration of newborn babies (**Figure 55**), the HemoNIR system (www.nirdiagnostics.com), which measures a number of blood parameters such as total-Hb, Met-Hb, and carboxy-Hb from a blood sample of less than 10 µl, and the IdentaColor system (www.identa.dk), which is a small portable tooth color measuring instrument allowing dentists to select the optimum color of the new ceramic insert.

1.11.3.2.6 Triangular distance sensor

Another application that relies on a head-over assembly of the optoelectrical devices is a microdistance sensor that works on the basis of the triangulation principle (Oka *et al.* 2001), i.e., the position of the spot on a sensor's detector is dependent on the distance to the object being measured. The distance sensor is divided into two functional units: a passive optical chip, again fabricated by LIGA technology, including curved mirrors, 45° mirrors, and alignment structures for cylindrical lenses, and an electro-optical chip with a laser diode, a photodiode, and a position-sensitive detector (PSD). Both chips are again mounted head-over to form an optoelectromechanical sensor system. For easy assembly, two microspheres of glass are used as position aligners of the LIGA and the silicon chip (**Figure 56**). First, the microspheres are placed into pyramidal grooves on the silicon base, thus centering themselves. Second, the optical chip with two respective cylindrical holes for the spheres is positioned head-over above the silicon chip and is carefully laid down. Starting from this moment, the assembly is a blind process because of the opaque substrates. The only requirement is that the cylinders are placed somewhere above the glass spheres, i.e., with a prealignment accuracy of several tens to several hundreds of micrometers. The upper chip is then

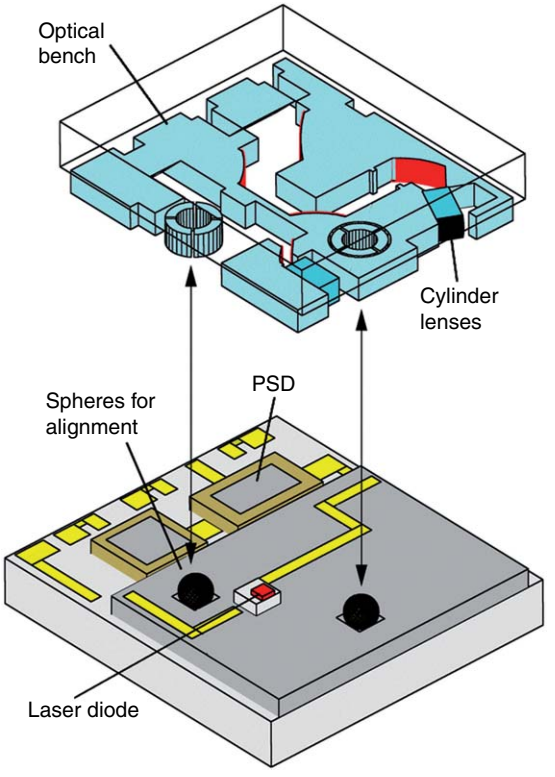

Figure 56 Two chips of a distance sensor are mounted head-over using glass balls as alignment aids. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

slightly pushed downward and aligns itself, while the cylinders slip above the spheres.

The optical components on the LIGA chip are made from PMMA either by direct lithography or by hot embossing and are coated with an evaporated gold layer in order to make the mirrors reflective. The two chips are shown in **Figure 57** before the head-over assembly is performed. Cylindrical lenses that were patterned on a separate substrate and released from it by sacrificial layer etching (*cf.* Section 1.11.3.2.1) are positioned in the illumination and detection light path of the optical bench after the gold evaporation. The light emitted from the edge-emitting laser diode is then focused by a lens and an additional curved mirror that is located directly in front of or behind the lens.

Due to the free lateral shape options of LIGA technology, the optical bench, especially the shape of the curved mirrors, is designed to allow for a linear output signal of the sensor. A 45° mirror at the end of the detection path guides the light toward the PSD,

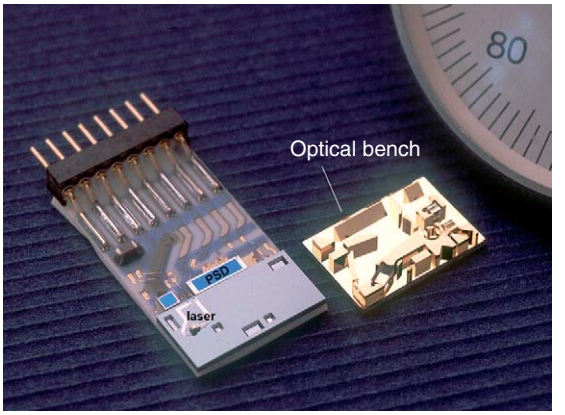

Figure 57 The LIGA-made optical bench and the electro-optical chip of a distance sensor before head-over assembly. PSD, position-sensitive detector.

which is a part of the electro-optical chip. The measured signal of the PSD is normalized and compared to a linear fit as shown in **Figure 58**. The linearity error that is well below 1% is also plotted in **Figure 58**.

1.11.3.3 Optical MEMS

In contrast to the optical systems presented so far, MOEMS, as they are sometimes called, typically combine optical function with a mechanical or an electromechanical function. In many cases, the latter is represented by an actuator in order to move mirrors or to control the optical path in any way that may be required. Generally speaking, one could postulate that mechanical function is provided by all kinds of alignment structures or positioning aids and by fixing and clamping structures. Electromechanical function is provided by actuators, heaters and coolers, and also by mechanical sensors. The electrical part of it mostly requires electrical conductivity of the devices. Hence, in contrast to the earlier part of the chapter, we will now deal with LIGA microstructures that are electroplated in metal.

1.11.3.3.1 Optical cross connector with rotating mirrors

A first example for this kind of LIGA microsystems is an optical cross connector. A fiber switch array combines a LIGA-fabricated micro-optical bench, as described above, with rotating mirrors that are arranged in a matrix scheme (Ruzzu *et al.* 2000). **Figure 59** shows the concept for an $N \times N$ switch. The light from the fibers is collimated onto the mirror surfaces and refocused onto the output fibers

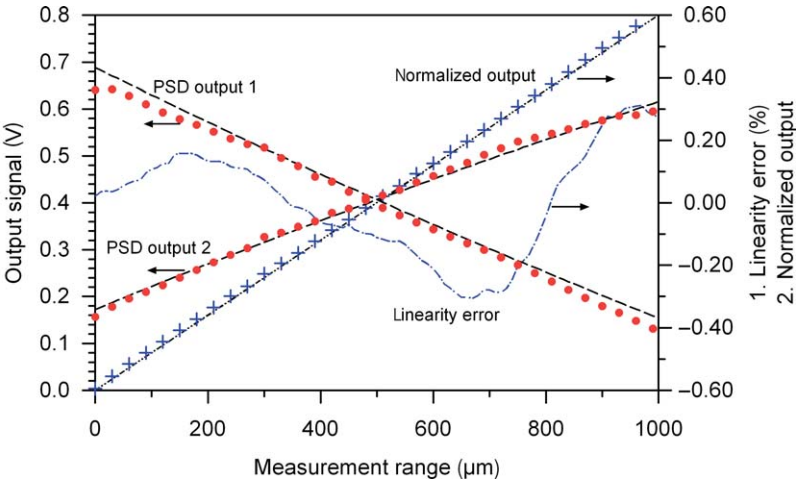

Figure 58 Normalized position-sensitive detector (PSD) output signal as a function of the distance of the measured object. The red line represents the measured results and the blue line a linear fit to the data. The right axis of the graph shows the linearity error of the sensor.

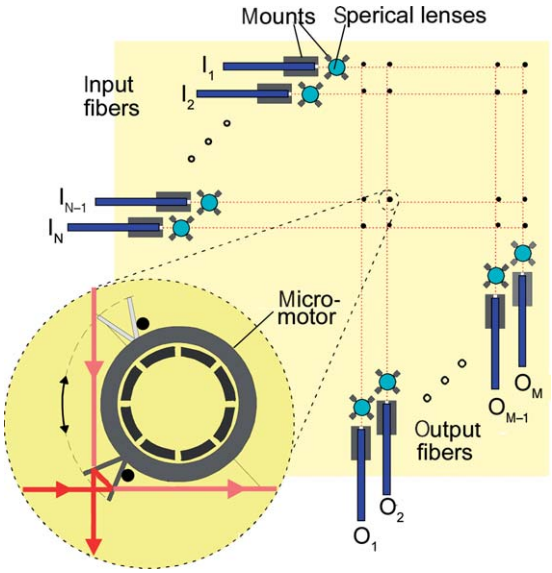

Figure 59 Schematic view of an optical cross connect; rotating mirrors at the beam junctions can be switched either to reflect the beam or to let it pass. Figure 60 Optical bench with lens and fiber alignment structures and electrostatic micromotors made from nickel. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

by spherical glass lenses. Fibers and lenses are passively aligned with the help of fiber mounts, and the alignment stops in the optical bench. In order to achieve uniform insertion losses for all channels, the fibers are arranged in such a way that all optical path lengths are equal. The mirrors are attached to the outer side of the electrostatic micromotors that swivel the mirrors in and out of the beam path. Mechanical stops define the correct end position of the mirrors. The mirrors were designed as double mirrors in order to ensure a precise 90° reflection. The optical benches, the static motor parts, and the mirror stops are fabricated simultaneously using X-ray lithography and subsequent electroplating of nickel on a sacrificial layer. The rotors with the attached double mirrors are manufactured similarly on a separate substrate. They are released from it and are manually placed above a ring-shaped bearing surrounding the stators. The fiber mounts out of PMMA are patterned on a third substrate. **Figure 60** shows a close-up view of a fully assembled 2×2 switch matrix. On the left side, the fiber on the

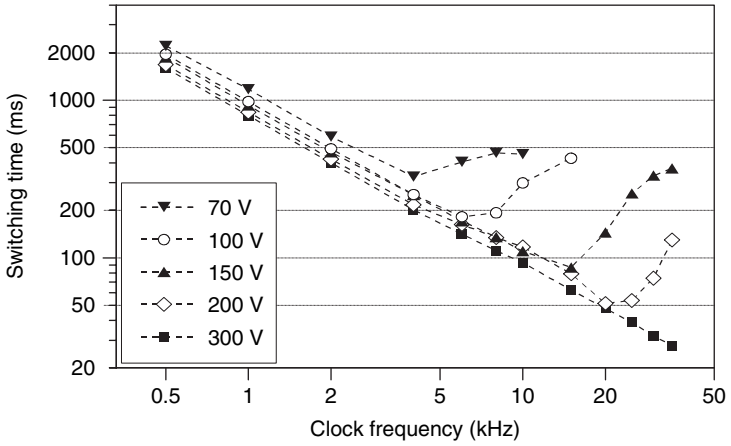

Figure 61 Switching time as a function of the clock frequency for various driving voltages. (Source: Ruzzu A, Haller D, Mohr J, Wallrabe U 2003 Optoelectromechanical Switch Array with Passively Aligned Free-Space Optical Components. *J. Lightwave Technol.* **21(3)**, 664–671.)

fiber mount and a lens can be distinguished. They are pushed toward the stop structures of the optical bench. The mirror in front of the lens is in the on position and the mirror below in the off position.

The electrostatic motors are designed as wobble motors. In contrast to other wobble motors as described (e.g., in Samper *et al.* 1999), the stator poles do not surround the rotor, but they are placed inside the ring-shaped rotor in order to allow the attachment and movement of the mirror (see **Figure 59**). The motor is actuated at voltages ranging from 70 to 300 V. **Figure 61** gives the switching time as a function of the clock frequency at which the voltage is applied successively to the stators. The lower the driving voltage the lesser the clock frequency at which the motor gets out of step. The shortest switching time was 30 ms at 300 V. An optical characterization of the system results in a crosstalk greater than 90 dB between the channels, in a minimum insertion loss of 3 dB with a repeatability of 0.5 dB.

1.11.3.3.2 Oscillating modulator for infrared light

Besides using electrostatic actuation, a unique feature of LIGA technology is to use electromagnetic forces. In this case, the structures are electroplated in permalloy, which is a soft magnetic alloy of 80% nickel and 20% iron. A first application example is a modulator, i.e., a chopper for infrared light and used for the suppression of noise in infrared spectrometers by using lock-in techniques (Krippner *et al.* 1999). The working principle becomes clear from the demonstrator, which is shown in **Figure 62**. Alignment structures for input and output fibers are patterned onto a ceramic substrate in parallel with a movable shutter, looking like a little hammer. The hammer is a part of a magnetic circuit, which is constituted by the coil in the upper part of the picture, and the yoke that guides the magnetic flux generated through the current in the coil toward the hammer. Due to the decrease in the resistance of the magnetic circuit the shutter is pulled backward between the pole shoes of the circuit, thus enhancing the metallic cross section for the magnetic field. Such an actuator is often called a variable reluctance actuator. The yoke for the coil was manufactured

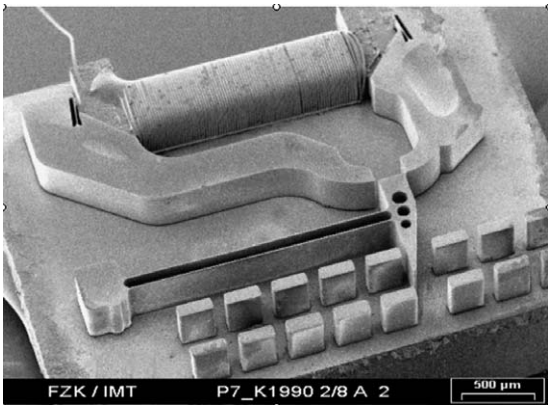

Figure 62 Electromagnetic actuator made from NiFe and operated as a chopper to modulate infrared light. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

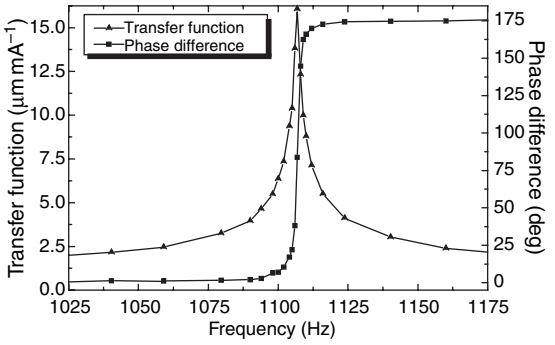

Figure 63 Normalized displacement of the shutter and phase shift as a function of excitation frequency.

on a separate substrate and released. The coil is wound on a turning machine and then assembled onto the substrate using alignment and clamping structures. A sinusoidal current generates a periodic force field and hence an oscillation of the shutter. Figure 63 shows the amplitude per milliampere current in the coil and the phase shift at an excitation close to the resonance frequency, which is about 1100 Hz.

For integration of the chopper in a spectrometer, the fiber alignment structures are skipped. The chopper is inserted head-over in the light input path of the spectrometer like in the assembly approach discussed earlier with distance sensors. This is facilitated by four stops on the edges of the yoke and the fixing block of the shutter, which were patterned simultaneously for this purpose. Figure 64 shows a close-up view of the very precise position of the shutter tip directly in front of the input fiber of a spectrometer in its alignment groove.

1.11.3.3.3 Fourier transform infrared spectrometer for infrared light

Another example using a variable reluctance actuator is a Fourier transform infrared spectrometer (FTIR). The design is based on a Michelson interferometer that consists of an optical bench for the passive alignment of the optical components and an integrated actuator (Wallrabe *et al.* 2005). The optical bench and the actuator are again made of permalloy of height 380 µm. The dimensions of the complete system are 11.5 mm × 9.4 mm (Figure 65). The light to be analyzed is delivered to the system via an optical fiber. It is collimated with a fused silica ball lens of 650 µm diameter. At the beam splitter, the light is separated into two rays, one reflects off the fixed mirror and the other travels toward the movable mirror. Both rays are reflected and travel back to the beam splitter where they interfere with each other. The interference signal is recorded with an InGaAs PIN photodiode that is sensitive in the wavelength range of 850–1700 nm. For recording the signal, the position of the movable mirror has to be determined very precisely. Hence, monochromatic laser light is used. The laser light is also delivered to the spectrometer through an optical fiber and propagates in a second optical channel parallel to the white light to be analyzed.

Figure 66 shows the movable plunger of the variable reluctance actuator, which is attached to a set of four folded cantilever beams and which is surrounded by fixed core structures thus forming two magnetic circuits that are driven by two coils. Because variable reluctance motors deliver only pulling forces,

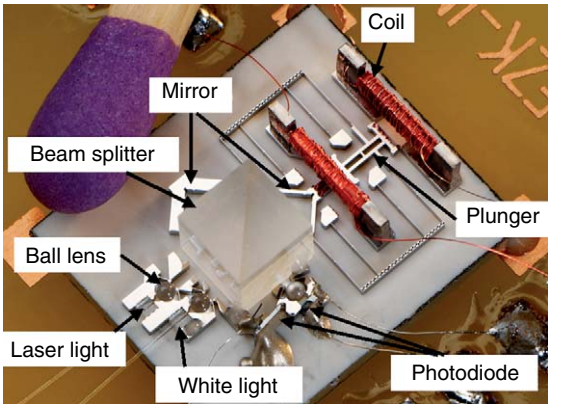

Figure 65 Three-dimensional view of spectrometer including optical bench (*left side*) and actuator (*right side*). (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

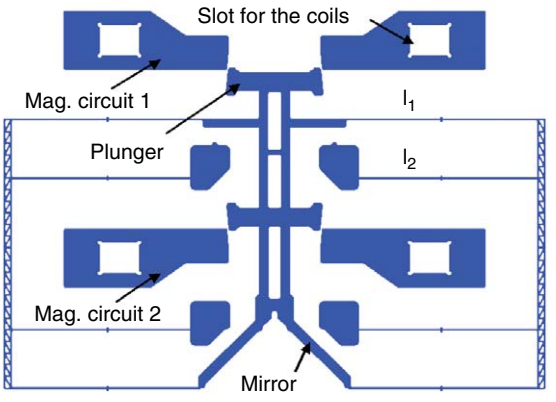

Figure 66 Schematic of actuator and magnetic circuits; the coils are placed into the respective slots. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

the displacement length was increased by using two coils, one for pulling the plunger toward the beam splitter and the other to pull it in the opposite direction. The separate coils are assembled into slots prepared in the fixed magnetic circuit.

For spectral analysis, the optical bench was equipped with all-optical components (see Figure 65), and the laser light at a wavelength of 1540 nm was delivered through a monomode fiber that ensures a good collimation of the beam. In this first experiment, only one coil was activated for which a displacement of the actuator of 54 µm was achieved leading to a spectral resolution of 25 nm. A measured white light spectrum is given in Figure 67. It shows a distinct minimum at a wavelength of 1.5 µm, which is related to the spectrum of the optical fiber used for the light input, as can also be seen from Figure 67.

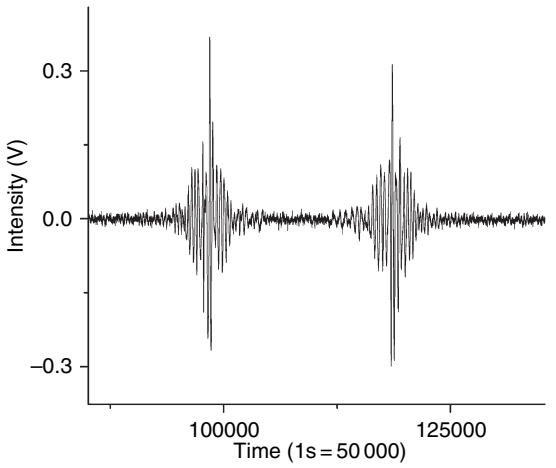

Figure 67 White light spectrum in comparison to absorption spectrum of optical fiber.

1.11.3.4 Mechanical Applications

Besides integration of electromechanical actuators in optical microsystems, another more and more upcoming field of application of LIGA technology is of pure mechanical nature. The accuracy of the X-ray lithography combined with the option of a copy of the pattern in a variety of metals represents an outstanding technology feature for mechanical applications. Currently, perhaps the most important application is concerned with gears. Three different approaches on LIGA-made gears are discussed in the following sections.

1.11.3.4.1 Micro Harmonic Drive®

Microgears are key elements in microdrive systems. They allow to reduce the speed and enhance the torque of miniature electromagnetic motors, which deliver typical output torques of several microNewton meters at speeds up to 50 000 rpm (www.faulhaber-group.com, www.maxonmotor.com). Only when combined with a gearbox the motors become applicable for many applications in microrobotics and automatization.

The Micro Harmonic Drive®, which is commercialized by Micromotion GmbH in Germany (www.mikrogetriebe.de), represents a high-precision microgear with extremely high reduction ratio. It is an assembly of a set of six separate gears in total (Slatter *et al.* 2006) that can be seen in Figure 68. The basic components are the so-called wave generator featuring a sun gear wheel and two planetary gear wheels. The sun gear is the one that will be connected to the driving unit, i.e., to the motor. The wave generator is placed in a set of three other gear wheels: the flexspline, the circular spline, and the dynamic spline. The dynamic spline serves as the torque output of the system. Hence, it is connected to the device that can be driven by the gear system, e.g., a microrobot. The flexspline features teeth at its inner and outer surface, whereas the others have teeth at only their inner surfaces. In addition, the flexspline has two teeth less than the others.

The working principle becomes clear from Figure 69. The overall diameter of the wave generator is slightly larger than the inner diameter of the flexspline gear, which is thin enough to allow for flexible deformation. Once the wave generator

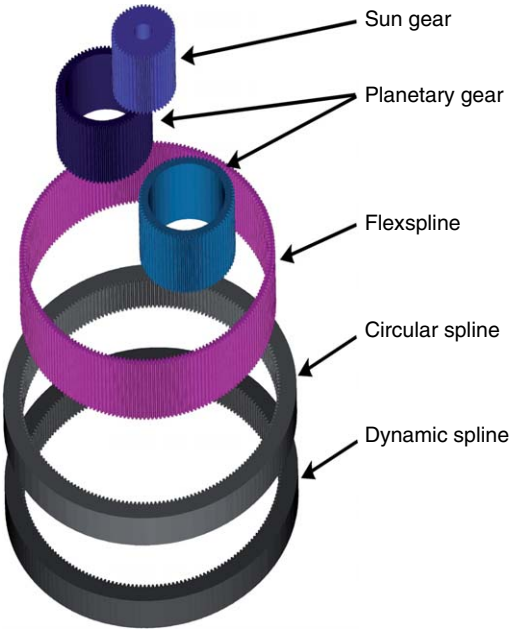

Figure 68 Gear components before assembly. (Source: Slatter R, Degen R, Burisch A 2006 Micro-mechatronic actuators for Desktop factory applications. *ISR/ROBOTIK 2006 - Joint conference on robotics*, Munich, Germany, May 2006. VDI-Bericht Nr. 1956, VDI Wissensforum IWB GmbH, Germany, pp. 137–150.)

is inserted into the flexspline, the flexspline is deformed to an elliptical shape. Thus, the outer teeth at the long axis of the ellipse are engaged with the respective teeth of the circular spline. With the rotation of the wave generator, the deformation and the tooth engagement travel along the circular spline. After a full rotation of the wave generator, the circular spline has moved by exactly the difference of the two teeth. The dynamic spline that is tightly connected to the circular spline moves correspondingly.

The large number of teeth on the outer gears compared to the travel of only two teeth during one rotation results in very large reduction ratios of the Micro Harmonic Drive system. Depending on the size of the system (8–10 mm diameter) reduction ratios between 160:1 and 1000:1 can be achieved, and the rated torque that can be loaded to the system varies from 7 to 24 mN m (Slatter *et al.* 2006). Due to the fact that the planetary wheels of the wave generator are also a bit deformable, the Micro Harmonic Drive exhibits excellent accuracy and almost zero backlash. Thus, the repeatability is 10 arcsec.

All gears are manufactured by X-ray lithography and subsequent electroplating of nickel–iron and final polishing of the surface. The NiFe has a fairly low Young's modulus of 135 kN mm^{-2} and a good fatigue behavior (Abel 1996). The lifetime is more than 2500 h at rated torques and speeds corresponding to many millions of cycles. **Figure 70** shows a section of a silicon wafer with flexspline and planetary gear wheels after electroplating, polishing, and stripping of the resist. Finally, they will be released from the substrate by sacrificial layer etching.

1.11.3.4.2 Cycloid gear system

A simple shadow casting by DXL results in patterns with high-quality vertical walls. However, the versatility requirements for current micropart applications include more complex 3D geometries and multilevel

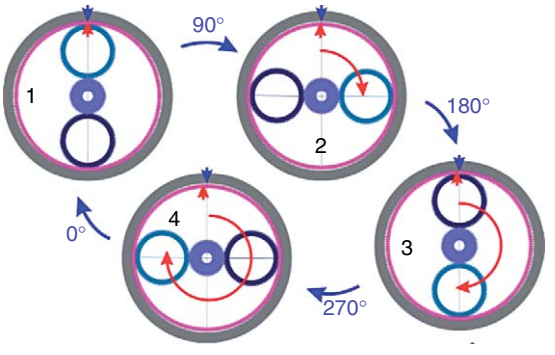

Figure 69 Operation principle of the Micro Harmonic Drive®. (Source: Slatter R, Degen R, Burisch A 2006 Micro-mechatronic actuators for Desktop factory applications. *ISR/ROBOTIK 2006 - Joint conference on robotics*, Munich, Germany, May 2006. VDI-Bericht Nr. 1956, VDI Wissensforum IWB GmbH, Germany, pp. 137–150.)

Figure 70 Flexspline and planetary gear wheels electroplated in NiFe on a Si wafer. (Source: Slatter R, Degen R, Burisch A 2006 Micro-mechatronic actuators for Desktop factory applications. *ISR/ROBOTIK 2006 - Joint conference on robotics*, Munich, Germany, May 2006. VDI-Bericht Nr. 1956, VDI Wissensforum IWB GmbH, Germany, pp. 137–150.)

configurations. One example of a 3D LIGA mechanical structure is another cycloid gearbox. A cycloid gear formation remains an advantage for miniaturization, because it does not need a planar arrangement of several gears. However, the layered formation of gear components requires an accurate planarization and height controllability of the microparts, for which sequential planar formation by the multiexposure LIGA technique can be quite fitting.

Figures 71 and **72** show a prototype of such a 2-mm-diameter microcycloid gear system (Hirata *et al.* 1999). The entire gear train consists of a casing and three vertically stacked disks and gears. Each part is composed of three different levels. The first level, 40 μm high, is fabricated by UV lithography, and the second and the third level, 195 and 250 μm high, respectively, are processed by aligned X-ray lithography. The alignment error between two X-ray lithography processed layers is within the ±5 μm range. The thickness of the layers is controlled by mechanical surface machining with an accuracy of ±3 μm for the UV lithography-processed structures and of ±10 μm for the DXL-processed structures.

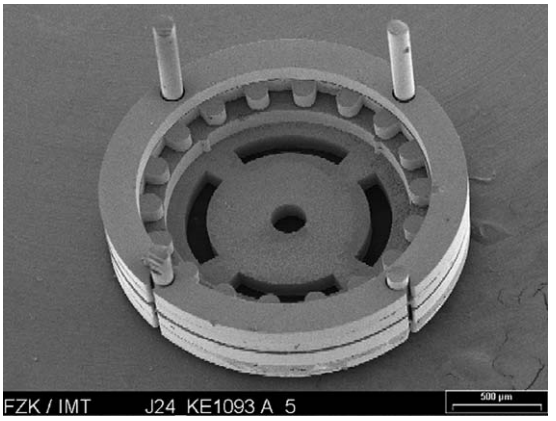

Figure 71 The casing of a microcycloid gear system fabricated by multiexposure X-ray lithography combined with UV lithography. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

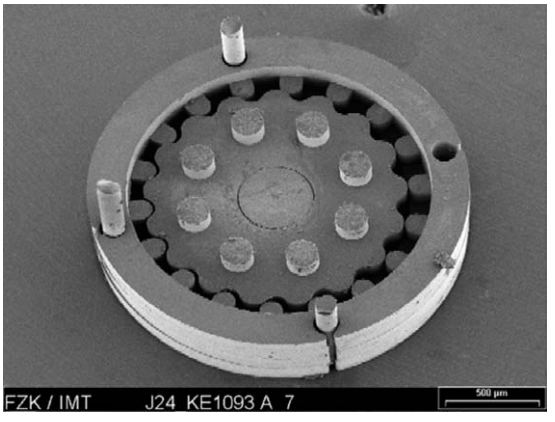

Figure 72 Microcycloid gear system with assembled central gear; the thin cylinders on the outer ring are pieces of optical fibers simply used as alignment aid. (Reprinted with permission by William Andrew Publishers from MEMS: A Practical Guide to Design. Analysis and Applications, Edited by Jan Koruink and Oliver Paul, 2006.)

For the assembly of the gears, three disks were initially positioned just one on top of each other using a vacuum gripper under a stereomicroscope. The correct alignment was done afterward by introducing short pieces of optical fiber (diameter 125 μm) as alignment pins into the respective holes (diameter 135 μm) in the disks. Finally, dynamic tests of the gear system were successfully conducted with a mechanical torque input by an electrical motor. A proper rotational speed reduction was observed in the operational input range of 3–1500 rpm with the designed gear ratio of 18.

1.11.3.4.3 Gears for watch movements

Gears become attractive to luxury watch industry for use in mechanical movements if they fulfill the extreme accuracy requirements so that lubrication becomes unnecessary and if they can be made simultaneously from precious materials. Hence, watch gears are fabricated from hard gold in small series, i.e., a few thousand pairs per annum (Meyer *et al.* 2005), at the Forschungszentrum Karlsruhe in cooperation with the synchrotron source ANKA (ankaweb.fzk.de/). **Figure 73** shows a set of gears and levers that have been patterned by X-ray lithography and electroplating. Beryllium masks are used to ensure the required accuracy in several hundred thick PMMA layers, and a new electrolyte for hard gold, which is an alloy of 99% gold and only 1% additives, mainly Cd and As (Dambrowski *et al.* 2006), was developed. It leads to almost pure (24 carat) golden microstructures with a Vickers hardness of already 160 HV. Further hardening of the sidewalls by ion implantation of beryllium increases the hardness by an additional factor of 3 (Meyer *et al.* 2005). Meanwhile, the implantation process has been modified and less toxic elements are used. The top surface is polished by fly cutting. Besides the esthetic motivation, golden gears benefit from the facts of being nonmagnetic and noncorrosive.

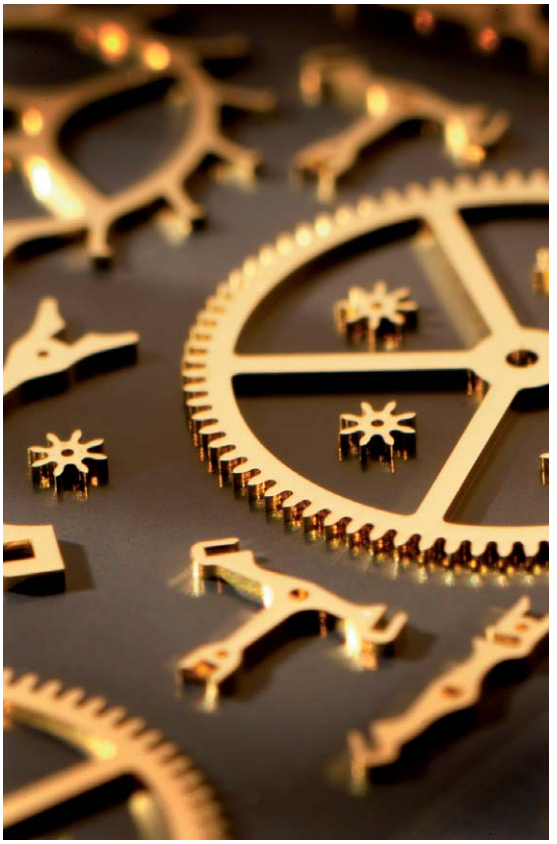

Figure 73 Watch gears and levers electroplated in hard gold.

The reproducibility of the optimized process is excellent as can be seen from **Figure 74**. It shows a trend chart of dimensional deviations of a test pattern, which was patterned on 200-μm-thick PMMA after the development. The variation is on the order of ± 0.5 μm.

1.11.3.4.4 Turbines

We conclude the section on mechanical application of LIGA technology with a hydrodynamic rotating microdrive, which provides an alternative to electrostatic or electromagnetic micromotors when electricity has to be avoided either for medical reasons or due to the risk of explosion hazards. Therefore, a microturbine has been developed, which is normally operated with water but may also run on gas. It was originally developed for use on cardiac catheters to drive a cutter for plaque removal.

In contrast to classical macroscopic turbines, microturbines feature a planar design. The turbine shown in **Figure 75** is assembled from various microcomponents (Wallrabe 1998): an electroplated metallic rotor with radial blades is mounted on a shaft, a nozzle plate made from PMMA by X-ray lithography surrounds the rotor, and a housing also made from PMMA, however using injection molding, forms the distal tip of the cardiac catheter. The fluid is delivered from the back side through the outer annular tube of the housing. It is injected into the rotor through the nozzle plate and is drained back through the inner annular ring. The hollow cylinder in the center of the turbine housing is a tribute to their application on catheters. It allows for positioning the catheter using a guide wire, which is a commonly used technique in catheter labs.

The nozzle geometry (minimum width 15 μm) is one of the parameters, which define the power and the torque as well as the operation pressure. The number of rotor blades and nozzles is kept coprime, thus guarantying a mostly steady torque generation.

The assembled turbine system is shown in **Figure 76**. For better visibility of the nozzles it is coated with gold. The turbine is operated with water at 37 °C. At 88 ml min^{-1} the pressure drop across the turbine is about 7 bar. The turbine achieves an idling speed of 1250 rps and a maximum power of 45 mW corresponding to a torque of 8 μN m at 900 rps.

1.11.3.5 Other Applications

This subsection describes two very new applications of LIGA technology. One deals with radio frequency (RF) MEMS for RF devices, which has been a main playground for silicon technology so far. The other concentrates on very small structures with still fairly high aspect ratios in the submicrometer range.

1.11.3.5.1 RF resonators

A commonly used device in RF technology is a microcapacitor with variable capacitance. Various variable capacitors have been patterned in silicon technology, in many cases with the capacitor plates positioned horizontally, i.e., in parallel to the substrate. A possible design for a vertical plate capacitor as it can be fabricated by means of LIGA technology is sketched in **Figure 77**. The capacitor consists of a cantilever, which is connected to a ground electrode, and a neighboring capacitance electrode. The cantilever is released from the substrate and can move back and forth. In order to vary the gap width of the capacitor, an additional actuator electrode is placed on the opposite side of the cantilever. If the cantilever

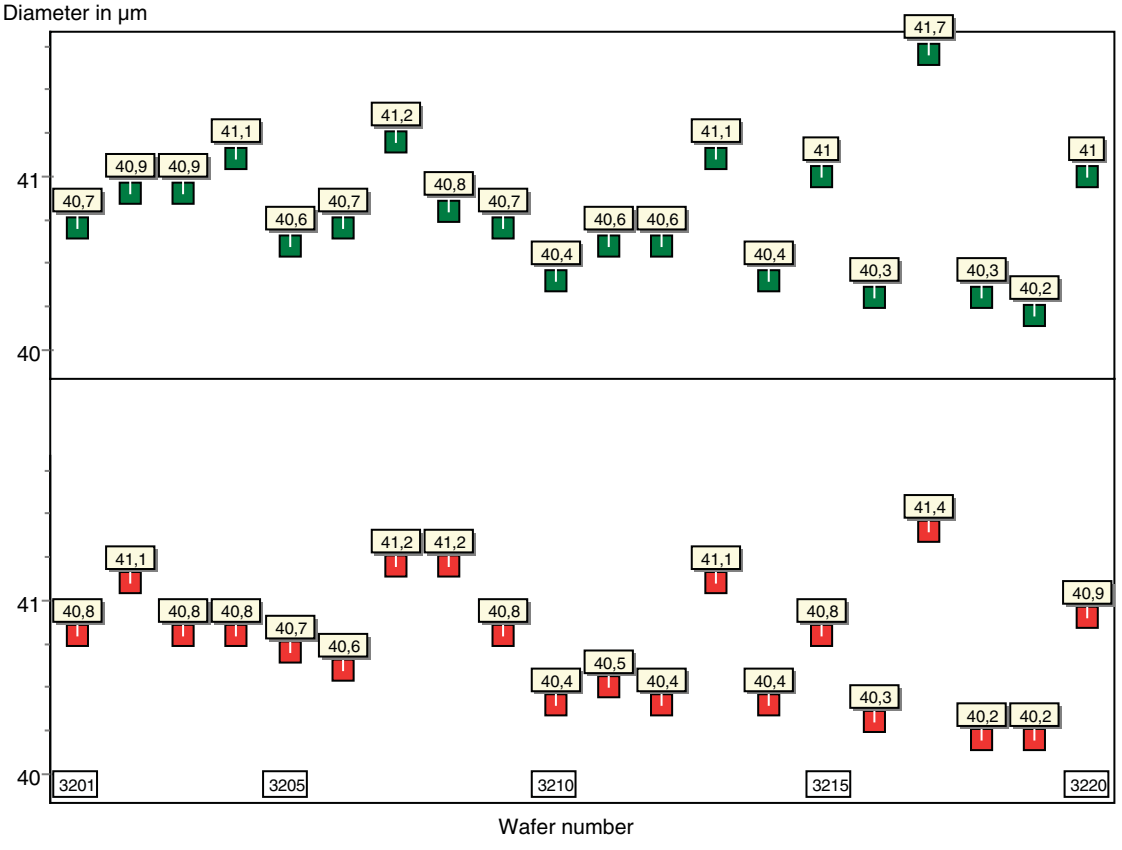

Figure 74 Trend chart of size reproducibility on 200-µm-thick polymethylmethacrylate (PMMA) test patterns after development.

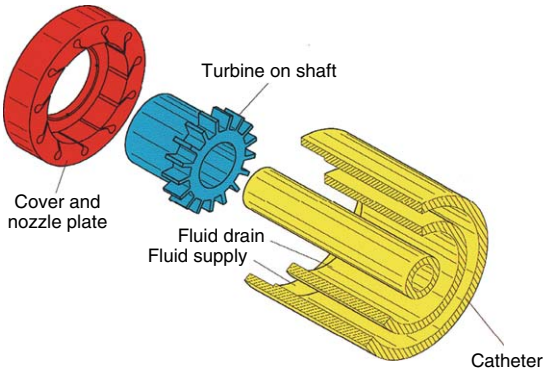

Figure 75 Schematic view of a turbine for cardiac catheters; the outer diameter is 2.5 mm.

Figure 76 Assembled turbine system; for visualization the sealing cover plate is still missing.

is actuated toward the actuator electrode, an increase in the tuning range over a two-plate capacitor can be achieved only if the actuator gap is made larger than the capacitance gap (Haluzan and Klymyshyn 2004). This increase in the tuning range at the cost of higher tuning voltages keeps the RF signal and the control signal separate from each other.

The capacitors are made by X-ray lithography with subsequent electroplating of metal and, as a final step, time-controlled sacrificial layer etching to release the cantilever locally from the substrate.

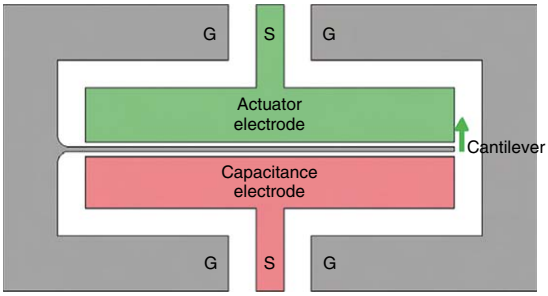

Figure 77 Sketch of three-plate variable capacitor. The additional ground structure on the right-hand side facilitates testing using standard three-pin wafer probes.

The benefits of this approach are the following: RF applications require good, preferably metal, conductors. The plating process of LIGA allows for the use of not only nickel, which is the most commonly plated metal in LIGA but also high-conductivity metals, such as copper and gold. The typical smooth sidewalls reduce those losses that originate from the skin effect. The penetration depth decreases with increasing frequency and is normally less than 1 µm for high-conductivity metals. Hence, when the penetration depth is of the same order as the surface roughness, high losses are induced in the rough surface. Additionally, LIGA can be performed on substrates with low dielectric losses such as quartz or alumina ($\epsilon_r = 9.8$ at 10 GHz).

Figure 78 shows a variable capacitor that is electroplated in 100-µm-thick nickel (Achenbach *et al.* 2007). The capacitance gap width is 1.6 µm and the actuator gap width is 6 µm. The length of the cantilever and of the electrodes is 1 mm. In the original PMMA form that was then filled with metal, the very small capacitance gap appeared as an extremely thin and long PMMA line. In order to improve the stability of such a fragile structure, which, in addition, has a respective small contact surface to the substrate and thus a very reduced adhesion, supporting auxiliary structures have been patterned, which can be figured out in the center of **Figure 78**.

Figure 79 shows the measured Q factor of the capacitor with a very low series resistance from **Figure 78** (Achenbach *et al.* 2007). At 3 GHz, it is still 33 and reaches a value of 175 at a frequency of 1 GHz. These already competitive results can be still improved by further reduction of the series resistance. Copper and gold show higher conductivity by a factor of 3–4 and are currently electroplated instead of nickel.

Other LIGA-made RF components are also subject to research and development. These are 3-dB line couplers with a center frequency of 18 GHz (Kachayev *et al.* 2003) or cavity resonators with center frequency at 24 GHz (Ma *et al.* 2005). In the latter case, very thick resist layers up to 2 mm need to be patterned with the specific advantage of still smooth surfaces. For details we refer to given references.

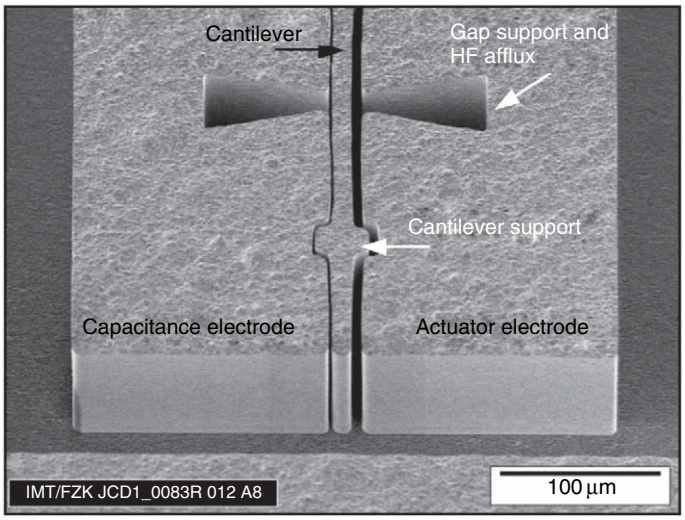

Figure 78 Scanning electron microscope (SEM) of a 100-µm-thick variable capacitor electroplated in nickel. The capacitance gap is 1.6 µm and features supporting auxiliary structures. (Source: Achenbach S, Klymyshyn D, Haluzan D, Mappes T, Wells G, Mohr J 2007 Fabrication of RF MEMS variable capacitors by deep X-ray lithography and electroplating, *Microsyst Technol*. **13(3–4)**, 343–7.

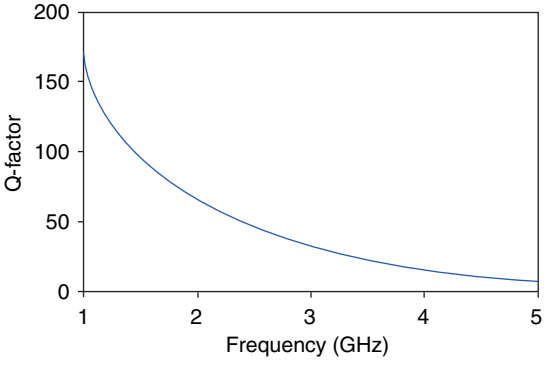

Figure 79 Measured average *Q* factor as a function of frequency for the 100-μm-thick nickel variable capacitor.

1.11.3.5.2 Submicron structures

A new approach for LIGA technology is driven by structures with feature sizes well below 1 μm. The feasibility of nano-LIGA is still under evaluation. First, submicron structures have been patterned successfully in polymer as well as in metal. The obtained aspect ratios are not yet the same as for the LIGA structures as discussed above, but aspect ratios of about 10 have been proven so far. The limiting factor that occurs during the development and subsequent drying of submicron polymer structures is an insufficient stability of those structures with respect to capillary forces. **Figure 80** shows the effect of the capillary force acting on a set of PMMA columns of 550 nm diameter and 5 μm resist thickness (Achenbach *et al.* 2004). Although the adhesion of the columns to the substrate is sufficient to keep

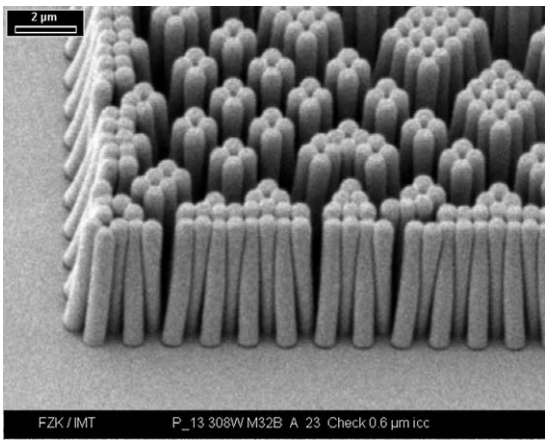

Figure 80 Scanning electron microscope (SEM) of polymethylmethacrylate (PMMA) columns of 550 nm diameter and 5 μm thickness. The deformation is a result of capillary forces during drying.

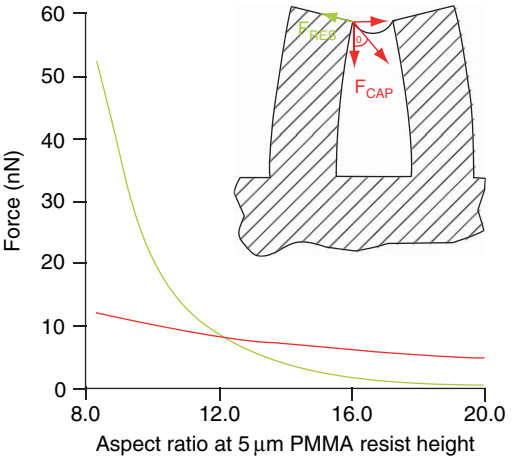

Figure 81 Comparison of capillary force and reset force as a function of aspect ratio for infinite resist lines (polymethylmethacrylate (PMMA), thickness 5 μm). The inset shows the capillary force and the induced opposing reset force.

them in place, they are bent and clustered forming a relative regular crystalline pattern. **Figure 81** compares the capillary force with the opposing elastic reset force given by the geometry of the microstructure as a function of the aspect ratio (Mappes *et al.* 2007). In this case, an infinite PMMA line was considered for a resist thickness of 5 μm. At an aspect ratio of approximately 12, the capillary force becomes larger than the reset force. Hence, the structure will become unstable and will show respective deformations.

In addition, diffraction of the X-rays at the edges of the absorber structures on the X-ray mask during the exposure needs to be considered for submicron structures. This is typically not a severe task in DXL. Even large proximity gaps between mask and resist surface during the exposure do not cause dramatic damage in case of larger LIGA structures. For submicron structures, however, diffraction becomes visible, as can be seen from **Figure 82**. Here, an array of PMMA columns approximately 1 μm diameter shows small pits in the center of the columns that appear after the development. They resemble the Poisson's spot observed behind a circular obstacle, as is known from the optics lecture. **Figure 83** shows a predicted resist profile after a simulation of dose deposition under consideration of diffraction as derived in (Nazmov *et al.* 2000) and subsequent development.

One prospective application of these regular submicron structures with high aspect ratio are filters for

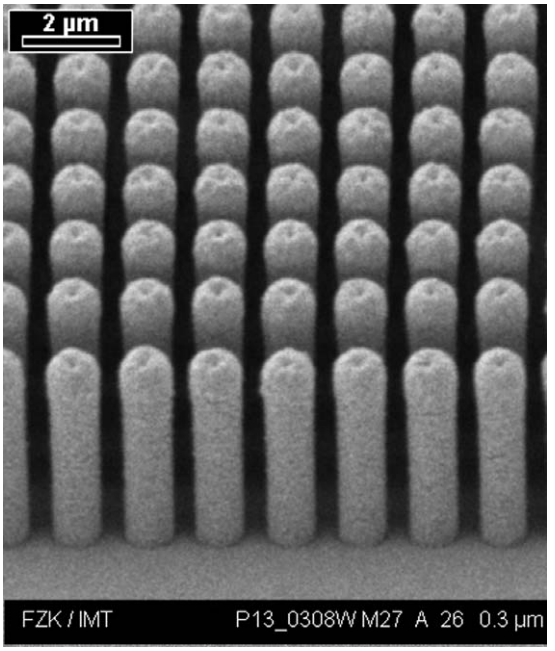

Figure 82 Array of polymethylmethacrylate (PMMA) columns of approximately 1 µm diameter and resist thickness 5 µm. The proximity gap during exposure was 125 µm.

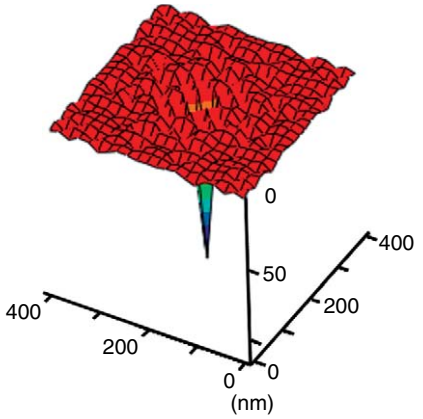

Figure 83 Simulated surface profile of a circular column after development.

infrared light. For an infrared filter, a fairly thick metal mesh with a grating constant on the order of 1 µm is required (Mappes *et al.* 2006). The filter's quality and efficiency is directly dependent on the metal thickness, hence it calls for high aspect ratio structures. An array of PMMA columns of 5 µm thickness, which are similar to those above, is therefore electroplated in gold. After stripping the PMMA, the gold mesh features a thickness of 4 µm with a linewidth of 720 nm, as can be seen from **Figure 84**. Similar meshes have been made free of defects with more than 5600 columns with a grating constant of 1.34 at a column diameter of 1 µm, as shown in **Figure 85**.

1.11.4 Outlook

Originally, LIGA was developed in Germany for a very specific purpose, namely, to manufacture nozzles for the separation of uranium isotopes in large enrichment facilities. The requirements of the technology were high aspect ratio and minimum feature sizes in the micrometer range. Its potential became evident in the 1990s when numerous examples for structures and devices were presented. The lead in MEMS technologies, however, was assumed by silicon micromachining, and not by LIGA, in spite of its technical superiority for many applications. One main reason for this is the required technical infrastructure, process know-how, and cost issues. Silicon-based technologies on the one hand could exploit the vast technology base developed for chip making with an existing investment worth billions of dollars. LIGA, on the other hand, was new and confined to research laboratories. Besides the process itself, the laboratories invested a huge amount of money and brainwork to develop suitable machines, such as X-ray scanners and micromolding machines. Furthermore, as a key process step, LIGA required access to a synchrotron radiation facility, again a research laboratory, and thus often unacceptable for industries establishing manufacturing plants. Most of the synchrotrons offer worldwide access to their facilities. An hour of exposure time is currently on the order of €200 per beamline, which – to be honest – does not take into account the investment of the equipment, i.e., the beamline and the scanner. For the implementation of a new exposure setup with its own beamline, overall costs of approximately €2 000 000 may arise. Nevertheless, this is a demonstration of the strength and superiority of LIGA; several industrial LIGA products have been launched by industries and synchrotron radiation facilities and are currently widely used for microfabrication (**Table 2**).

As a consequence of the weaknesses of LIGA, the developers of LIGA have focused their efforts over the past few years on quality management, stabilization of processes, standards, and cost. Small volume production was demonstrated and reliability of processes was dramatically increased. The concept of deliver mold inserts on demand was verified, and at least small- and medium-sized companies are increasingly accepting that they can now simply purchase a mold insert for their production in their plant.

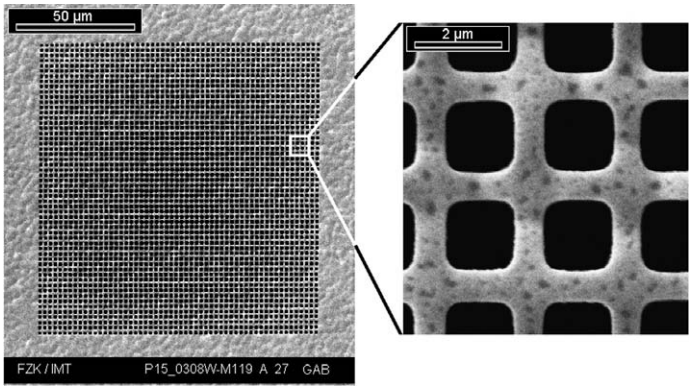

Figure 84 Infrared filter made from electroplated gold. The trench width is 720 nm and the thickness is 4 µm.

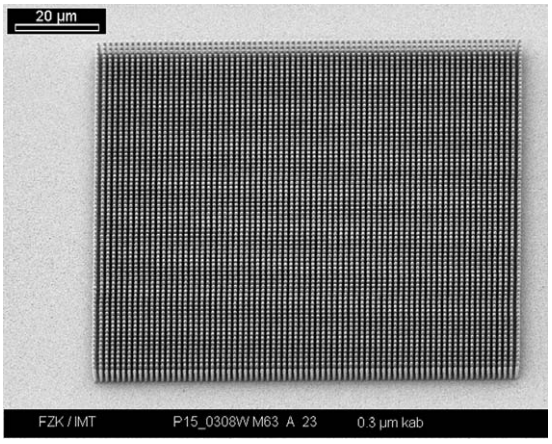

Figure 85 Array of more than 5600 defect-free polymethylmethacrylate (PMMA) columns of 1 µm diameter.

Furthermore, a new so-called Direct-LIGA concept is currently tested where the components are produced directly by X-ray lithography with or without subsequent electroplating, similar to semiconductor manufacturing, at an acceptable cost. This approach uses only the first (LI) or the first two (LIG) steps of LIGA, which can become cost-effective in terms of throughput, especially for a moderate number of pieces. Two highly encouraging approaches are pursued: new resists such as SU-8 reduce the exposure times by one to two orders of magnitude and the ability to expose very large areas in one exposure step.

Besides these efforts in making LIGA acceptable as a manufacturing technology for various industrial products, cutting edge research in and with LIGA remains a hot topic. The goals include research in new materials, new replication techniques, and new lithography approaches exploiting the short wavelength nature of X-rays. Questions such as How small can we really get? Can we overlap our top-down technologies with the typical bottom-up approach in nanotechnology? and at which dimensions? are currently being addressed. Making devices much smaller than is possible today will open up entirely new fields in research and applications.

Biographies

Jürgen Mohr, born in 1957 received his diploma in physics in 1983 and his Ph.D. in mechanical engineering in 1987 from the University of Karlsruhe with an emphasis in micro system technologies. He has been with the Forschungszentrum, Karlsruhe since 1987, first as a research associate working in the field of X-ray lithography for micro fabrication (LIGA process). Since 1992 he is leading the X-ray lithography and micro optics group at the Institute of Micro Structure Technology of the Forschungszentrum. His interests are in the field of micro-fabrication by Deep X-ray lithography (LIGA process) as well as in micro optical components and systems based on polymers for sensor and telecommunication applications. He is a member of the IEEE-LEOS society. He has published more than 100 papers on various topics in micro technology and applications in mechanics, optics and the sensor field. Jürgen Mohr is co-author of two text books on micro technology.

Ulrike Wallrabe studied physics at Karlsruhe University, Germany. In 1992 she received her PhD degree for mechanical engineering of microturbines and micromotors. From 1989 to 2003 she was with the Institute for Microstructure Technology (IMT) at Forschungszentrum Karlsruhe where she focused on microactuators and MOEMS made by the LIGA technique. Since 2003 she holds a professorship for microactuators at the Department of Microsystems Engineering, IMTEK, at the University of Freiburg, Germany. Her focus lies in magnetic microstructures, coils, and adaptive optics. Ulrike Wallrabe has published more than 60 journal and conference papers, as well as three book chapters.

Dr. Jan G. Korvink obtained his M.Sc. in computational mechanics from the University of Cape Town in 1987, and his Dr. sc. techn. in applied computer science from the ETH Zurich in 1993. After his graduate studies, he joined the Physical Electronics Laboratory of the ETH Zurich, where he established and led the MEMS Modelling Group. This was followed by a move in 1997 to the Albert Ludwig University in Freiburg, Germany, where he holds a Chair position in microsystem technology and runs the Laboratory for Microsystem Simulation. Currently, Dr. Korvink is a vice dean of the Faculty of Applied Science and a member of the board. He has written more that 180 journal and conference papers in the area of microsystem technology, and co-edits the review journal *Applied Micro and Nanosystems*, see http://www.wiley-vch.de/books/info/amn. His research interests cover the modelling and simulation and low cost fabrication of microsystems.

1.12 Low-Cost MEMS Technologies

Bruce K. Gale, Mark A. Eddings, Scott O. Sundberg, Andrew Hatch, Jungkyu Kim, and Tammy Ho, Department of Mechanical Engineering, Salt Lake City, UT, USA

1.12.1 Introduction

While microelectromechanical systems (MEMS) technologies have demonstrated ever more amazing capabilities, the costs associated with MEMS processing have also grown. MEMS and microfabrication technologies have traditionally been dominated by expensive, complicated, cutting-edge equipment. Technologies such as photolithography, dry etching, physical vapor deposition (PVD), chemical vapor deposition (CVD), and related tools that have dominated the MEMS field since its inception are notoriously expensive and rely on processes and components that are inherently costly. Vacuum components, complicated electronics, and precision stages are required for most of these processes and all carry significant price tags. Typical research grade tools usually cost more than US$100 000 and normally a suite of tools is required for any MEMS chip to be fabricated. A basic MEMS research lab often costs more than US$10 million and can be much more expensive depending on the tooling and infrastructure (clean rooms, electrical, and gas systems) required. Manufacturing tools typically run over US$1 million and entire facilities can cost more than US$1 billion. For products where the cost of this equipment and tooling could be spread over millions of units each year, the use of these tools can be easily justified. For potential products where the number of parts each year is less, these large start-up costs can often be prohibitive. In the research arena, the high cost of setting up MEMS facilities often limits research in this field to those institutions with the deepest pockets. In addition, the traditional MEMS technologies are best suited to mass production, but for prototyping, they are often difficult to work with and can again be overly expensive. Thus, over the last decade, extensive efforts have been devoted to developing technologies for MEMS and for microfabrication that are accessible to all researchers, not just those focused on MEMS. Note that the technologies discussed in this work are primarily for generating microscale features between 1 and 100 μm or larger.

One of the first approaches to reducing costs in MEMS was to move to materials less costly than single-crystal silicon wafers, which is the traditional MEMS substrate. Glass, plastics, and some ceramics have proven to be suitable substrates for many MEMS applications and have also proven to be less expensive. Some of the earliest work in this field combined low-cost materials with some of the traditional MEMS processes that were also low cost, such as wet etching and spin coating to produce glass microchannels (Manz *et al.* 1990). Some of these materials have also been found to have better properties than silicon for some applications in biology, microfluidics, optics, chemistry, and medicine. As researchers began to explore new materials, new technologies had to be developed in many cases, since the traditional MEMS processes were optimized for silicon or were specific to silicon. Thus, many of the techniques discussed in this chapter are specific to nonsilicon substrates, while others can be used with any material. Many of these new processing techniques have proven to be capable, yet inexpensive. Unfortunately, for chips requiring low linewidths (<10 μm), traditional (or expensive) MEMS techniques have proven difficult to replace, but for MEMS devices where lateral dimensions are not as critical or relatively large (>10 μm) and it is primarily vertical dimensions that are very small (<1 μm), the techniques discussed in this chapter have proven their mettle.

Low-cost MEMS and microfabrication techniques typically fall into one of the following four categories:

(1) Low-cost photolithography techniques
(2) Photolithography replacements
(3) Rapid prototyping techniques
(4) Low-cost mass production technologies

The first category, low-cost photolithography techniques, is primarily directed toward producing inexpensive photolithography masks. A standard chrome mask on a glass substrate typically costs more than US$5 per square centimeter and can easily be double or triple that amount depending on the

needed quality. For a device that requires multiple masks, the mask-making costs can multiply quickly. In a prototyping situation where several design cycles may be required, the mask cost can be the primary cost driver for a project and can exceed US$1000 per mask. Techniques that may be included in this category are laser and ink-jet printed masks, xurography, and shadow masking using masks made with traditional machining tools. The second category, photolithography replacements, is characterized by techniques designed to eliminate the need for masks, UV exposure systems, optical aligners, and expensive chemicals. The least expensive UV exposure systems of any quality (providing collimated, uniform light) cost at least US$20 000 and systems that provide the ability to align different layers often exceed US$250 000 for basic systems. Techniques in this category include xurography, screen printing, and laser cutting. The third category, rapid prototyping techniques, is designed to eliminate the difficulties and costs associated with producing small-volume prototypes using traditional MEMS tools. Most MEMS processes are fantastically well developed for mass production, since they operate as batch processes, but that also means that it often costs just as much to make one part as it does to make hundreds of parts. Since there is a limited benefit to multiple parts during prototyping, the cost cannot be spread out and can be significant. In addition, microfabrication techniques are typically relatively slow, and even relatively simple designs can take weeks to manufacture and outsourced designs are often not delivered for 6 months or more. Thus, many of the inexpensive prototyping techniques are also much faster, saving money as well as time. Some of the techniques that can be used for low-cost prototyping of MEMS include lamination, xurography, laser cutting, soft lithography, and screen printing. The fourth category, low-cost production technologies, is primarily aimed at technologies for MEMS devices that do not require the substantial infrastructure required for traditional MEMS, but can still produce similar volumes at a relatively lower cost. Techniques in this category typically involve molding, embossing, or stamping. Each of these categories will be addressed in detail in this work. The reader should note that the low-cost techniques can usually be combined with more traditional MEMS techniques to maximize productivity while minimizing cost.

An important consideration in MEMS fabrication is the packaging of the completed MEMS devices. Conventional wisdom is that MEMS packaging can account for up to 80% of the total cost of a MEMS device, primarily because many MEMS packages must be custom designed. To overcome these packaging costs, a number of approaches have been proposed. The most successful involve modifying or using traditional integrated circuit (IC) packages, but this is often not possible for fluidic or optical systems. Some MEMS designers have managed to essentially eliminate packaging. A few of these methods as well as a few methods for minimizing packaging costs will be reviewed with their related manufacturing techniques.

1.12.2 Low-Cost Photolithography Techniques

Many engineers and scientists have worked to reduce the cost of performing basic photolithography processes or steps. Two primary approaches have been taken. The first approach is to reduce the cost of making the photolithography masks (see Section 1.12.2.1). The second approach is to eliminate the processing steps after photolithography by creating the desired microstructures using the photolithography process (see Section 1.12.2). This approach can be combined with the first approach. A third approach is to eliminate photolithography entirely, which will be discussed in Section 1.12.3.

As noted earlier, standard photolithography masks can be a substantial expense and outsourced masks often take significant time to receive. Most photolithography masks are typically made of precisely patterned UV-absorbing materials such as chrome (most common), iron, or photopatternable emulsions on a glass substrate. Chrome masks are patterned using a tool called a pattern generator, which exposes a layer of photoresist deposited on the metal layer. The photoresist is then developed and the underlying metal layer etched to produce the mask pattern, which can then be reproduced multiple times. The pattern generators are robotic instruments with precise movement and optics to produce high-quality patterns, and are thus relatively expensive. A typical mask can take several hours of machine time to produce, and complex masks can easily take days. The multiple steps required to produce the masks, the precise tooling, and long tool-use times lead to substantial mask fabrication expenses. Thus, to reduce these costs, several alternatives to metal masks have been explored.

1.12.2.1 Low-Cost Photolithography Mask Fabrication

Although typical chrome mask generation with e-beam lithography is very accurate (<1 μm feature sizes) it is very expensive (>US$500 per 4 × 4 in mask) and can have a long turnaround time. For this reason, alternatives to chrome mask generation have been evaluated in depth by many groups. Laser printing, microfiche and photoreduction, microscope projection, microfluidics, xurography, and direct laser writing have all been implemented as creative photomask alternatives (Narasimhan *et al.* 2004).

1.12.2.1.1 Laser printed masks

Fabricating photolithography masks by printing the positive/negative mask onto a transparency using laser printing is a common technique. Creating masks with this technique is appealing because it can significantly reduce the cost and time of fabrication (Qin *et al.* 1996). High-resolution laser printers can have resolutions from 5000 to 20 000 dpi and can print linewidths down to 10 μm with a local accuracy of 2 μm. The equipment is expensive but there are many outsourcing locations for printing on transparencies (<US$40 per transparency). Laser printers use a process where a photoreceptor, which is a photosensitive drum or belt that rotates, is electrostatically charged. A laser diode is then directed at a moving mirror, which aims the laser beam onto the photoreceptor and reverses the charge wherever it hits. The surface is then exposed to a toner, a fine plastic powder with coloring, and the toner is attracted to the areas on the photoreceptor where the laser beam hit. The photoreceptor is rolled over the paper in order to transfer the image and the paper is then passed through rollers, which provide heat and pressure to bond the toner to the paper. Following toner bonding, the photoreceptor is cleaned and the charge is removed. Therefore, laser printers rely on the spot size of the laser beam generated to determine the minimum feature size, which is determined by the laser quality used. The feedthrough mechanism is also important in providing the local accuracy. The two different methods used are mechanical feedthrough and a fixed internal drum. It has been found that the fixed internal drum is capable of a higher accuracy dot placement (Suleski and O'Shea 1995).

1.12.2.1.2 Photographic pattern reduction

Photographic reduction of prints, using 35-mm film or microfiche, can be used to further reduce the feature size capabilities for mask generation (Deng *et al.* 1999). This reduction allows the use of a regular office printer to create linewidths down to 15 μm, making mask generation very cost-effective (Deng *et al.* 2000). Using a high-resolution laser printer, photoreduction can yield minimum linewidths of 5–10 μm (about US$20 per 10 reductions) (Dotson *et al.* 2004). To further reduce feature sizes, microscope projection has been used. A printed photomask is placed in the field stop, diaphragm, of the microscope. Light passes through the photomask and objective and exposes photoresist on a substrate located on the stage. As the light passes through the objective (typically 40× or 100×), the pattern is reduced allowing feature sizes down to 1 μm to be achieved. The main disadvantage of this reduction technique is the limited area that can be exposed, although step and repeat operations could be used (Love *et al.* 2001, Whitesides *et al.* 2001).

1.12.2.1.3 Microfluidic gray-scale masks

Microfluidics has been used to create photomasks and even gray-scale masks, in order to create 3D structures. The microfluidics are fabricated by first printing a mask with the desired pattern and then exposing photoresist on a silicon wafer. Once the photoresist is developed, poly(dimethylsiloxane) (PDMS) is molded using the photoresist structures and then bonded to a spun PDMS thin layer. Dye is injected into the PDMS channels with varying concentrations. UV light is then passed through the PDMS channels onto a substrate with photoresist. Then, depending on the dye concentration, the developed structures vary in thickness, thus creating 3D structures (Chen *et al.* 2003).

1.12.2.1.4 Masks generated using xurography

Photomasks and shadow masks can be fabricated using xurography, a fabrication technique explained in depth in Section 1.12.3.5. For photomasks, a UV-opaque material is chosen to be patterned and the undesired material is peeled away, without removing the backing material. This mask is then transferred and adhered to a glass substrate, thus creating a photomask. For shadow masking, a material is cut with the desired pattern and transferred to a substrate, using adhesive or electrostatic interactions for adhesion. Material can then be deposited over the substrate (i.e., sputtering, PVD, e-beam evaporation). Once the material is deposited, the cut pattern is peeled away, removing the deposited material

where the pattern was adhered. This fabrication technique can provide minimum linewidths of ~25 μm (Bartholomeusz *et al.* 2005).

1.12.2.1.5 Laser electrodeposition for masks

Photomasks have also been developed using direct laser writing on an electroless Ni deposited substrate, an inexpensive deposition method requiring little equipment. This technique can use an inexpensive Ar^+ laser, rather than an expensive pulsed deep UV light source, but takes advantage of a high numerical aperture objective to increase the power density and decrease the spot size of the laser. The smallest feature size generated by this setup was 0.5 μm (Lorenz *et al.* 2004). This technique can provide a relatively simple, economical, and rapid alternative to e-beam lithography while still providing comparable feature size capabilities.

1.12.2.2 Direct Microfabrication Using Photolithography

A number of techniques have been developed to eliminate some of the steps after photolithography, and thereby reduce the total cost of the microfabrication process. These processes include direct fabrication of the microstructure during the exposure process. Examples of this type of work have been completed with both polymers and glass. In both cases, the only step after UV exposure is development using a solvent for the polymers and an acid for the glass.

1.12.2.2.1 Photopatternable polymers

The development of MEMS and microfluidic components often require the use of complex 3D geometries. The rapid fabrication of 3D curves, vias, porous membranes, and tubes have been made possible through the implementation of photoactivated polymers. The basic operating principle of photopatternable polymers is the introduction of a UV source onto a photosensitive polymer, initiating a cross-linking reaction across exposed regions. Excess polymer and reactants are generally washed away leaving the microstructure. Two of the more common techniques used in photopatternable polymers include liquid-phase photopolymerization and SU-8 lithography.

1.12.2.2.1.(i) Liquid-phase photopolymerization

The technique often described as liquid-phase photopolymerization provides a rapid, inexpensive prototyping option for fabricating microstructures. Molds and layered structures are possible in minutes without the use of costly clean room facilities. Variations of this method have been widely explored by Beebe *et al.*, making possible the swift creation of 3D microchannels, filters, fibers, and tubes.

For basic mold or structure patterning, a generic cartridge fixed to an adhesive gasket with the thickness of the desired structure is placed upon a substrate such as a microscope slide and is filled with UV-sensitive polymer through sample inlet ports (Beebe *et al.* 2000, Khoury *et al.* 2002). A photomask is then placed over the cartridge and a UV source exposed to pattern the polymer within the cartridge. The exposed polymer is then flushed with solvent, removing any unexposed polymer waste, thus revealing the patterned structure. The quality of the resulting structures is dependent upon the resolution of the equipment used and the chemical properties of the polymer. Typically, PDMS is poured over the polymer structures and microfluidic channels are created by direct molding. Three-dimensional channel networks can be created by using slight variations on this technique and stacking multiple layers of polymerized material (Mensing *et al.* 2005).

Other complex structures such as fibers and tubes that utilize the microscale characteristics of multiple combined laminar flows and photopolymerization are possible under different configurations (Jeong *et al.* 2004, 2005). The fabrication apparatus consists of a PDMS substrate containing a microchannel, with an inlet and outlet pipette inserted into the ends of the microchannel to provide sample delivery. A separate channel that intersects the inlet pipette is cored into the PDMS to provide sheath flow around the sample flow. A UV source is placed above the outlet pipette to polymerize the sample flow inside the sheath flow in order to produce microfibers. The addition of another smaller pipette inside the inlet pipette enables the addition of a nonpolymerizable core flow that results in microtubes as the sample flow is polymerized at the outlet pipette (**Figure 1**).

The fabrication of microfilters and porous membranes is accomplished through randomly generated patterning (Moorthy and Beebe 2003). A photosensitive polymer is prepared consisting of monomers, a photoinitiator, a cross-linker, and additives such as water. After the UV source is applied and polymerization has occurred the additive is removed, leaving behind the porous network within the polymer.

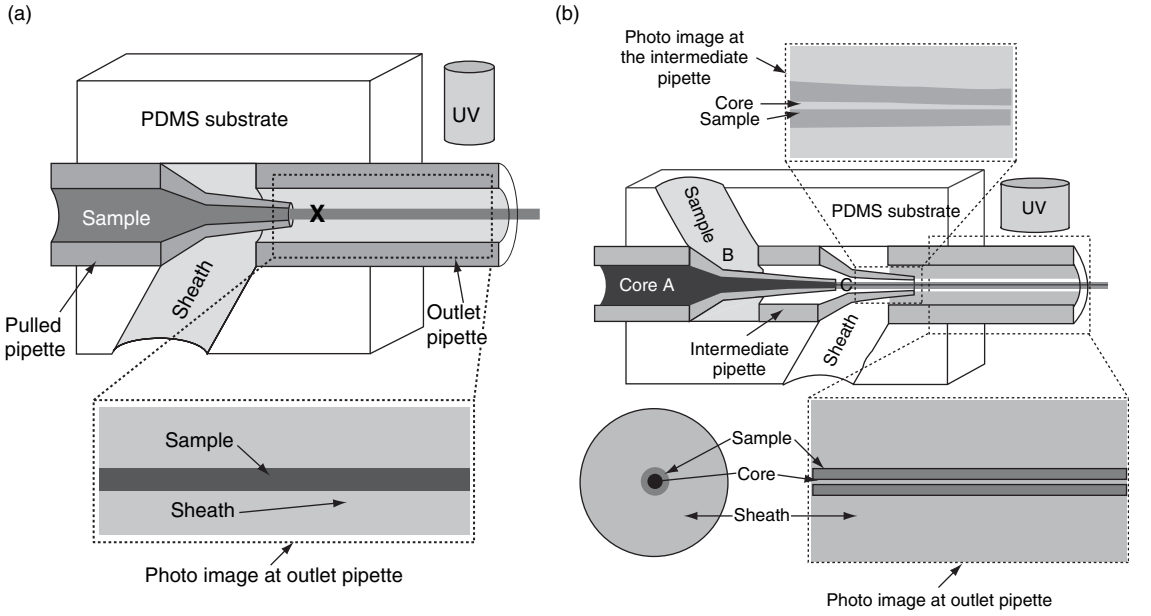

Figure 1 A representation of the fabrication apparatus: (a) microfibers; (b) microtubes. PDMS, poly(dimethylsiloxane). (Source: Jeong W J, Kim J Y, Kim S J, Lee S H, Mensing G and Beebe D J 2004 Hydrodynamic microfabrication via 'on the fly' photopolymerization of microscale fibers and tubes. *Lab Chip* **4**, 576–80; reproduced with permission from the Royal Society of Chemistry.)

The technique is advantageous for microsystems as the size of the pores is easily controlled by the concentrations of the reagents and the membrane can be created in any location such as a chamber or a microchannel located within a device. The ability to create filter regions locally offers many possible applications in microfluidics.

1.12.2.2.1.(ii) SU-8 lithography The negative photoresist Epon SU-8 or SU-8, which was first developed by IBM, has found wide use in MEMS thick-film-resist applications (Despont *et al.* 1997, LaBianca and Gelorme 1995, LaBianca *et al.* 1995, Leek *et al.* 1995, Shaw *et al.* 1997). The unique optical properties, harsh environment durability, and lithographic contrast have made SU-8 a popular photoresist for high aspect ratio structures. The use of SU-8 has enabled researchers to produce high-resolution structures for direct molding or protective coatings for electroplating. Drawbacks to using SU-8 include several baking sessions to condition the photoresist and clean room facilities to reduce dust and particles that may affect film quality. However, with proper equipment and facilities, high-resolution, durable processing is possible in an afternoon for a relatively low cost (**Figure 2**).

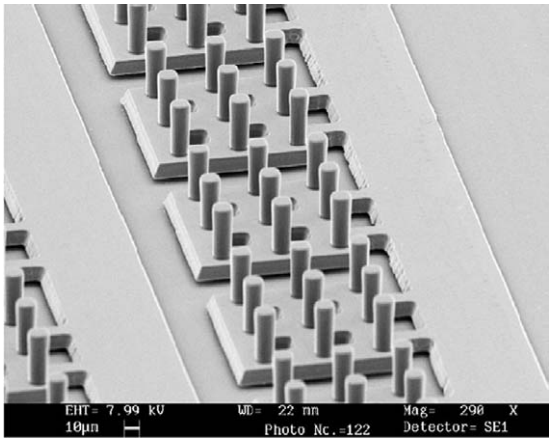

Figure 2 SU-8 pillars fabricated on an array of silicon cantilevers. The pillars are $10 \times 10\ \mu m^2$ in size and 30 μm high. (Source: Conradie E H, Moore D F 2002 SU-8 thick photoresist processing as a functional material for MEMS applications. *J. Micromech. Microeng.* **12**, 368–74; reproduced with permission from the Institute of Physics.)

There are many varieties of SU-8 that have been developed by varying the solvent contained in the photoresist. The solvent used will generally affect photoresist viscosity and wettability for different types of substrates such as silicon and glass. These

properties will determine the quality and thickness of the spun layer.

The ability to control layer thickness is an import feature of SU-8 rapid prototyping. Direct PDMS molding and optical waveguides are the most common applications for SU-8 lithography. Tight control of structure width and height has elevated SU-8 to the photoresist of choice for creating microchannels in PDMS (Anderson *et al.* 2000, Duffy *et al.* 1998). Also, when producing molded microchannels, there is usually only one mask step, so alignment is eliminated along with the expensive equipment associated with the alignment process. The process of using SU-8 or some other type of mold for PDMS casting is called soft lithography (see Section 1.12.4.1). The SU-8 and substrate surface is chemically coated to allow clean, unhindered peeling of the PDMS microchannel replica. An additional slab of PDMS is placed on top of the grooves to form microchannels. The PDMS layers will combine through an oxygen plasma treatment or partial curing of layers. Following a final bake a single PDMS slab remains with embedded microchannels. Other PDMS microcomponents such as pumps, actuators, and sensors are also possible through SU-8 molding (Unger *et al.* 2000). While the SU-8 processing is somewhat time-consuming, once a master mold is made, repeated PDMS molding is possible.

SU-8 can be used to make microchannels directly or by a subsequent bonding step. SU-8 exposure without development followed by a series of SU-8 application and exposure steps can lead to the production of buried SU-8 channels or 3D SU-8 networks (Gracias *et al.* 2005). Variations of this process using laminated layers of SU-8 can achieve a similar result (Abgrall *et al.* 2005). Simple patterning of SU-8 followed by a bonding step using adhesives or other materials can be readily used for creating microfluidic channels, though the bonding process is not always simple (Gale *et al.* 2002).

Direct use of SU-8 in MEMS components has also been shown to form optical waveguides. Because of the excellent optical properties of SU-8 waveguides, they have been used as biosensors and in other detection schemes (Chang-Yen and Gale 2003). For rapid and efficient prototyping, direct integration of the optical waveguide reduces coupling losses and interference from the microsystem platform. The direct fabrication of SU-8 into MEMS devices facilitates this integration by removing additional packaging and fabrication steps.

1.12.2.2.2 Photosensitive glass

Photosensitive glass allows for direct fabrication of glass microstructures, which can eliminate a number of later processing steps. In most cases the elimination of the later steps allows for an overall reduction in the cost of device fabrication, which is necessary to offset the relatively high cost of obtaining photosensitive glasses.

Photosensitive glass has a unique set of characteristics that allow the etch rate of the glass to be modified using common lithographic techniques, creating a 20-fold increase in the etch rate of the modified areas. This physical change allows for direct fabrication of glass structures and makes it possible to create anisotropically etched features in the glass without the need for masking the glass during the chemical etch itself. **Figure 3** shows diagrams for this process.

The unique chemical behavior of photosensitive glass is due to its special composition. Each brand of this type of glass has a proprietary recipe. The important constituents of all types of photosensitive glass are the introduction of metallic ions – in this case silver (Ag^{+}) – and cesium oxide (CeO_2) into the glass matrix (Stookey *et al.* 1978). When the photosensitive glass is exposed to UV light or other high-energy sources such as a proton beam (Gomez-Morilla *et al.* 2005), infrared femtosecond laser (Hongo *et al.* 2005), or X-rays (Shimizugawa *et al.* 2003), the cesium

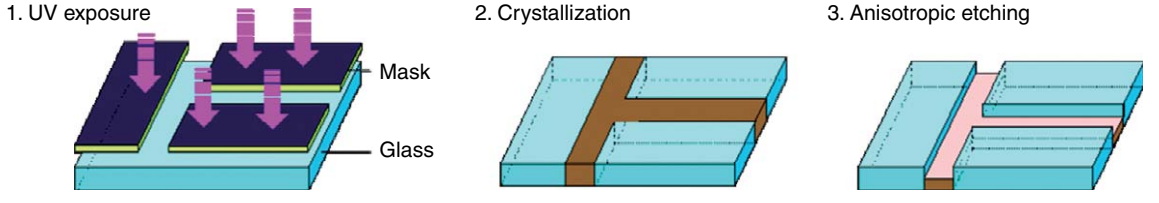

Figure 3 Microfluidic structures can be fabricated in photosensitive glass by first masking and exposing the glass to UV light, then heat treating the glass, and finally covering the entire surface with an HF-containing solution.

causes the metals to precipitate out of the glass matrix. The nucleation of the metals and other additives during heat treatment causes a visual discoloration of the exposed areas and a local weakening of the molecular network. It is this alteration of the glass matrix that causes the exposed areas to etch at rates much higher than the rates for the unexposed regions. Because of these unique properties, photosensitive glass has some distinct advantages and disadvantages. Since the chemical etch is anisotropic in nature, virtually straight sidewalls are formed. This contrasts with the curved etch profile associated with isotropic etching. In addition, photosensitive glass can be etched with high aspect ratios, while the typical isotropic etch can never be more than half as deep as it is wide. **Figure 4** shows a structure that was formed by anisotropically etching photosensitive glass.

Photosensitive glass is often used to create microfluidic channels, which requires another layer to seal or close off the channel. Multiple layers of photosensitive glass may be bonded using fusion bonding techniques (Olsen and Serpa 1978) and other traditional glass-bonding methods such as pressure-assisted bonding, chemical bonding, water bonding (Ito *et al.* 2001), and glass–metal bonding. Anodic bonding is not typically used with photosensitive glass due to mismatch problems in the thermal expansion coefficient between the glass and silicon. Other channel sealing methods using tapes, PDMS, and other polymers have been demonstrated. Embedded 3D channels have also been created in photosensitive glass using femtosecond lasers (Masuda *et al.* 2003), but this technology is certainly not inexpensive.

1.12.3 Photolithography Replacements

A number of techniques have been developed to circumvent the need for any photolithography steps in the production of microscale devices. These techniques typically use some sort of cutting or machining process to produce microstructures that can then be reproduced using molding. For those techniques not amenable to later molding, the processes, even though they are serial in nature, are sufficiently fast and inexpensive that they can easily compete with photolithographic processes. Some of these processes, such as ink-jet printing and screen printing can be direct replacements for photolithography since they can be used to deposit a resist material directly. Microcontact printing (μCP) can also be used to deposit resists and other materials as a replacement for photolithography, but as it is a subset of soft lithography, which is discussed elsewhere (Section 1.12.4.1.2), it will not be discussed here. Techniques such as xurography and laser cutting of laminates produce microdevices directly (or masks

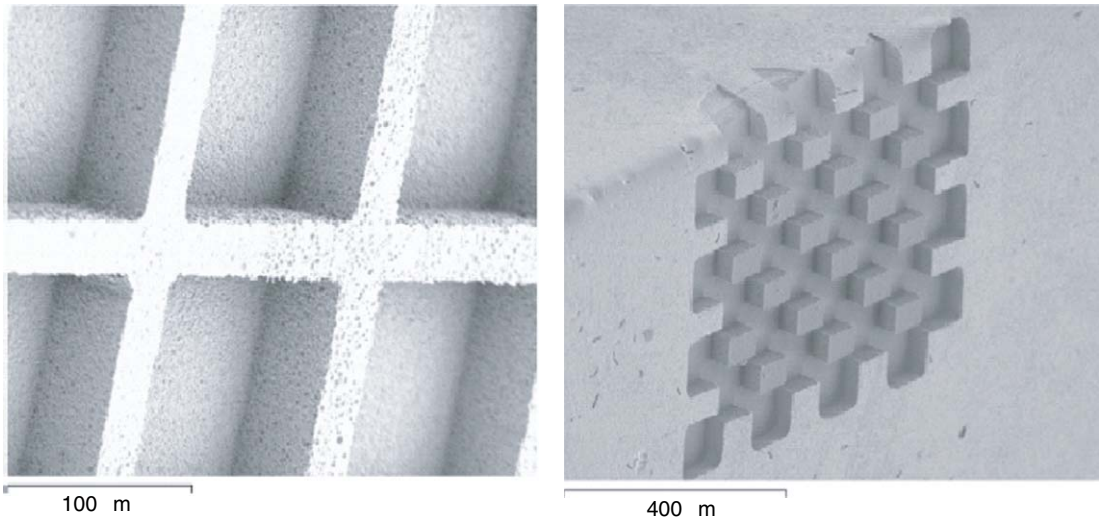

Figure 4 Features made using an anisotropic etch in photosensitive glass. (Source: Gomez-Morilla I, Abraham M H, de Kerckhove DG, Grime G W 2005 Micropatterning of foturan photosensitive glass following exposure to MeV proton beams. *J. Micromech. Microeng.* **15**, 706–9; reproduced with permission from the Institute of Physics.)

directly) and can eliminate not only the photolithography process, but all of the subsequent etching and deposition processes.

Traditional machining techniques are also beginning to enter the microdomain and impressive demonstrations of efficient, relatively inexpensive devices fabricated using micromilling, microelectro discharge machining (microEDM), and related technologies are becoming more common (Hupert *et al.* 2006). These techniques, though, tend to be serial and very slow, so they are typically only useful for making molds that are later used to produce microdevices. Thus, they will not be explored further here, especially since there is significant literature already available on these traditional techniques.

1.12.3.1 Ink-Jet Printing

In general, two types of deposition methods are used with ink-jet printing: continuous-mode technology and the more frequently used drop-on-demand (DOD) technology. The continuous-mode print head uses a pressurized fluid chamber to create a continuous fluid stream, which is divided into droplets by pulsing the fluid with a transducer. These droplets are electrostatically charged and are able to be deflected in order to either hit or miss a moving target substrate. The DOD method uses a volumetric change, at ambient pressure, in the fluid to create droplets either by the displacement of a piezoelectric element (Wallace 1989) or by forming a bubble in the ink by heating a resistive element (Aden *et al.* 1994).

1.12.3.1.1 Feature size capabilities

For ink-jet printing, the properties of the print head, the substrate material, the dispensed ink, and the mechanical resolution of the printer are key factors in determining the minimum feature size capabilities. The dispensing head of ink-jet printing determines the amount of fluid dispensed per deposition. The DOD method is preferred because it is able to form much smaller droplets (~20–100 μm in diameter) than the continuous-mode system (diameters up to 0.5 mm may be produced). Also, the continuous mode has relatively high priming volumes and is not very consistent for droplet placement. The piezoelectric print head is usually chosen over DOD with microfabrication because it allows a larger range of ink compatibility when compared to the thermal print heads, which are generally limited to water-based inks, unless the head is redesigned for each differing solvent that is desired to be used within the ink.

The temperature and hydrophobicity/hydrophilicity of the substrate material are important in providing minimum microfeatures. Heating the substrate that the ink will be deposited on, generally in the range of 100–300 °C, improves the deposition quality. One reason for this is that the evaporation of the ink is almost immediate once in contact with the substrate, thus eliminating many wetting problems such as surface tension causing bulging or pinching, uneven surface wetting due to contamination, dust particles that can wick the ink, and scratches that may be on the surface, which creates a capillary effect causing the ink to spread. Also, with rapid ink evaporation, multiple layers can be deposited relatively easily and quickly (Fuller *et al.* 2002) to form 3D structures (Gothait 2003). The surface chemistry (hydrophobic or hydrophilic properties) is also important in defining the minimum feature size. Hydrophilic and hydrophobic regions can be defined on the substrate surface to help control where the ink is deposited by having the ink attracted to certain regions and repelled from others (Sirringhaus *et al.* 2000). These surface regions can be fabricated on the substrate surface using common microfabrication techniques or inexpensive alternative methods.

The dispensed ink composition is another important attribute. Viscosity, evaporation rates, surface tension, solvent used, and adhesion promoters are important properties for ink. High viscosity and low evaporation rates are generally recommended for dispensing because the print head is less likely to get clogged. The surface tension and ink-base chemical makeup plays a key role in determining how much the ink will spread once in contact with the substrate. Several solvents that change the homogeneous film formation on the substrate (water, terpineol, acetophenone, anisole, butyl acetate, ethyl acetate, methyl benzoate, toluene, and *p*-xylene) can be used (Tekin *et al.* 2004). The adhesion promoters within the ink determine how well the ink will bind to the substrate. For conductive inks, the size, dispersion, and stability of the metallic nanoparticles in the ink are very important. Clogging can occur if the particles are too large or if aggregation occurs among the metallic nanoparticles. These physical properties also determine the conductivity performance of the metallic ink once deposited on the substrate.

The mechanical resolution of the ink-jet printer plays a role in the quality of microfeatures

achievable. This depends on the mechanical resolution of the print axes. Accurate positioning of the ink-jet head allows for less dimensional errors when fabricating devices and determines minimum linewidth and minimum spacing between features.

1.12.3.1.2 Ink-jet printing applications

Applications for microfabricating devices using ink-jet printing technology includes solder printing, conductor trace printing, printing of adhesives and dielectrics, printing of optical polymers, and multiple-layered structures.

Ink-jet printers have been found capable of depositing conductive (Lee *et al.* 2005, Mei *et al.* 2005) and magnetic inks (Voit *et al.* 2003) efficiently and, therefore, ink-jet printer speed and resolution have been used for addressing specific electronic fabrication needs and creating magnetic mass storage patterns. The deposition of solder bumps on circuit boards and even fabrication of the entire circuit board – the traces, dielectric coating, and solder bumps – all using an ink-jet printer has been demonstrated. It has been shown that up to 600 bumps per second can be achieved using this technology without needing to have contact with the board during fabrication, thus providing the electrical interconnects necessary. Solder bumps as small as 24 μm have been printed (Hayes *et al.* 1999a). Furthermore, it has been shown that the entire circuit board interconnects can be fabricated using solely ink-jet printing. **Figure 5** shows a diagram of how the traces, dielectric coating, and solder bumps could all be fabricated with an ink-jet printer (Hayes *et al.* 1999b).

Printing of thermosets, thermoplastics, and UV-curable adhesives can also be deposited (Meyer 2001) for component bonding or even for the creation of waveguides. For this application, wettability between the surface and the deposited material is important. If the surface energy of the substrate is too high, the adhesion to the subsequent material may not work well. A low-wetting coating can help the flow of adhesive on the substrate without adversely affecting the adhesion.

Three-dimensional ink-jet printing is now regularly used to do rapid prototyping of all kinds of devices (some rather large). On the microscale, some of the most interesting applications include fabrication of microfluidic devices (Cooley *et al.* 2001) and tissue engineering (Saunders *et al.* 2005).

1.12.3.2 Screen Printing

Screen printing is able to provide an inexpensive and versatile manufacturing method for depositing material on almost any surface with precision. This fabrication technique is able to minimize the amount of material waste during deposition by directing it to specified locations, unlike the traditional techniques of spin coating and PVD, which are incapable of this material control. It has been found that screen printing can achieve linewidths and line spacings down to 50 μm (Hughes and Ernster 2003).

The basic principle of ink deposition using screen printing is to pass a squeegee over a screen, forcing ink through the screen onto a substrate. Off-contact printing and contact printing are the two main

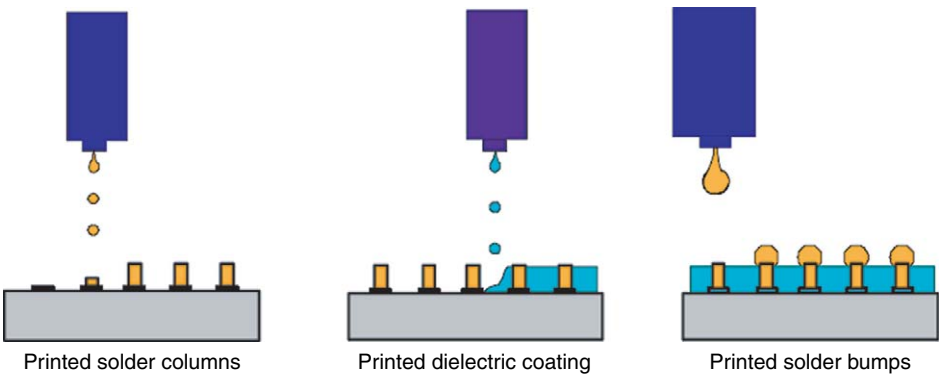

Figure 5 Process diagram for building chip-scale packages by printing solder columns, followed by a dielectric coating between the solder columns, and finally the solder bumps on top of the solder columns. (Source: Hayes D J, Wallace D B, Cox W R 1999 Microjet printing of solder and polymers for multi-chip modules and chip-scale packages. *Proc. IMAPS Int. Conf. High Density Packaging and MCMs*, Denver, CO, USA, pp. 242–7. © 1999, reproduced with permission from IMAPS – International Microelectronics and Packaging Society.)

methods used. Off-contact printing allows the screen to be in contact with the substrate only where the squeegee is located and is the most commonly used technique. Stretching the screen mesh, by applying pressure to the squeegee, causes the screen to come in contact with the substrate and forces the ink particles to pass through the screen. When the screen is released from tension it snaps back, leaving the ink adhered to the substrate, as illustrated in **Figure 6**. Contact printing allows the entire screen to be in contact with the substrate during the printing process and the ink is deposited on the substrate by the force of the squeegee applied to the ink particles. Following ink deposition using one of these methods, the ink is allowed to settle and is then dried, generally between 100 °C and 150 °C, in order to evaporate the solvent out of the ink. Heat treatment may then be given to the dried ink by firing it in a kiln at a temperature between 600 °C and 900 °C (Jeong *et al.* 2001).

Screen printing components include the ink, squeegee, stencil, screen, and substrate. Each of these components introduces variables into the system that will need to be optimized:

(1) The properties of the ink: The ink viscosity affects the printed thickness of the substrate – the lower the viscosity the thinner the print. Drying and firing cause the ink to shrink and must be accounted for when designing a stencil.
(2) Screen printer settings: If the screen distance is small and the screen tension is less, ink will remain in the screen; if it is too large, a thicker pattern that can damage the screen is generated. The faster the squeegee passes over the screen the thinner the film, but if this is too fast it could result in gaps or inconsistencies within the printed pattern. Increasing the squeegee pressure can result in a thicker print. The increased angle and differing geometry of the squeegee can also increase pressure on the ink, yet it does not increase pressure on the screen.
(3) Geometry of the stencil: The tolerances and feature sizes of the stencil generated on the screen determine the minimum feature sizes available for the printed pattern.
(4) The screen: The mesh size, mesh material, and wire diameter/geometry help determine the thickness of the film printed – the smaller the mesh the thinner the print.
(5) The substrate: If the substrate is not flat or not parallel to the screen, film thickness will vary across the substrate (Jabbour *et al.* 2001, Parikh *et al.* 1991).

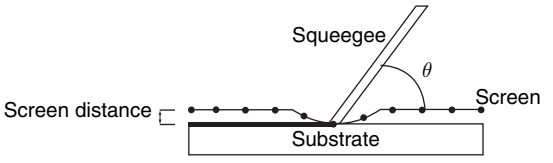

Figure 6 Illustration of off-contact screen printing method. The screen distance and squeegee angle are defined. As the squeegee passes, the screen is stretched to contact the substrate, while forcing ink particles through the screen simultaneously. Once the screen is released from tension it snaps back to its original position, leaving the ink adhered to the substrate.

Many applications of screen printing for microfabrication have been demonstrated. One common use is in generating solar cells that are up to 15% efficient in using screen printing fabrication (Doshi *et al.* 1996, Rohatgi *et al.* 2003, Sakai *et al.* 2005). Screen printing has been used to produce disposable electrochemical sensors (Xu *et al.* 2004). A thick-film screen printing has been used to create diaphragms within ceramic capacitive pressure microsensors (Sippola and Ahn 2005). Flip chip packaging has used screen printing of solder as an inexpensive fabrication method (Chow *et al.* 2000). Fabrication of photodiodes with a response time of 0.32 s and a rise time of 0.48 s has also been achieved using screen printing (Yahaya *et al.* 1998).

1.12.3.3 Stamping

Stamping relies upon the fabrication of a master mold that can generate replica patterns. Molds for creating stamps are typically etched structures in silicon wafers, lithographically patterned SU-8, or electroplated metals. Polymeric materials that are soft and elastic are typically used for the molding of the stamp contact head. PDMS works well for most stamping applications due to its transparency, flexibility, and biocompatibility. For high-resolution applications, more rigid materials are required for the stamp head. However, a trade-off occurs as more rigid materials do not provide the same levels of surface contact that flexible materials provide. In these cases a combination or hybrid material can be used to attain a high degree of contact and resolution. Other important parameters to consider when using

stamping processes are the aspect ratios of the patterning features. For high aspect ratio structures, a tendency to buckle is possible depending on the flexural strength of the material and the applied pressure necessary. Low aspect ratio structures, if spread far apart, may experience bowing from the bulk material between structures that may impede clean stamp patterning. Stamping in microfabrication is typically referred to as microcontact printing and is discussed in much greater detail in Section 1.12.4.1.2.

1.12.3.4 Laminate Microfabrication

Laminate, or layered, fabrication approaches have been developed to enable device assembly from thin sheets of polymer plastics, SU-8 films, photopolymer dry films, PDMS, and other materials. Because of their relatively inexpensive and easily machinable characteristics, polymers have moved to the forefront as materials used for rapid prototyping and fabrication. Polymer laminates have much to offer in the field of MEMS because of their ability to make 3D microfluidic devices that can be passively or actively driven by interfacing with other components. Laminate fabrication techniques allow for quick fabrication times, reduced costs, and 3D structures that are capable of incorporating hybrid elements such as electrodes, filter membranes, pumps, and sensors. Although the use of hybrid elements complicates fabrication and design since multiple patterns and a difficult assembly process are required, rapid fabrication methods, cheap material selection, and simple bonding techniques make laminate fabrication possible and useful (Sasserath and Fries 2002). Laminate MEMS fabrication has been demonstrated commercially as the primary fabrication method used by a company called Micronics based in Washington, USA. The company uses laminate technologies to do both rapid prototyping and commercial production of microfluidic chips for researchers and businesses. Presented here are methods and techniques demonstrating how laminate microfluidic chips can be quickly patterned and bonded together to make 3D microfluidic devices. The limitations of the different techniques are discussed and the major applications presented.

1.12.3.4.1 Laminate materials

Laminate microfluidic chips can be made using a variety of materials and fabrication methods. The two most common materials are thin polymer plastics, which can be bonded using adhesives or thermal processes, and PDMS, which can be bonded using surface plasma treatments and pressure, or thin layer cross-linking and baking. Other laminate layering methods include SU-8 and dry film photoresists that can be photopatterned using photolithography and bonded together to form multilayer laminate structures.

1.12.3.4.1.(i) Polymers Thin polymer sheets, such as Mylar or polystyrene, are commercially mass produced and can be purchased to fabricate polymer laminate chips. These materials are typically ordered as large rolls of thin sheets or can be purchased as smaller precut sheets. Sheet thicknesses can range anywhere from 10 μm to hundreds of microns if desired. Sheets can be made of different polymers and can be coated with various adhesives depending on the desired application of the laminate card and the intended use of buffers and samples. The thin polymer sheets and adhesives are assembled as a five-layer sandwich consisting of the polymer, adhesive layers, and siliconized release layers, as shown in **Figure 7**. The polymer and adhesive materials are generally compatible with aqueous solvents and their selections may vary depending on the solutions with which it will interface. The sandwich of polymer, adhesive, and release layers can all be patterned at the same time and are most practically and inexpensively patterned using a CO_2 laser.

1.12.3.4.1.(ii) SU-8 films SU-8 is a commercially available negative-resist photopolymer that can be spun on to a release substrate and patterned using UV light. The unexposed SU-8 is then typically etched away using an SU-8 developer leaving the patterned SU-8 structure behind. If the SU-8 is spun on to a thin release layer such as polyester (PET), the thin layer of SU-8 can be dried and then attached to another layer of SU-8 using plasma treatment and a slight pressure. The non-cross-linked SU-8 layer can then be cross-linked by UV light passing through the thin PET layer and the uncrosslinked SU-8 will be peeled away along with the PET layer, resulting in a dry release of the SU-8 (Abgrall *et al.* 2006).

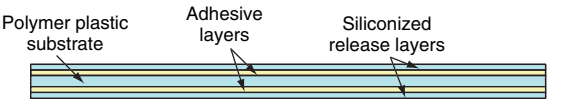

Figure 7 Illustration of how sandwiches of Mylar, adhesive, and release layers are patterned and assembled together.

1.12.3.4.1.(iii) Dry film photoresist Dry film photoresist tape is a prefabricated thin sheet of negative photoresist that is intended to be photopatterned using UV light, quickly bonded to another substrate, and developed using a photoresist developing reagent. Its advantages include reduced process times, reduced UV light intensity exposure, and uniform photoresist thickness. One example of its use is to form photopatterned channels and to sandwich it between two layers of different materials to form microfluidic channels. The use of SU-8 and dry film photoresist layers allows for smooth surfaces and smaller channel thicknesses because of its use in photopatterning, but still requires expensive photomasks, photoresist development, and UV sources and alignment (Tsai *et al.* 2006).

1.12.3.4.1.(iv) Poly(dimethylsiloxane) PDMS is another material that can be used to form 3D laminate microfluidic components and is relatively inexpensive when compared to glass. Some of the advantages of using PDMS include cost, bond strength, softness/deformability, thermal properties, and transparency. PDMS is a soft two-part polymer that is patterned by pouring a thin layer of uncrosslinked PDMS on photopatterned structures, such as SU-8, or by a process of injection molding, then cured using heat or other cross-linking activation processes. Multiple-patterned structures of PDMS can be assembled together using a plasma treatment and pressure, or by applying a thin coating of uncrosslinked PDMS between two partially cured layers, which will create a hermetic cross-linking between each layer when completely cured. This technique has been used to develop a protein array printing method using continuous flow microspotters fabricated from five separately patterned layers of PDMS using injection molding (Chang-Yen and Gale 2005). Some disadvantages associated with PDMS are channel collapsing and poor adhesion effects if channels are too small or too close together. In addition, this material must usually be patterned on the surface of another mold or pattern, which reduces its rapid prototyping abilities and increases costs.

1.12.3.4.2 Laminate patterning methods

Several methods are available for patterning thin laminate layers, including photolithography, as discussed earlier. Examples discussed here include the patterning of polymer laminate cards using a laser, particularly a CO_2 laser. Other polymer plastic patterning methods include techniques using a cutting plotter known as xurography and stamp cutting.

1.12.3.4.2.(i) CO_2 laser cutting Laser ablation and laser cutting first became popular in micromachining because structures could be patterned quickly in a substrate from a simple drawing rather than by using traditional micromachining methods such as photolithography. This process can be taken one step further by using a CO_2 or other laser to completely cut through a polymer sheet rather than only remove a portion of it (Verporte and Rooij 2003). CO_2 lasers can operate anywhere between 10 and 400 W but most materials would typically only require 85 to 120 W lasers to cut through the layers of plastics and adhesives common for MEMS dimensions. Laser cutting is also relatively inexpensive; a typical CO_2 laser can be purchased for less than US$10 000 and is very flexible in its patterning abilities. Though laser cutting is a serial process, the lasers can work very quickly and a significant numbers of parts can be generated rapidly.

The pattern to be etched into the polymer plastic can be drawn in a computer-aided design (CAD) program and input into the translation stage control software of the laser to automate the cutting out and patterning of each polymer layer. This allows for a rapid prototyping setup where fabrication can move from the design stage to the actual patterning and cutting stage within a number of hours. The smallest feature sizes demonstrated using a CO_2 laser in Mylar is about 50 μm; however, 75 μm is the practical limit of the technology and the average dimension of commercial processes are typically 100 μm and higher (Weigel *et al.* 2001). Laser cutting speeds vary depending on the power of the laser, the speed of the equipment used, and the thickness and material properties of the substrates to be cut. One limitation of CO_2 lasers and laminates is that they primarily melt the polymer film and so a thin ridge of material is often left at the edge of the cut, occasionally making bonding or precise manufacturing difficult.

1.12.3.4.2.(ii) Other laminate patterning techniques As mentioned previously, there are other methods used to cut and pattern polymer laminate cards. Xurography is a method that uses a sharp blade controlled by an automated knife plotter to remove structures from a sheet of polymer plastic (Bartholomeusz *et al.* 2005). This technology is equally useful for rapid prototyping; however, it is a slower patterning process, which can possibly deform the material at the edge of cuts and does not have such small feature sizes or tolerances. For more information on this technology, refer to Section 1.12.3.5.

Another method that is highly practical in mass producing laminate structures is stamp cutting. This can be done by forming sharp cookie cutter type structures to cut out the desired features in the laminate by applying a high pressure. Although stamp cutting is a low-cost method of mass producing layers, it is not as useful for creating quick prototypes and for varying patterns. The possible feature sizes and tolerances using stamp cutting techniques are limited by the stamp's fabrication methods, the material thickness, and the complexity of the design to be cut out. Other methods and materials can be used to fabricate layered microfluidic structures such as powder blasting, molding, and others such as is common in patterning PDMS, SU-8, and dry film photoresists mentioned previously.

1.12.3.4.3 Laminate card assembly

Each laminate layer that is to be used to produce a 3D microfluidic device or lab card is patterned one at a time. Once the 2D patterns are designed in each layer, the patterned layers are cleaned and the release layers are removed to expose the adhesive. This layer is then brought into contact with another polymer layer and pressure is applied to bond them together. Each polyester layer can vary as to whether or not it will have adhesive coatings on them. Typically, the assembly is alternated with one layer having adhesive on both sides of the polyester sheet and the next layer having a patterned polyester sheet with no adhesive layers on either side, as illustrated in **Figure 8** with the assembly of a 17-layer lab card (Weigl *et al.* 2003). This helps reduce the thickness of adhesive layers between each polymer layer and simplifies purchased material selections. Layers can also be bonded using a thermal bonding process or UV adhesives. Devices fabricated using this technology typically have depth tolerance of less than 1 μm and a width tolerance of about 10 μm. Typical channel dimensions of these devices are 100–3000 μm in width and 50–400 μm in depth (Weigl *et al.* 2001).

In addition to the design of each layer forming the microfluidic device, numbers and alignment holes are cut out to properly align each card during the assembly stage. The patterned layers are then aligned with each other in their proper sequence, as shown in **Figure 9**. Typical alignment tolerances are in the 1- to 30-μm range depending on how tightly the alignment marks fit with the guide rods. Once the entire 3D device is put together, it is tightly pressed to ensure a sound adhesive bond. In some cases the plain laminate layers can be chemically treated (e.g., with oxygen plasma) to change their wettability, thus modifying the internal surfaces of the channels. Other materials like PDMS or glass can be fabricated and aligned using their typical micromachining processes.

Not only can 3D lab cards be fabricated from multiple layers of the same material, but hybrid circuit structures and varying materials can be used as well. For example, one or two layers of thin Mylar can be sandwiched between glass slides for added structural integrity or optical properties. Polymers, metals, glass, silicon, and dry stored chemical compounds can be incorporated into the devices during assembly. For example, dry stored reagents and dyes can be stored in small cavities inside the lab card where it can be rehydrated and used during one of its operation steps (Weigl *et al.* 2001). Another example of the added benefit of assembling MEMS devices as laminate layers is that necessary interconnects and packaging components can be inserted between the last and second-to-last layers of the card, eliminating the need of manifolds and adhesive bonds for packaging.

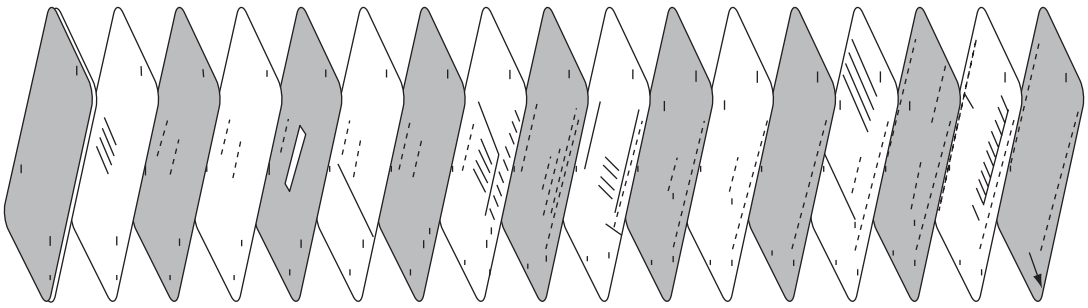

Figure 8 Illustration of how 17 layers of patterned Mylar cards are assembled in alternating layers, the light-colored cards have double-sided adhesive on them and the dark-colored cards have no adhesive on them. (Source: Weigl B H, Bardell R L, Schulte T, Battrell F, Hayenga J 2001 Design and rapid prototyping of thin-film laminate-based microfluidic devices. *J. Biomed. Microdevices* **3(4)**, 267–74. ©2001, reproduced with permission from Elsevier.)

(b) The layers are pressed together and the alignment tubes are removed. (c) A picture of the finished card with dye running through 100 and 200-μm channels for visualization. (Source: Bartholomeusz D A, Boutte R W, Andrade J D 2005 Xurography: Rapid prototyping of microstructures using a cutting plotter. *J. Microelectromech. Syst.* **14(6)**, 1364–74. Figure ©2005, reproduced with permission from IEEE.)

Because of the speed and simplicity of patterning and assembling Mylar or other plastic laminate layers using a CO_2 laser, complex 3D lab cards can be very quickly assembled from simple 2D layers. The entire process of moving from a CAD design to a complete 3D finished product can take place in less than 4 h, as opposed to days or weeks using other prototyping and fabrication methods. Micronics, a company heavily involved in this technology, uses a class 10 000 clean room facility and is capable of producing over 100 000 laminate devices annually, with an average production of 40 000 new prototype cards per year.

1.12.3.4.4 Applications and examples of laminate technologies

Laminate methods have been used to create a wide variety of microfluidic devices. Micronics has developed a microcytometer card, a T-sensor card, and an H-filter card (Weigl *et al.* 2001). The 3D laminate approach has been used to develop devices that enable the analysis of whole blood using 3D fluid control and on-chip sample preparation.

The ability to easily incorporate hybrid elements into laminate cards allows a variety of applications. Applications for this technology include being able to develop passively driven point-of-care medical diagnostic devices for use in third world countries and remote areas. This can be achieved by incorporating reagents and analysis tools on chips or in hand-held devices. Another example of how hybrid elements can be used in laminate chips includes components to fabricate ferrofluidic micropumps. A ferrofluidic plug is placed inside the chip and combined with valves and externally moving magnets as seen in **Figure 10**, and a small pump is made for pumping highly controllable flow rates (Yamahata *et al.* 2003).

Owing to the 3D layout of laminate cards, gravity, absorption, and capillary action can all be used as pumping mechanisms to allow for passively driven microfluidic devices. They can also function as actively driven devices by easily interfacing with manifolds or other devices for portable point-of-care diagnostic devices. Because of the inexpensive nature of the materials used and the rapid fabrication processes achievable using CO_2 laser cutting techniques or stamping, the lab cards are well suited as disposable products and are convenient for research and development applications.

1.12.3.4.5 Limitations of laminate technologies

There are several limitations associated with the laminate approach to MEMS and microfluidics. Since a CO_2 laser is being used to cut and pattern each laminate layer, typical laser limitations will still exist. One is that the laser beam can only be focused small, so a limit of about 50 μm to about 75 μm applies to any features. In addition, the use of lasers will cause striations in the sidewalls of the cut material, as noted by Yilbas (1997), as well as bumps next to the cut wall. Striation effects will vary depending on the power of the laser and the speed of the cut; as a general rule, the slower the cutting speed the larger the striation widths. In addition to feature size limits and striation effects, tolerances in the cutting and alignment processes can be problematic. If decent laser patterning equipment and effective alignment techniques are used for patterning and assembly, finished laminate cards can have width tolerances as

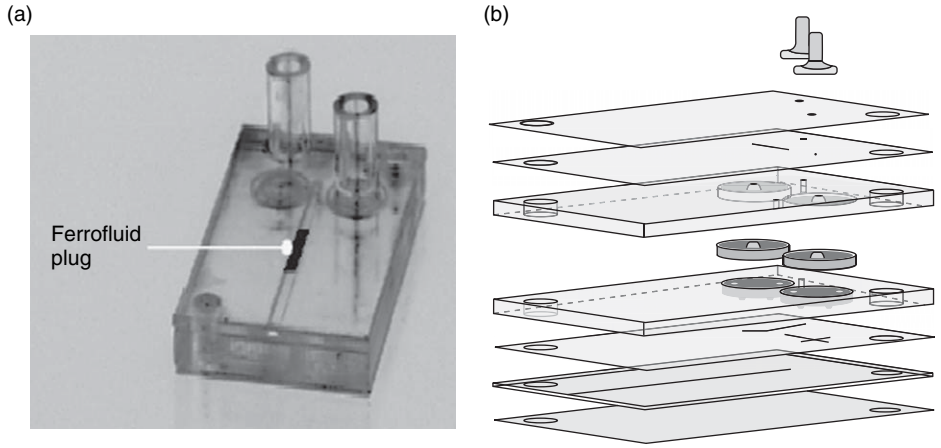

Figure 10 (a) Photograph of an assembled ferrofluidic micropump constituted of seven layers of polymethylmethacrylate (PMMA), two silicone check valves, and a ferrofluidic plug. (b) Burst view of seven PMMA layers with other microcomponents to form the ferrofluidic pump. (Source: Yamahata C, Chastellain M, Parashar K, Petri A, Hofmann H, Gijs M A M 2005 Plastic micropump with ferrofluidic actuation. *J. Microelectromech. Syst.* **14(1)**, 96–102. Figure © 2005, reproduced with permission from IEEE.)

low as 10 μm and depth tolerances of less than 1 μm (Weigl *et al.* 2001). Limitations on striations, feature sizes, and tolerances can be improved using photopatterned techniques such as SU-8, and dry film photopolymers, but these methods are also slower and more expensive.

Another inherent limitation of laminate fabrication is the bonding strength and feature spacing limits when bonding layers together. Although different adhesives and bonding methods have their own advantages and disadvantages, the more the number of layers to be assembled together, the more the chance of a bond failure. Other limitations of laminate MEMS include the material properties of the different materials used. Problems such as thermal stability, optical properties, rigidity, strength, sensitivity to light or long-term storage, varying thermal coefficients of expansion and reactivity of the materials with solvents and solutions are also present. In addition, when combining hybrid elements having different material properties, stresses and strains may occur and fabrication times will likely increase.

1.12.3.4.6 Summary for laminate technologies

Complex 3D lab-on-a-chip cards can be quickly and easily developed by stacking multiple layers of patterned materials. Using laser cutting techniques, each layer can be rapidly patterned without the need of photolithography masks, molds, or other time-consuming techniques. Most polymer plastic materials are suitable for a variety of applications and can be used for fluorescence detection and other optical detection methods due to its transparency. A fabrication setup can be purchased at a relatively low cost and prototyping and fabrication can take place very quickly.

By taking advantage of 3D structures, passively driven devices can be made to operate by themselves or actively driven devices can be made to interface with other equipment. Hybrid elements and multiple materials can be easily incorporated into the lab cards design without extensive design modifications and time-consuming processes. Surface modifications of the internal laminate layers can be made using chemical treatments such as oxygen plasma treatments.

Limitations include striation patterns and deformations in laser cut edges, dimensional tolerance of about 10 μm and feature size limits of about 50 μm, material property limitations, adhesive bond limitations, and minimal feature spacing limitations of about 100 μm. The tolerances and minimal design features given, however, are acceptable for most microfluidic applications. In addition, useful devices can be made at a low cost, making them convenient for disposable lab cards and affordable prototyping cards. Overall, this is a fast and affordable method of creating high-performance microfluidic devices made from inexpensive materials suitable for a variety of applications.

1.12.3.5 Xurography

Cutting plotters have been used in the graphic design industry for some time, generally cutting designs out

of adhesive-backed materials should be used in creating signs or other artwork. The cuts are made by dragging a knife blade through the material to be used. Once the cuts have been made, the undesired material is peeled away and discarded. A transfer tape is then applied to the top surface of the remaining material so that the design can be moved from its material backing to the desired substrate.

Many of these cutting plotters have good mechanical resolution with a step size down to 5 μm with some plotters. At the beginning of 2005, Treise *et al.* used a cutting plotter to fabricate planar microfluidic channels by creating the channel design out of a vinyl film using a cutting plotter and sandwiching the channel between a Plexiglas backing, with inlet and outlet holes, and an adhesive covering layer. Later in 2005, Bartholomeusz *et al.* extensively validated this microfabrication process with multiple materials and multiple fabrication techniques. This group found that microfeatures could be fabricated down to linewidths of approximately 20 μm with some materials. They coined this microfabrication method xurography, using the Greek root words *xuron* and *graphe*, which mean razor and writing, respectively. This prototyping method is intriguing because a microdevice prototype can have a very short turnaround time; microdevices can be designed, fabricated, and tested within a working day.

1.12.3.5.1 Dimensional capabilities of xurography

The feature sizes obtainable in xurography depend on several factors associated with a cutting plotter. The minimum step size of the cutting plotter, blade sharpness, blade angle, material properties of the substrate, cutting speed, cutting force, and cutting mode are all key factors that determine the smallest features possible and will be discussed in greater detail.

The minimum step size for cutting plotters is divided into two categories: mechanical resolution and addressable resolution. The mechanical resolution is defined as the smallest step size of the stepper motors and generally ranges from 5 to 25 μm, depending on the machine used. The resolution of the particular cutting plotter helps to define how small the features are that can be achieved. Most of the high-resolution cutting plotters have a mechanical resolution of 5 μm and can range in cost from about US$4000 to US$5000. The addressable resolution is defined as the programmable step size allowed by the software. In general, the smallest step size range that can be output is 10–25 μm.

The blade size and geometry plays a significant role in the ultimate resolution of xurography. Differing blade thicknesses may be purchased, generally either 0.9 or 1.5 mm. Thicker blades are typically used for thicker materials. The blade sharpness is also a critical factor in deciding final feature sizes. If the blade is dull the material may start to tear, resulting in rougher edges. Also, the thickness of the blade increases at the tip as the blade becomes more dull, which limits the size of features that can be generated (Arcona and Dow 1999). The blade angle also plays a role in feature size. The three most commonly used blade angles are 30°, 45°, and 60°, as measured from the surface being cut to the edge of the blade. These blades range in price from approximately US$15 to US$85 per blade, depending on the manufacturer, angle, and material of the blade. The 45° blade provides a good all-purpose cutting angle. The 30° blade has more of the blade immersed in the material while the 60° blade is minimally in contact with the material being cut, which needs to be taken into consideration when planning for overcut in the design.

Bartholomeusz *et al.* determined the equations necessary to define what qualities determine the minimum feature sizes capable with xurography and found that the material properties of the substrate being cut play a large role in the minimum feature sizes possible. A thinner, softer material, with low Poisson's ratio and a high shear stress at the adhesive interface, yields the smallest features.

The cutting plotter settings (cutting speed, cutting force, and cutting mode) are also important in determining minimum feature size. The cutting speed is usually set to the lowest speed, which is 1 cm s^{-1} for most cutting plotters. If the speed is too fast the features will not form well due to tearing and features may possibly be missed when there is a change in direction. It is also important to have the proper cutting force. It should be set high enough so that the material is completely cut but controlled so that the backing of the material is only slightly scored. If the backing is cut too much the blade will become dull, leading to poor device geometry.

The majority of high-resolution cutting plotters have three cutting modes. The first mode is the drag knife mode, which uses a swivel blade. This mode simply drags the knife through the material and uses the frictional forces to make turns in the cut. This mode can have problems in cutting features that have sharp turns and may break the blade at some turns if the material is hard enough. The second mode is the

true tangential cutting mode, which will cut at corners by lifting the blade completely out of the material, rotating the blade with a motor, then inserting the blade back into the material. This mode can perform overcuts to ensure the material is completely cut and is a good mode for thicker materials. The third mode, the emulated cutting mode, uses a swivel blade as well. However, it will lift the blade just to the top of the material and then pivot to make a turn in the cut and will then be lowered back into the material. This mode helps to protect the blade during turns. Overcuts can be performed with this mode as well, insuring that the material is completely cleaved.

1.12.3.5.2 Xurography applications

Xurography has proven capable of prototyping microfabricated devices by creating either positive or negative features. Prototyping methods have been used in shadow masks, electroplated microchannels, micromolding (MM), and laminated microfluidic structures; another group more recently developed a variation on laminates, producing microchannels using a double-layer adhesive material. These applications will be discussed in greater detail.

Electroplated microchannels take advantage of Rubylith® material as a sacrificial layer. The material is patterned with the cutting plotter and the undesired material is peeled away. This pattern is then transferred to a substrate, which then undergoes sputtering of a titanium seed layer followed by a gold seed layer. The substrate channel ends are covered in Kapton tape, in order to prevent the inlets of the channel from being coated in metal, and then placed in an electroplating bath, depositing nickel onto the gold seed layer. Once the nickel metal is deposited, the Rubylith® is then dissolved with acetone, leaving hollow nickel channels behind.

MM over a xurography-created pattern can be done by creating positive features with a cutting plotter out of a thermal laminate or an adhesive-backed material. This material is then transferred and adhered to a dish that PDMS can be poured into, thus creating a mold. The dish and features are covered with a silane coating to prevent the PDMS from sticking to the mold. PDMS is then poured into the dish, degassed in a vacuum chamber, and cured in an oven. Once cured the PDMS is peeled from the mold, leaving microfeatures in the PDMS (Kim and Gale 2005).

Laminated microfluidic structures can be used to create 3D prototypes. This is done by cutting parts of the channel and access ports on single slices, with alignment holes cut on opposing corners of each layer. Several of these layers can be stacked together, aligned by sticking glass capillary tubes through the alignment holes, and then adhered together by applying heat and pressure (Bartholomeusz *et al.* 2005).

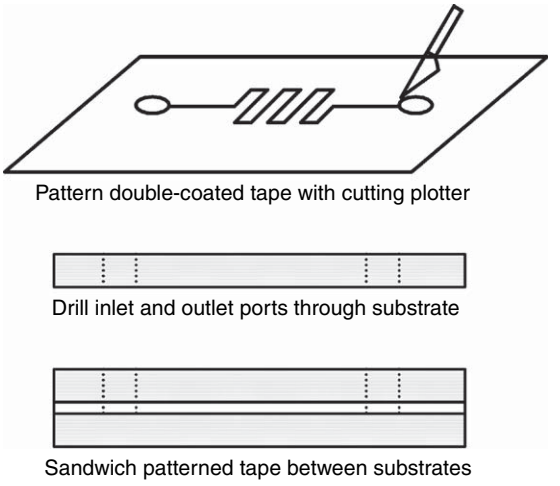

Figure 11 Microchannel fabrication process using a double-coated tape. The double-coated tape is patterned with the cutting plotter and the undesired material is peeled away. Holes are then drilled through a substrate to create inlet/outlet ports for the microchannel assembly. Lastly, the patterned double-coated tape is sandwiched between two substrates, one that has been drilled and one that has not, to seal the microchannel. (Source: Bartholomeusz D A, Boutte R W, Andrade J D 2005 Xurography: Rapid prototyping of microstructures using a cutting plotter. *J. Microelectromech. Syst.* **14(6)**, 1364–74. © 2005, reproduced with permission from IEEE.)

A double-layer adhesive material patterned with a cutting plotter and sandwiched between two subtrates for channel fabrication has been used as a very quick and simple method for microfluidics. This method involves cutting the desired channel dimensions and inlet/outlet ports out of a double-layer adhesive material using the cutting plotter. One of the substrates to be used has holes drilled at the inlet and outlet port locations for access to the channel. The double-layer adhesive material is then sandwiched between the two substrates, thus creating a microchannel (Sundberg *et al.* 2006). **Figure 11** shows the fabrication process for these microchannels.

1.12.4 Low-Cost Methods for Rapid Prototyping

In many instances, low-cost, proof-of-concept devices are the objective and more expensive techniques for further prototyping or mass production can be used

later if concepts can be demonstrated early on. Traditional MEMS methods can be extremely slow and expensive for prototyping due to the high fixed costs associated with the tooling and the difficulties in developing new processes on these tools. Outsourcing using traditional MEMS tools, which may be more cost-effective, usually has lead times of 6 months or more, which can be problematic as new concepts are being explored and there is the risk of failure in early attempts. Thus, a range of rapid prototyping techniques for MEMS devices have been developed to provide proof-of-concept before the more expensive and slow processes are applied. Note that most of these rapid, inexpensive processes are designed to implement mechanical functions, as most electrical processes are best implemented in traditional silicon and best prototyped using computer simulations.

One of the best processes for rapid prototyping in MEMS and microfluidics applications is soft lithography, which is discussed at length in its myriad forms. Other techniques for inexpensive rapid prototyping include powder blasting, photopatternable polymers (Section 1.12.2.2.1), xurography (Section 1.12.3.5), and laminate technologies (Section 1.12.3.3), the latter three have already been discussed.

1.12.4.1 Soft Lithography

Soft lithography involves the use of soft polymers that are molded over molds typically produced using photolithography. The earliest version of soft lithography, μCP (Xia and Whitesides 1998), then allows for that pattern to be replicated many times by stamping materials onto a substrate (thus the term soft lithography, Xia and Whitesides 1998, Xia *et al.* 1999). In more advanced versions of soft lithography, the molded polymers can be used as mechanical devices, most typically in microfluidics. A number of other variations of soft lithography have developed, and each will be discussed. The major advantage of soft lithography is the simplicity of the process that makes it easy for the chemist, biologist, and material scientist who want to apply these advances to their own research. The fabrication processes used to create plastic devices using soft lithography are based on replication (casting, embossing, or injection molding) and are faster and less expensive than those used on glass and silicon. The low cost of both the raw materials and the processes associated with soft lithography allows the production of potentially disposable devices. The soft polymers used with soft lithography tend to produce devices that are robust and easy to handle, which is not the case with glass and silicon microdevices. Soft lithography is also applicable to nonplanar surfaces and 3D microsystems, which is typically not the case with more traditional microfabrication techniques (Gates 2004, Xia and Whitesides 1998).

With polymers, researchers have been able to fabricate high-quality microsystems, even those on the nanoscale. We call these unconventional fabrications softlithography due to the use of a soft material and the ability to generate micropattens.

Generally, the soft lithography procedure starts by making a mold structure based on the initial idea using traditional lithography or other methods. A soft polymer is then poured over the mold and cured to produce a polymer part. The most commonly used polymer in soft lithography is PDMS as it has a number of useful properties such as reasonable strength, optical clarity, and short cure times; moreover, it has the capability of conforming to even nanoscale patterns (Roger and Nuzza 2005). Usually soft lithography is organized into two categories depending on the pattern transfer method: MM and μCP. MM includes replica molding (RM), microtransfer molding (μTM), micromolding in capillaries (MIMIC), and solvent-assisted micromolding (SAMIM). μCP is used for elastomeric stamping in order to transfer the pattern onto a substrate (Gates 2004, Xia and Whitesides 1998, Xia *et al.* 1999). In this section, the main elements of soft lithography and the primary methods of soft lithography are introduced along with a review of recent applications.

1.12.4.1.1 Material for soft lithography

Soft lithography relies on soft polymers that are appropriate for stamping, molding, and embossing. Those polymers that have a low interfacial energy, that are chemically inert, that have a high thermal stability, and that are easily modified appear to be the best candidates. Many research groups have explored a variety of materials for soft lithography including materials such as polyimide, polyurethanes, Novolactm™ resins, and PDMS, which is the most commonly used.

1.12.4.1.1.(i) PDMS material properties PDMS has several useful material properties for stamping and molding. It provides a surface that has a low interfacial free energy, is chemically inert, has good gas permeability and good thermal stability, and is

optically transparent. The surface properties of PDMS are also relatively easy to modify. The commercially available PDMS most commonly used is Sylgard™ 184 produced by Dow Corning. It consists of two parts – a silicon base and a curing agent. For basic soft lithography, the base and the curing agent are mixed well and poured over the master mold. To remove the bubbles in the liquid-state PDMS, the mold with the liquid PDMS is put into a vacuum chamber until the bubbles are completely removed. The PDMS can then be cured at room temperature (~2 days) or at elevated temperatures (a few hours). The physical properties of Sylgard™ 184-PDMS include a high tensile modulus (1.8 MPa) and high physical toughness (4.77 MPa), low shrinkage after curing (1.1%), and high elongation (160%). PDMS also has a low free surface energy ($\gamma = 21.6\,\mathrm{dyn\,cm^{-2}}$) that makes it possible to release the PDMS structures easily from the mold. The low thermal conductivity ($k = 0.2\,\mathrm{W\,m^{-1}\,K^{-1}}$) allows PDMS to be used as a thermal isolation material. PDMS has a thermal expansion coefficient of $310\,\mu\mathrm{m\,m^{-1}\,°C^{-1}}$ and is thermally stable below 150 °C. (Clarson and Semlyen 1993, Dow Corning Co. 2005, McDonald and Whitesides 2002).

The gas permeability of PDMS and the impermeability of PDMS to liquids are also useful characteristics for some chemical applications, especially in microfluidics. For example, a unique gas permeation pump has been developed by using these properties (Eddings and Gale 2006). PDMS also has good biocompatibility properties and it is possible to implant within the body and to make the cell culture chips because of its nontoxic properties (El-Ali *et al.* 2006).

The fabrication of nanoscale features has to be performed carefully with PDMS. One reason is the difference in the thermal expansion coefficient between the PDMS and the mold. This difference can cause distortion of the replicated features. The other reason for distortion is shrinkage during the curing of the prepolymer. To combat these drawbacks during the fabrication of nanoscale features, no solvent evaporation can occur and a low-temperature curing environment needs to be used. During the peel-off step (removal from the mold), distortion of fabricated structures may also occur. Also, for μCP, the stamping feature needs to have high mechanical stability to prevent the collapse of the feature, so it is important to consider the stamping geometry. To overcome these potential problems, different versions of PDMS have been developed including harder PDMS and UV-curable PDMS. With these modified PDMS, features, aspect ratios >4:1 are possible without collapsing (Quake *et al.* 2000, Roger and Nuzzo 2005).

1.12.4.1.1.(ii) Surface modification of PDMS

While the bulk properties of PDMS make it generally useful, the surface properties of PDMS are often difficult to control and pose challenges when working with many liquids and proteins. PDMS is strongly hydrophobic, which can make filling reservoirs difficult and can cause channels holding aqueous solutions to collect bubbles since the solutions dewet from the surface. PDMS structures can also become distorted when they contact organic solvents and hydrophobic analytes. The low surface energy of PDMS also makes it difficult to deposit other materials on PDMS (though PDMS does bond well to itself). For applications that need surface electrodes to produce an electric field, such as in capillary electrophoresis (CE), in electrochromatography, and in electroosmotic pumps, electrode deposition can be problematic. The PDMS surface is also highly active in that the molecules at the surface are continuously being replaced by PDMS in the bulk, making long-term control of PDMS surface properties difficult. To overcome some of these challenges, several techniques for modifying the surface of PDMS structures have been developed.

The surface of PDMS is highly inert; therefore, surface modification can be difficult to achieve. Nevertheless, several surface coating approaches have been developed including plasma, covalent, and dynamic modification methods.

Oxygen plasmas, which are composed of ionized oxygen at high energy, have been used to create hydrophilic PDMS surface through oxidation. Oxygen plasma can be used to form silanol groups (–OH) at the end of methyl groups ($-CH_3$). As the silanol groups are polar, the treated surface is easily wettable with polar solvents. This method is commonly used to treat the surface of PDMS because the process can be completed in only a few minutes, it does not require the use of chemicals, and it has good repeatability and consistency. With this treatment, PDMS can be used to implement the electroosmotic flow and bonding between molded PDMS and flat PDMS/glass. Unfortunately though, oxygen plasma treatments cannot be used for microsystems that require long-term stability. Usually, the plasma treatment is effective for less than 3 h in the

presence of aqueous solutions (Duffy *et al.* 1998, Makamba *et al.* 2003).

To overcome the mobility of the surface in PDMS, static coating, such as by covalently linking ionizable molecules to PDMS monomers on the surface, was developed for permanent PDMS surface modification. To bind these ionic polymers to PDMS, UV graft polymerization, silanization, or CVD is usually used. UV graft polymerization is used to create reactive sites (radicals) on the PDMS surface, which otherwise has no functional group on the surface. UV or ionizing radiation can generate free radicals that can be used as the initiation site for a polymeric chain on the surface of PDMS. UV graft polymerization has been shown to produce stable surface properties and is relatively easy to perform; the surface polymers have low penetration into the bulk PDMS. Silanization has been used to make an immobilized polyethylene glycol (PEG) layer on the surface of PDMS. Before stacking the PEG layer on the PDMS, the PDMS surface is oxidized in oxygen plasma and immersed into Si–PEG–Si solution. This technique is usually used to inhibit protein adsorption on the surface of PDMS. CVD can be used to deposit thin films of various materials and can also be used to modify the surface of PDMS. This approach was used to deposit reactive coatings of poly(*p*-xylylene carboxylic acid pentafluorophenolester-co-*p*-xylylene) (PPX-PPF) and poly(*p*-xylylene-2,3-dicarboxylic acid anhydride). Without the need for further activation, the high chemical reactivity of these functional groups supported conversion with biological ligands or proteins and was used for surface patterning of PDMS using μCP (Barbier *et al.* 2006, Hu *et al.* 2002, 2003, Lahann *et al.* 2003, Slentz *et al.* 2002, Xia *et al.* 2004). Another surface modification method is the use of a surfactant, which has a hydrophobic tail that can adsorb to the hydrophobic PDMS surfaces easily. This hydrophobic tail interacts strongly with the PDMS, while the charged head stretches out of the surface and changes the surface charge density. Neutral poly(oxyethylene)-based surfactants and cationic surfactants are usually used to modify the surface of PDMS (Badal *et al.* 2002).

1.12.4.1.2 Microcontact printing

μCP is the most important patterning technique among the soft lithography methods. In μCP printing, like in conventional printing techniques, the patterned stamp is brought into contact with a substrate to transfer an ink, a solution of an alkanethiol, or other molecules to a surface modified substrate and create patterns on the substrate, as shown in **Figure 12**. The technique was developed to deposit arrays of self-assembled monolayers (SAMs) within a few seconds (Jackman *et al.* 1995). A precisely arranged monolayer builds up rapidly at the area of contact (Gates 2004, Xia and Whitesides 1998, Xia *et al.* 1999). μCP of SAMs on a substrate as a resist layer or protective layer from etchants has been demonstrated as a rapid photolithography replacement technique (Geissler *et al.* 2002). Bernard *et al.* (1998) were able to pattern distinct regions of antibodies and other proteins on polystyrene substrates for further use in binding assays.

Because of the complexity of working with biomolecules, several considerations must be understood when selecting the solution to be patterned. Biomolecule solutions that will not contribute to PDMS swelling should be employed to retain the patterned resolution on the molded PDMS stamp head. Solvents that will diffuse or that have a high affinity for PDMS rather than the substrate should also be avoided to promote uniform, concentrated

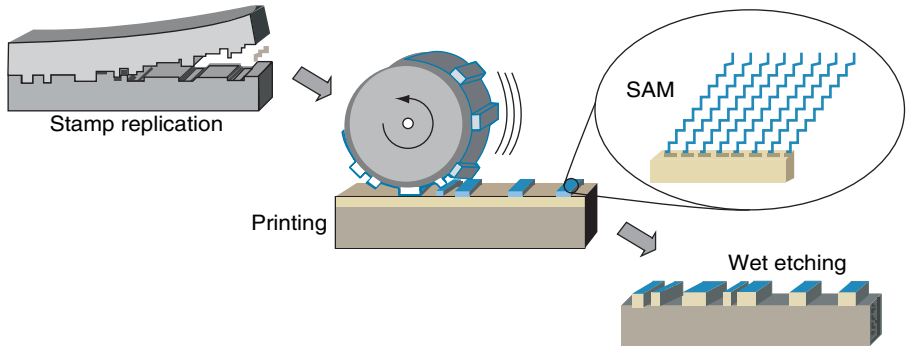

Figure 12 The microcontact printing procedure with an elastomeric stamp. SAM, self-assembled monolayer. (Source: http://www.research.philips.com/technologies; reproduced with permission.)

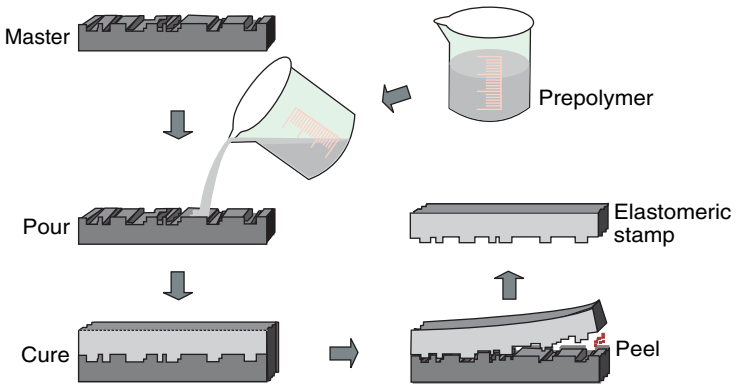

Figure 13 The stamp replication process. After curing the polymer, the elastomeric stamp is peeled off the master and uses the master for microcontact printing. (Source: http://www.research.philips.com/technologies; reproduced with permission.)

printing. Other important criteria include low vapor pressures at ambient conditions and narrow diffusion characteristics, which will assist in printing resolution and biomolecule stability (Delamarche *et al.* 2003).

The stamp for μCP is usually made from an elastomeric polymer PDMS. This material allows for conformal contact with the substrate combined with advantageous chemical and physical properties important for the molecule transfer behavior. Stamps are fabricated by casting prepolymers on a master with a negative of the desired pattern, curing it, and peeling the cured stamp off the master as shown in **Figure 13**. Depending on the stamping method, the technique is referred to as planar stamping or rolling stamping. One particular advantage of μCP is its ability to print on nonplanar surfaces with a modified planar stamp (Jackman *et al.* 1995). In roller stamping, altering the configuration slightly by curving the PDMS stamp can also achieve unique circular patterns (Franssila 2004).

The resolution of μCP is generally as good as the method used to make the mold, since μCP can replicate even nanoscale features. Recently, the resolution of μCP has been improved by solving problems such as surface diffusion, disorder at the edges of the printed SAMs, and the isotropic nature of many of the etching and deposition methods. These problems are eliminated by the use of what is called nanotransfer printing (nTP). In nTP the SAMs are used as covalent glues and release layers for transferring material from relief features on a stamp to a substrate. This approach is a purely additive technique that can generate complex patterns of single or multiple layers of functional materials with nanometer resolution over large areas in a single process step (Loo *et al.* 2002a, b).

An interesting development in μCP is to use PDMS itself as the ink material. This method, which is referred to as decal-transfer printing, utilizes a PDMS stamp to transfer other structures (such as membranes) made of PDMS. Coating the handle PDMS stamp with an organic material aids the release of the carried structures (Childs and Nuzzo 2002, Childs *et al.* 2005).

μCP can be used to pattern other microdevices. μCP has been used to make a charge pattern on thin electrets (e.g., polymethylmethacrylate (PMMA)). This technique can pattern regions of charge with lateral dimensions down to at least 100 nm (Jacobs and Whitesides 2001). μCP can be used to make patterns within microchannels as well. For example, selective adsorption of fibronectin and bovine serum albumin onto the patterned microfluidic channels and the deposition of various proteins within multiple patterns using laminar flow have been accomplished using μCP (Khademhosseini *et al.* 2004). Dozens of other applications of μCP and related techniques have been outlined in other review articles (Gates *et al.* 2004).

1.12.4.1.3 Micromolding with soft lithography

Several variations of MM using soft lithography exist including RM, μTM, MM in capillaries, and solvent-assisted MM.

1.12.4.1.3.(i) Replica micromolding MM is used to create useful structures in the soft polymers associated with soft lithography. The molds are then sometimes used to create structures in other materials. To create the PDMS mold or structures, any micromaching technology can be used to construct the pattern, but traditional silicon etching is often used. After making the original mold out of silicon or any other material, the surfaces of the patterned silicon

must be coated with silane to allow easy separation between PDMS and the patterned silicon. The prepolymer is coated on the patterned silicon and then polymerized. After curing the prepolymer, the polymer is peeled off from the master and can be used for further processing steps or used directly.

SU-8 is also used regularly to make master replica molds for PDMS molding (Mata *et al.* 2006). More information on using SU-8 to make these molds is available in Section 1.12.2.2.1.(ii). After completion of the SU-8 lithography, the SU-8 master mold has to be coated with silane to allow the molded polymer to peel off easily after curing. The prepolymer can then be cast over the SU-8 master, cured, and released. This approach has been used to produce structures under 100 nm in size.

Once a polymer (PDMS) mold has been generated, it can then be used to produce multiple copies of the original mold. The PDMS mold can be used to make multiple PDMS copies or other materials can be used. Generally, the prepolymer is not able to penetrate into PDMS and each PDMS mold can be used about 20 times before the molds begin to fail (Gates 2004). Using the RM method, it is possible to make copy nanostructures with high resolution (even copying a protein structure on the surface of the mold). For example, structures as small as 1.5 nm were replicated with a PDMS mold (Gates and Whiteside 2003). To accomplish this feat in a practical way, the feature is fabricated with a focused electron beam in PMMA and replicated in a PDMS mold. Then, polyurethane (PU) can be used to replicate the original structure using the PDMS mold. Thus, this method can replicate nanopatterns over large areas rapidly and at low cost.

1.12.4.1.3.(ii) Microtransfer molding In μTM, the elastomeric mold is filled with a polymer precursor, and the excess prepolymer is removed (**Figure 14**). The soft mold is pushed up against a substrate, the patterned feature in the soft stamp is cured while in contact with the substrate by appropriate ways, and the stamp is peeled off. By repeating this procedure, a multilayer structure can be created on a single substrate.

Compared with μCP, μTM can produce thick and multiple layers easily. But, μTM requires the use of a viscous prepolymer that consumes more time for curing and for filling the capillaries of the patterns. To speed up the process, hydrophobic dendrimers (G4 aldehyde, CHO end group) can be used to fill the capillaries of the stamp within 30 s. By controlling the concentration of dendrimers in the solution inking the PDMS stamp, minimum feature sizes of 40 nm can be achieved (Thibault *et al.* 2006). The creation of 3D structures can also be completed in a single molding step called membrane-assisted μTM. In this process, a technique such as multiphoton absorption polymerization is used to create a master structure that has closed loops that are interrupted by thin membranes. After creating the loop structure with the MAP technique, the mold is immersed in PDMS to make the mold for μTM. The PDMS is cured and the PDMS mold is peeled off from the substrate. The PDMS mold is filled with molding material and the pattern is transferred to a substrate. While the PDMS mold contacts the substrate, the material being molded is cured and the mold is removed (LaFratta *et al.* 2006).

1.12.4.1.3.(iii) Micromolding in capillaries In MIMIC, a soft mold like those made with PDMS is contacted with the surface of a substrate to form a network of open microchannels (**Figure 14**). The soft stamp is pressed onto the substrate evenly and a prepolymer is applied to access holes in the mold. This process can be vacuum assisted to speed flow into the holes. The prepolymer flows into the cavities formed by the soft mold on the substrate and fills the cavities automatically due to capillary forces. After curing and peeling it from the soft mold, the polymer structure remains on the surface of substrate. For long capillaries, the rate of filling decreases significantly owing to the viscous drag of the fluid in the capillary and the distance over which the fluid has to be transported, which should be considered during the design phase. The rate of filling also decreases as the cross-sectional dimension of the capillary decreases and as the interfacial free energy of the surface decreases (Gates 2004, Xia and Whitesides 1998, Xia *et al.* 2003). Recently, a preceramic polymer that is transparent, solvent-resistant, thermally stable, and biocompatible was fabricated using MIMIC. Transparent poly(silazane) glass-derived microchannels and structures can be fabricated based on this technique. The structures may be useful in the field of micro-total-analysis systems (Asthana *et al.* 2006).

1.12.4.1.3.(iv) Solvent-assisted micromolding SAMIN combines RM and embossing concepts simultaneously. SAMIN uses an elastomeric PDMS mold in combination with an appropriate solvent (**Figure 14**) – instead of a rigid mold and high temperatures and pressures – to emboss the polymer.

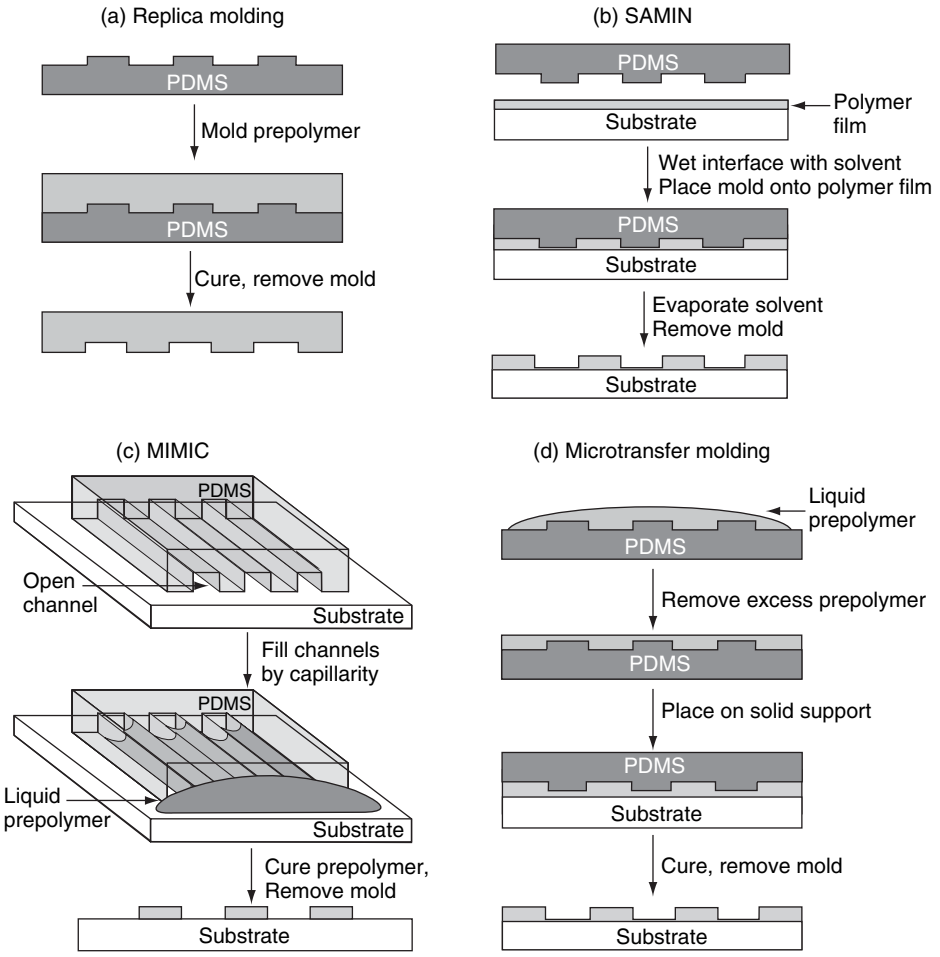

Figure 14 A schematic of four different micromolding techniques. (Source: Gates B D, Xu Q, Love J C, Wolfe D B, Whitesides G W 2004 Unconventional nanofabrication. *Annu. Rev. Mater. Res.* **34**, 339–72. © 2004, reproduced with permission from Annual Reviews, www.annualreviews.org.)

The solvent is either applied to the PDMS mold or retained in the polymer film before placing the two surfaces in contact. A small amount of solvent is dispensed on a patterned PDMS stamp and the stamp is placed on the polymer to be molded. The solvent causes swelling in the polymer and causes expansion of the polymer into the patterns of the stamp. The gas-permeable mold prevents trapping of air pockets and nonuniform solvent evaporation. The mold is then removed to reveal a relief structure complementary to the topography of the mold. For this technique, the wetting of the PDMS mold by the solvent and conformal contact between the PDMS mold and the substrate are the most important factors for successful fabrication (Gates 2004). The application of SAMIN to nanoscale features has been limited primarily by the lack of appropriate masters rather than by the fundamental characteristics of this process. To overcome this limitation, composite elastomeric mold like hard PDMS can be used to make smaller features (~20 nm) (Odom *et al.* 2002).

A limitation of elastomeric PDMS mold is that swelling may occur when PDMS is used with organic solvents. This swelling causes distortion of the pattern in soft lithography and may lead to pattern collapse in the mold. Surface modification of the PDMS mold with poly(urethaneacrylate) has been shown to reduce the rate of solvent absorption into PDMS (Lee *et al.* 2006).

1.12.4.1.4 Packaging of components fabricated using soft lithography

In microfabrication, packaging is defined as all the integration and connection steps after fabrication of the fundamental device is complete. It includes postprocessing release, package/substrate fabrication,

assembly, testing, and reliability assurance. The package provides functional interfaces between microdevices and the environment (Lee *et al.* 2003). These interfaces are directly related to the application. Thus, unique packaging approaches have been developed for use with soft lithography.

1.12.4.1.4.(i) Bonding One of the most basic packaging steps is bonding. Two PDMS substrates can be bonded to each other using a variety of techniques. The most common technique for bonding PDMS substrates is the use of an oxygen plasma to oxidize the surface followed by rapidly placing the two substrates in contact with one another. The seal between the two pieces of PDMS can be sufficiently strong such that the two substrates cannot be peeled apart without failure in the bulk PDMS. The bond strength has been found to be highly dependent on the measured contact angle of the PDMS after exposure to the oxygen plasma. The lower the contact angle, the better the bond (Xie *et al.* 2005). As a result, a contact angle below 5° provides a good bond strength (Bhattacharya *et al.* 2005). An identical process can be used to bond PDMS to glass substrates.

Several other methods for bonding PDMS are available. For example, placing two partially cured substrates (or even if only one is partially cured) in contact before final curing results in a good bond strength between PDMS substrates. These films of uncured PDMS can also be placed between layers of cured PDMS to produce a high-quality bond.

Rigid polymers like PMMA are often used in making rigid molds or stamping structures for soft lithography. To package micro- or nanofabricated structures with PMMA, thermal bonding, lamination, adhesives and solvent-assisted bonding are usually used. Surface modification such as air plasma treatment, hydrolysis and aminolysis are also available to assist in developing strong bonds. A comparison of techniques and a determination of the optimal methods for bonding PMMA without damage to the microstructures is available (Brown *et al.* 2006).

1.12.4.1.4.(ii) Microfluidic packaging In microfluidic systems made by RM, the channel inlets and outlets often need to be connected to pumps or other fluid components. Several methods have been used to accomplish this task. The most basic are glued interfaces, where connecting tubing is attached with an adhesive (often PDMS) to the channels. One method for use with SU-8 master molds requires that an inlet and an outlet post structure be created after fabrication of the microchannel structure on the silicon wafer. Essentially, the packaging channels are molded into the PDMS. With this mold, the PDMS replica can be peeled off and connections with a syringe needle can be made. Usually, oxygen-reactive ion etching and epoxy bonding are used to bond PDMS interconnects to various substrate materials such as glass, silicon, and other polymers (Li 2003).

A second method for creating a packaging channel is to use a coring tool. In this case, a channel is cored from the surface to the buried microchannel and a syringe needle is inserted into the hole and a press fit is used to keep the channel sealed. The use of a needle that has a larger diameter than the coring tool leads to a good fit and a good seal within the microfluidic structure (Christensen *et al.* 2005). Using this concept of an interference fit, seals designed for various pressures were fabricated and tested for leakage and internal wear due to repeated insertion of a tube. The sealing pressure is a function of the contact pressure in each design due to the low stiffness of PDMS. On the basis of this result, guidelines can be set for selecting the appropriate sealing method and for modeling more complex captive connectors (Friedrich *et al.* 2005).

1.12.4.2 Powder Blasting

Abrasive blasting or sand blasting is a widely used material removal process. The microfabrication version, typically called powder blasting, has been demonstrated as a viable, low-cost option for the fabrication of MEMS and microfluidic devices, especially for brittle materials (**Figure 15**). The resolution possible for powder blasting is reduced by the size of the particles, which typically range from 10 to 50 μm and the complexity of the mask patterning undertaken. However, a high etch rate and no clean room requirement make powder blasting an attractive alternative to standard wet and dry etching techniques. These advantages make powder blasting an ideal candidate for rapid prototyping applications.

Powder blasting utilizes a pressurized air beam containing ceramic particles such as Al_2O_3 to create 3D microstructures. By adjusting and controlling parameters such as the beam pressure, beam diameter, beam–substrate separation distance, beam angle of incidence, mask pattern, and mask undercutting, novel 3D features are possible (Belloy *et al.* 2000, 2001, Slikkerveer *et al.* 2000). Masking for the

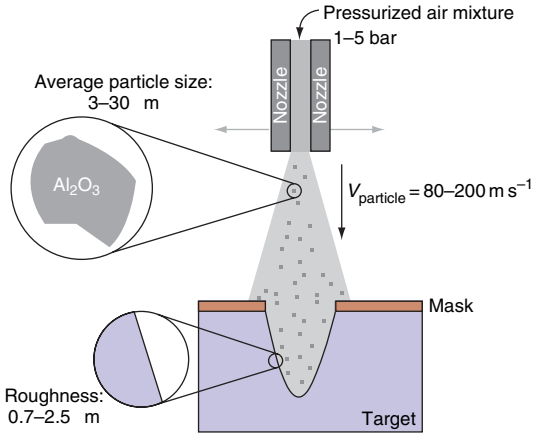

Figure 15 A schematic of the powder blasting process using Al_2O_3 as the blasting particle. (Source: Wensink H, Jansen H V, Berenschot J W, Elwenspoek M C 2000 Mask materials for powder blasting. *J. Micromech. Microeng.* **10**, 175–80; reproduced with permission from the Institute of Physics.)

powder blasting process consists of an etch-resistant coating such as a polymer that is patterned on top of the substrate. Pawlowski *et al.* demonstrated the use of PDMS/SU-8 polymers for an etch mask. PDMS was found to have an etch rate 15 times smaller than glass, allowing for high mask integrity in the course of experiments. With the patterning and etch-resistant capabilities of the PDMS/SU-8 combination, 30-μm structures were reported (Pawlowski *et al.* 2005).

1.12.5 Low-Cost Methods for Volume Manufacturing of MEMS

In many cases, traditional MEMS technologies can be used to produce inexpensive microdevices since the fixed costs associated with the expensive tools can be spread over a large number of devices. For example, precision MEMS accelerometers for use with car airbags can sell for less than US$2 each. For volumes that do not reach millions of parts per year, and for devices that are not easily fabricated using traditional techniques, molding and embossing techniques are the most cost-effective for mass production. Several of these techniques will be reviewed for their application to microdevices.

1.12.5.1 Injection Molding

The utilization of injection molding has made possible the mass production of polymer components for various industries. The extension of injection molding to MEMS and microfluidic components is helping to develop academic and commercial devices without the need of costly MEMS foundry facilities. Injection molding offers solutions such as low cost (for large volumes), high tolerances, and fully automated production. The limitations for injection molding are often high tooling costs (for small volumes), shrinkage, and partial mold filling. These limitations are often exacerbated for microscale components as even tighter tolerances are required for mold inserts, shrinkage, and mold filling. For microscale applications, mold inserts are often fabricated by high-precision laser ablation, lithography, EDM, or other costly micromachining techniques that may cost more than the injection molding equipment. However, recent discoveries at the academic and commercial level have begun to address some of the obstacles that have deterred the use of injection molding for microsystems.

1.12.5.1.1 Process overview

The injection molding process generally encompasses four basic steps: melting, injection, cooling, and ejection of the finished part. The entire cycle time will vary from seconds to minutes, based on the polymer, part size, mold complexity, and equipment used. While there are a considerable number of different injection molding machines, they all consist of three major components: the injection unit, the mold cavity, and the clamping unit.

The typical injection unit consists of three basic components: a hopper, a heated barrel, and reciprocating screw, as shown in **Figure 16**. Polymer in the form of pellets is forced through the hopper into the heated barrel, where the temperature of the polymer is raised above its melting point. A shear force is then applied by the reciprocating screw, which contributes to polymer melting through viscous heating. Polymer flow is also improved by shear thinning that occurs in the melted polymer. At this stage, the reciprocating screw is driven forward by a hydraulic drive, injecting the molten polymer into the mold cavity, which forms the shape of the desired component. A mechanical or hydraulic clamping unit opposes the force of the injection, holding the mold plates together. Backward polymer flow is prevented from returning to the barrel cavity by a nonreturn valve that sits at the tip of the reciprocating screw. The mold is allowed to cool, allowing the polymer to solidify. The mold is then opened and the part is ejected from the mold. After the mold cycle is

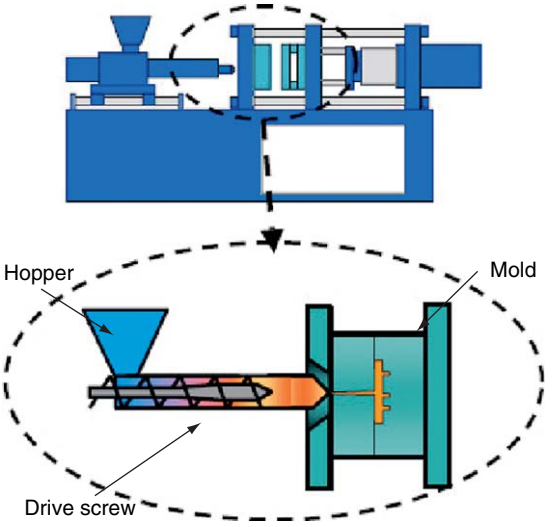

Figure 16 A schematic of a typical injection molding machine showing the hopper, drive screw, and mold. (Source: Becker H, Heim U 2000 Hot embossing as a method for the fabrication of polymer high aspect ratio structures. *Sens. Actuators* **83(1)**, 130–5. © 2000, reproduced with permission from Elsevier.)

completed, the screw retracts and the process is repeated (Bryce 1996).

1.12.5.1.2 Microscale injection molding

Standard injection molding processes require slight modifications when microscale components are fabricated. Microscale injection molding processes focus on the release of delicate microstructures from the mold and proper mold filling in microcavities. Mold release agents are generally used to assist in component release from the mold cavity; however, for certain applications the mold release may adversely affect device biocompatibility. To circumvent this step, the mold cavity walls are given a slight incline, provided the incline is acceptable in the final part. If vertical sidewalls are required, special care must be taken to reduce the effects of friction that may hinder the smooth release of the components from the cavity (Heckele and Schomburg 2004). It has been reported that an average surface roughness value of less than 300 nm will work for most low aspect ratio applications. To ensure proper release for high aspect ratios features (>5) a surface roughness of less than 100 nm is necessary (Pfleging *et al.* 2003).

Complete mold filling is critical for the success of microscale injection molding. A typical strategy for proper filling of the mold is to evacuate and heat the mold cavity. Compression effects (also known as diesel effects) in mold filling, where compressed air is trapped in blind corners and polymer surfaces are burned, provide a unique challenge when optimizing an injection molding process. Evacuation of the mold cavity is an effective strategy designed to remove regions of trapped air that may leave voids in the final polymer component. Another strategy imposed to improve mold filling is heating of the mold cavity. Because of the large surface area-to-volume ratio typical in microscale components such as microchannels, a rapid equilibration temperature occurs between the molded polymer and the temperature of the mold. The equilibrium change in temperature for microscale injection molding has been found to be up to two orders of magnitude faster than conventional molding (Whiteside *et al.* 2005).

The optimization of injection molding parameters and processes is often based on operator experience and trial and error. However, recent modeling tools have been developed by companies and researchers to provide computer simulations of the filling process (Yao and Kim 2002). Moldflow Corporation has developed a commercial tool specifically for microscale flow analysis, referred to as Micro Moldflow Analysis™. The implementation of these simulation tools will help speed up the injection molding parameter selection stage, while simultaneously reducing injection molding cost and operator time.

1.12.5.1.3 Microscale applications of injection molding

As academic research does not generally require high-volume production of polymer components, most injection molding research remains unreported in commercial production settings. However, some recent novel attempts have been reported for microfluidic injection molding applications. Edwards *et al.* used a modified SU-8 mold directly as an insert. Aluminum and titanium were sputtered on the SU-8 to reinforce structural integrity of the structures and facilitate better release of the polymer (Edwards *et al.* 2000). Madou *et al.* combined deep reactive ion etching (DRIE), PDMS, and epoxy to create a mold. DRIE etched the channels, followed by PDMS cast to form the negative pattern of the structures. The epoxy resin was then used to cast the master replica (Madou *et al.* 2001). Kim *et al.* (2002) reported creating micromachined mold inserts by electroplating nickel on PDMS. Svedberg *et al.* used injection molding to produce microelectrospray tips for electrospray ionization for coupling with a time-of-flight mass

spectrometer. Svedberg *et al.* fabricated a mold insert by patterning photoresist on 100-mm silicon wafers and wet etching microchannels into the silicon. Nickel was electroplated to form a mold, which was then placed into a compact disk (CD) injection molding machine using polycarbonate (PC) and PMMA (Svedberg *et al.* 2003). Melin *et al.* used a CD Zeonor injection molding technique that combined e-beam evaporation of silica with a PDMS–Zeonor membrane to create a cell culture device. Zeonor provided quick cycling times and the ability to create multiple devices on an individual CD. The device dramatically increased the volume of devices produced in a given week compared to the same process undertaken with soft lithography (Melin *et al.* 2005). Dang *et al.* (2005) reported a method for mass producing 10-channel CE devices for high-throughput genetic analysis. In an attempt to reduce the costs required for serially producing CE chips in glass, Dang *et al.* explored polymer molding for their CE chip design. The design consisted of 10 square channels (50 μm), with 100 μm separating the channels. The mold was generated using deep X-ray lithography to create a master PMMA chip. The channel walls were inclined (85°) to allow for better release of the molded part. For durability, nickel was electroplated onto the PMMA master to ensure sustainable, defect-free molded parts (Becker and Gartner 2000, Yang *et al.* 2001, Dang *et al.* 2005, McCormick *et al.* 1997, Ouellette 2003). The continued development of novel rapid prototyping techniques for mold inserts will greatly enhance the influence injection molding has on microsystem fabrication.

1.12.5.2 Casting

The use of casting for rapid prototyping overlaps with other mold-based microfabrication techniques. Casting encompasses the various types of mold patterning processes such as standard lithography, etching, or laser ablation to create a master pattern to form a replica part in polymers, ceramics, and metals. For most microsystem applications low-cost biocompatible polymers like PDMS are used to produce the replica parts (see Section 1.12.4.1). The mold patterning technique selected will ultimately determine the cost, time, durability, and resolution of the formed parts.

1.12.5.2.1 Applications

The use of casting has been an important rapid prototyping tool for microfluidics researchers. The Whitesides and Quake Research groups highlighted the advantages of casting PDMS for microfluidic systems. Duffey *et al.* demonstrated the implementation of a CE microfluidic configuration in an oxidized PDMS chip (Duffy *et al.* 1998). Anderson *et al.* showed the possibility of creating complex 3D microfluidic networks using casting techniques. Interweaving channels and serpentine channels were cast using multilayer lithography steps (Anderson *et al.* 2000). Unger *et al.* illustrated the capabilities of multilayer PDMS devices that could be used for the active movement and control of fluids through pneumatic actuation of a thin membrane. Microvalves and peristaltic micropumps have been characterized and reported (Studer *et al.* 2004, Unger *et al.* 2000). Since these initial demonstrations of casting for microfluidics, complex microfluidic devices for biological assays and protein deposition have also been reported. McDonald *et al.* (2001), by utilizing PDMS casting, created a disposable microfluidic network for an enzyme-linked immunosorbent assay (ELISA) detection assay. Bernard *et al.* utilized reactive ion etching to etch channels in a silicon wafer for casting microfluidic biomolecule deposition tools in PDMS. The PDMS deposition tool confined solutions of interest to channels that would pattern a substrate with biomolecules. A second deposition tool will replace the first perpendicular to the original flow lanes, creating intersecting regions where binding events can take place (Bernard *et al.* 2001). Xurography (see Section 1.12.3.5) has also been used to form a casting master for direct molding with PDMS (Bartholomeusz *et al.* 2005). The development of novel, low-cost mold patterning techniques will continue to make casting an integral part of rapid prototyping in research development applications.

1.12.5.3 Hot Embossing

Hot embossing, like injection molding, uses polymers as the primary structural material. Using polymers in conjunction with a simple fabrication process allows hot embossing to be one of the ideal methods for fast, inexpensive replication of microsystems. Additionally, this process is good for creating high aspect ratios and small structures. The feature size and quality depend mainly on the master mold and its fabrication process. Depending on the application, master mold fabrication methods can range from classic photolithography to LIGA (LIGA is a German acronym for X-ray lithography (X-ray lithographie), electroplating (Galvanoformung)). Some limitations of hot embossing are a restriction to planar

features, difficulty in creating multidepth features, and a requirement that all polymers used have a glass transition temperature (T_g). Overall, with the wide range of polymers and master mold fabrication methods, hot embossing has the potential to fit the requirements of a large variety of applications.

1.12.5.3.1 Fabrication process

The first step in hot embossing is to choose a polymer that is compatible with both hot embossing and the application desired. Some common polymers used in hot embossing are PC, PMMA, polyetheretherketone (PEEK), and polystyrene (Becker and Heim 2000, Truckenmuller *et al.* 2002). PC, PMMA, and polystyrene are all transparent, which allows the use of these polymers in optical applications (Fleger *et al.* 2004). Other polymers, like PEEK, may be tougher and useful for applications with higher stresses.

The second step in developing a hot embossing process is choosing which fabrication method to use to create the master mold, which is a relief structure of the design. Photolithography is the classic method for mold fabrication with hot embossing. Photoresist on a silicon substrate can be electroplated with a metal, like nickel, to create metal master molds (Becker and Heim 2000, Fleger *et al.* 2004). Unfortunately, this method has limitations with regard to aspect ratio. An alternative method is DRIE, which can allow for high aspect ratios and vertical walls (Becker and Heim 2000). Here, a silicon substrate can be used as the embossing tool because the silicon can be directly etched instead of a resist layer. This method, though, can yield high surface roughness and is relatively expensive (Narasimham and Papautsky 2004). Another expensive method that also yields vertical walls and high aspect ratios but has very low surface roughness is LIGA (Becker and Heim 2000). Mechanical machining like computer numerical controlled machining has been used to machine steel or nickel molds. These types of masters have very long lifetimes, but are only good for relatively large featured designs (Narasimham and Papautsky 2004), though the ability of these tools is improving (Hupert *et al.* 2006).

The material used to develop the master mold is critical to determining the success of the hot embossing operation. The material generally needs to be stable at the glass transition temperature of the polymer and should be strong to withstand multiple uses; also, it should be thermally conductive and smooth on all mating surfaces. The surface roughness usually depends on what type of fabrication method is used to make the mold. Nickel masters are usually silicon substrates with nickel electroplated onto them. Electroplating, unfortunately, is associated with problems such as nonuniformity, bubbles, poor adhesion to the substrate, and difficulty in plating high aspect ratio structures (Narasimham and Papautsky 2004). Silicon is also used, but as mentioned before, the techniques used to etch silicon can lead to high surface roughness. A unique material used by Narasimhan and Papautsky (2004) is PDMS. Intuitively, PDMS would not be ideal material for hot embossing because of its soft malleable nature, but through parameter optimization quality devices were fabricated and the PDMS mold withstood multiple uses. Thus, master mold material is not restricted to typical stiff and hard materials.

To begin replication, the master mold is placed within a hot embossing press as seen in **Figure 17** (Becker and Heim 2000), which consists of two hot plates and a force mechanism. The master is placed on one hot plate and the polymer substrate is placed on the other. The two plates are heated independently while pulling a vacuum on the entire chamber. Once the hot plates have reached the desired temperature, a certain temperature above T_g, the two plates are pressed together for a specific force and time. After the allotted time, the plates are cooled while keeping the force constant. After cooling, the de-embossing step pulls the two plates apart (Heckele 2003, Simdikova *et al.* 2002). Another type of process is the continuous process in which the master mold is replicated on a heated belt. A polymer sheet is pushed through the heated belt and a base, thereby replicating the mold multiple times on a single sheet (Madou 2002).

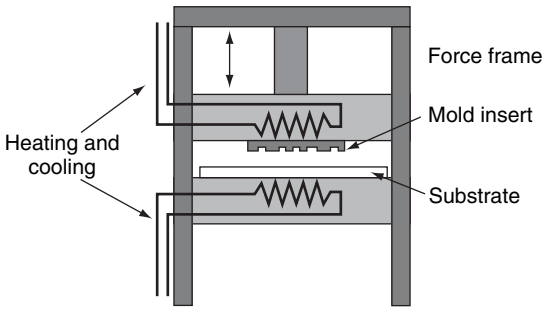

Figure 17 Basic setup for a hot embossing press (Source: Becker H, Heim U 2000 Hot embossing as a method for the fabrication of polymer high aspect ratio structures. *Sens. Actuators* 83, 130–5. © 2000, reproduced with permission from Elsevier.)

1.12.5.3.2 Process problems and limitations

Although the hot embossing process seems simple, there are many parameters that must be considered. Depending on the dimensions of the design, time, temperature, and pressure must be optimized to ensure full filling of the master mold channels. With small channel dimensions, the flow of the polymer into these spaces can be difficult. This concept is the same for deep or high aspect ratio structures. Optimization of the parameters was studied by Shen *et al.* (2002). When the temperature is raised, the height of the polymer reaches into channels increases. Although an increase in temperature leads to an increase in polymer flow, too large an increase will cause the polymer to no longer hold the shape of the mold. Also, the polymer and master materials have different thermal expansion coefficients, and if the operation temperature range is too large high stresses will be placed on the polymer material. An increase in pressure has the same effect as temperature, but increasing pressure can cause high stresses that may break the polymer substrate. By increasing the molding time, the polymer height can also be extended. The height, though, was found to increase to a maximum point and lengthening the time after this point has no effect.

A second challenge is the de-embossing step. With high temperatures and pressures a certain amount of adhesion occurs between the master and the polymer substrate; therefore, during de-embossing, when the two plates are pulled apart, damage can occur to the fabricated structures. To alleviate distortion, releasing agents or antiadhesive films may be used by coating the mold with a thin layer before pressing it into the polymer (Becker and Heim 2000, Madou 2002). Unfortunately, if hot embossing is used for a life science application, releasing agents are not preferred because they can contaminate the surfaces and reduce biocompatibility. A second method to reduce de-embossing damage is reducing surface roughness because high surface roughness can cause large amounts of friction. For structures having high aspect ratios above 0.5 to achieve good de-embossing, surface roughness must be less than 80-nm rms. Fortunately, some fabrication processes like LIGA can achieve surface roughness of 10-nm rms and ASE-processed silicon can achieve 8-nm rms (Becker and Heim 2000). A final method to alleviate high stresses is to create wall angles that are less than 90° (Becker and Heim 2000). By doing so, vertical forces are reduced. Some other problems that may occur in hot embossing are high stresses due to pressure on the substrate and bonding problems during packaging.

General limitations of hot embossing are largely based on the limitations of the mold fabrication process. For example, if typical wet silicon etching is used as the master mold fabrication, the shape of the channels within the polymer substrate will not be rectangular. The overall maximum aspect ratio is around 50 and the minimum feature size is in the nanometer range, which leads us to nanoimprint lithography. Hot embossing tooling can be relatively expensive, which is why it is preferable for low and midrange production. A hot embossing press can cost around US$150 000. Another cost consideration is choosing a polymer because they have a wide range of prices depending on the type of material. PC, for example, can cost about US$24 for a 12″ × 12½″ sheet. In contrast, a same-size sheet of PEEK will cost about US$600 (www.usplastics.com).

1.12.5.3.3 Advantages and disadvantages of hot embossing

Hot embossing has many advantages and disadvantages compared to other microfabrication methods. Hot embossing is good for small structures and high aspect ratios (Becker and Heim 2000). Another advantage is the simple fabrication process used in hot embossing, which is because of the small number of steps required for fabrication (Heckele 2003, Simdikova *et al.* 2002, Truckenmuller *et al.* 2002). After the master mold is created, fabrication of the fluidic channels can be done in minutes and repeated several times. The simplicity of fabrication inherently leads to another advantage, a strong potential for mass production. Mass replication also provides a possibility to design disposable parts (Truckenmuller *et al.* 2002). Other fabrication methods that are timely make disposability a costly function. The inexpensive cost of the polymers also makes it possible to manufacture disposable parts; low long-term costs is another advantage. Finally, many polymers are also biocompatible and are currently used in many medical applications.

Hot embossing also has many disadvantages. Because the channels are created by pressing a mold into a planar sheet, the features that can be created must also be planar. This is a huge disadvantage compared to traditional methods like UV lithography, where multiple layers can be manufactured easily. Hot embossing's cousin, injection molding, which also can be inexpensive and quick, can also create nonplanar features. Another disadvantage is the high residual stresses (Becker and Heim 2000). The use of temperature in conjunction with pressure on polymers, which are not the most durable materials, can

cause cracks and broken edges unlike in silicon wet etching. Corresponding to high residual stresses, multiple-depth features are difficult to make because of the required higher temperatures and pressures (Madou 2002). Hot embossing also has high initial costs. For example, if the master mold is made using LIGA, the cost of paying for a LIGA mold will be extremely expensive, along with having to buy the LIGA mold materials and a hot embossing press.

1.12.5.3.4 Hot embossing applications

Hot embossing is a relatively new method for microfabrication. Currently, the most common explorations are in the fields of optics, motors, bioMEMS, and IC packaging industry. In the IC industry this method is being explored as a packaging solution called molded interconnect devices (MIDs) (Kunststoffe 1998). The concept of these MIDs is to integrate an electronic circuit in a polymer housing. Through this packaging system the electronic parts can be arranged three-dimensionally and they can consequently reduce the materials needed and the total volume.

A common and simple use of hot embossing in optics is fabrication of waveguides. Fleger *et al.* (2004) accomplished this task by using a nickel master mold made using UV lithography with nickel electroplating and embossing into a PMMA substrate. The polymer waveguides were characterized by performing propagation loss and transmission measurements. Flegler also demonstrated the simultaneous manufacturing of microfluidics and optics on a chip using hot embossing.

Another unique example of using hot embossing is electrostatic comb drives. Zhao and Cui (2003) successfully designed a comb drive out of PMMA. In this case, the master mold was fabricated out of silicon using DRIE. Multiple embossing layers as well as metallization steps were employed, showing the flexibility and compatibility of the hot embossing process. The pull-in voltage, stroke length, and natural frequency were all reasonable and the process could easily compete with traditional silicon methods.

A final application example of hot embossing is a microfluidic analysis chip, which is the traditional use of hot embossing. A good example is from Truckenmuller *et al.* (2002). To create their mold, micromachined trenches were milled in brass plates. Next, the mold was placed into a hot embossing press with a two-layered substrate of polystyrene consisting of a thin top layer of high-impact polystyrene and a thick bottom layer of polystyrene. The substrate was coated with a heat-sealing layer and then typically pressed together with the mold in the embossing press. By placing an electrode in between the two layers of the polystyrene, Truckenmiller was able to create a fluidic device for CE.

Various other applications of hot embossing have been explored, with the majority of them being related to microfluidics. Overall, hot embossing can be a low-cost method for low-range to midrange fabrication of molded polymer microdevices.

1.12.5.4 Roller Embossing

The process of roller embossing is a rapid fabrication technique generally using a roller covered with a thin mold that patterns a polymer or some other moldable material. The embossed material is typically formed through a heat-forming or photocuring configuration. Roller embossing is a useful tool for creating large arrays of continuous microstructures. Chang *et al.* reported the use of roller embossing of a UV-curable photopolymer in a custom UV exposure facility to form polymer microlens arrays. Before fabrication, a flat mold is generated from electroplating nickel or some other durable metal onto a polymer microlens master substrate. The resulting flat mold consisting of microlens indentations is wrapped around a cylindrical device to form the roller. The UV-curable polymer is embossed onto a glass substrate as the roller presses the microlens arrays. The roller embossing is implemented within the UV exposure zone, allowing the polymerization and formation of the microstructures (Chang *et al.* 2006). Gallagher demonstrated roller embossing for fuel cell applications using curable polymer materials. The technique is used to form fluid flow cells on separator plates that sandwich the membrane electrolyte assembly (MEA). The flow cells are used to circulate coolant or supply reactants to the MEA (Gallagher 2004). A similar method has been used to fabricate antireflective microstructures for LCD displays (Parrika and Saarinen 2005).

1.12.6 Conclusions

Though MEMS and microfabrication have been dominated by processes that require expensive tooling, a large number of techniques have been developed that can help eliminate the high costs associated with traditional MEMS processes. One of the easiest ways to reduce costs is to use tools available in the mass consumer market, such as laser or

ink-jet printers for making masks. Techniques such as xurography can use commercially available double-sided tapes that can not only produce high-resolution devices, but also eliminate most of the processing steps such as lithography, etching, and bonding. The recent use of plastics has also been a major development that has the capability to drive down costs. Directly patterning plastics using photosensitive polymers may be the simplest, but laser cutting and molding of polymers is becoming increasingly commonplace. The adoption of rugged soft polymers for microfluidics research (soft lithography) has rapidly driven the field forward, since nearly any researcher can easily set up the facilities needed for prototyping. The precision with which plastics can be molded has led to interesting applications of techniques such as soft lithography, which allows nanoscale features to be generated repeatably and reliably. Thus, for some applications, the inexpensive techniques are replacing the more traditional MEMS techniques as the primary processing method as the function of plastics is more amenable to biomedical and microfluidic applications.

In many cases, the question is no longer, "Can an inexpensive microfabrication technique do the job?" but "Which inexpensive process is best for this application?" The answer to this question is not always simple, but a few guidelines can make the decision process simpler. For example, some of the techniques discussed in this chapter are limited in their ultimate resolution, such as screen printing, xurography, and laser printing, but for larger microscale devices they are the simplest and least expensive. Combining some inexpensive methods with some more expensive tools can lead to high precision at a relatively low cost. For example, using e-beam lithography to make a soft lithography mold can lead to inexpensive nanoscale structures, even if the e-beam step is rather expensive. Some of the techniques are better for prototyping than for mass production, such as soft lithography and xurography, but new efforts to commercialize these techniques may nullify this current limitation. The pure molding processes are typically more expensive unless high volumes of devices are fabricated, so they are typically precluded from prototyping. The one limitation of most of these techniques is that they do not necessarily work well with silicon, the traditional MEMS material. Thus, converting to a less expensive process often requires a change of material, but if circuits are not the focus, this conversion can often be painless, not to mention less expensive.

Biographies

Bruce K. Gale, currently Director of the Utah State Center of Excellence for Biomedical Microfluidics and an Assistant Professor of Mechanical Engineering at the University of Utah since 2001, has been working in the area of microfluidics and micro-total-analysis systems (μ-TAS) for the past decade. His interests include lab-on-a chip devices that require a variety of microfluidic components for the completion of complex and challenging medical and biological assays. These components fall into three broad categories: sample preparation, sample separation or analysis, and detection. His work has recently involved micromachined particle separation systems and detectors, microarray manufacturing methods, and sensors related to these applications. Specifically, he is working to develop a microfluidic toolbox for the rapid design, simulation, and fabrication of devices with medical and biological applications. The ultimate goal is to develop platforms for personalized medicine, which should allow medical treatments to be customized to the needs of individual patients.

Mark A. Eddings is a Doctorate student in Bioengineering at the University of Utah. He also received his undergraduate degree in Mechanical Engineering from the University of Utah in 2004. While working on his undergraduate degree, he worked as an Engineering Intern for Medron, a medical device manufacturing company, specializing in percutaneous catheters and other related devices. He has been an NSF IGERT fellow and is currently working in the Utah State Center of Excellence for Biomedical Microfluidics as a research assistant. His research interests focus on clinical applications of microfluidic immunoassays for therapeutic monitoring and point-of-care diagnosis. His previous research consisted of micropump development for lab-on-a-chip applications.

Scott O. Sundberg received the BS degree in mechanical engineering from the University of Utah in 2004. In 2005, he received the NSF IGERT fellowship for his current Ph.D. dissertation research in solution-phase DNA melting analysis for SNP genotyping and mutation scanning using nanoliter volumes. During undergraduate studies, he was an intern at Becton, Dickinson and Company, Salt Lake City, Utah. While there, he worked on a less painful injection device for transdermal drug delivery. He acknowledges his wife, Stacy, for the support she continually gives him.

Andrew Carter Hatch was born in Provo, Utah, on April 10, 1981. He graduated from the University of Utah with a BS in Biomedical Engineering having a focus on MEMS technology applications. In 2005, he performed a 14-week internship at Sandia National Laboratories, Livermore, CA, USA, where he researched the integration of on-chip protein concentration using a polymer membrane, with liquid gel protein separations in glass microchips. From 2005 to 2006, he performed research at the University of Utah, Center of Excellence for biomedical microfluidics, generating multilayered PDMS microspotters and testing their function and performance in generating protein arrays. He is currently working toward his Ph.D. in Biomedical Engineering at the Henry Samueli School of Engineering at the University of California, Irvine. After acquiring a Ph.D. degree he intends to pursue his research goals in MEMS technology and continue his career in academics as a university professor.

Jungkyu Kim was born in Busan, South Korea, in 1974. He received the BS in Biomedical engineering from Inje University in 2000 and the MS in Mechanical Engineering from Sogang University, South Korea, in 2002. In 2000, he joined the biomedical research center at the Korea Institute of Science and Technology (KIST) as a research scientist. He was involved in the development of an artificial bone and joint using tissue engineering techniques for 4 years in KIST. Between 2003 and 2005, he received the Korea Science and Engineering Foundation (KOSEF) fellowship. Currently, he is pursuing a Ph.D. degree in Bioengineering at University of Utah. He is working on a project that involves the implementation of a microscale system for DNA extraction and amplification in Utah State Center of Excellence for Biomedical Microfluidics. This project uses a nanoporous membrane that will be implemented in a microscale system to extract the DNA, amplify the DNA using PCR, then monitor the reaction in real time using optics.

1.13 Micromachining

Holger Reinecke and Claas Müller, Department of Microsystems Engineering - IMTEK, University of Freiburg, Freiburg, Germany

1.13.1 Introduction

Mechanical machining processes have been used for decades in the production of components from different materials. In particular, the method used for the processing of metals and alloys such as copper, brass, bronze, and steel is used for the fabrication of single products, such as tools, as well as standard products.

In the field of precision engineering, components requiring micrometer precision have been produced for several decades. Most often, these are components in the watch and the clock as well as the optical industry, or tools that are needed for the manufacture of plastic components that are used within these industries.

Machining processes such as precision milling and turning and electroerosive processes such as wire and spark erosion are used in manufacturing processes. In processes that make use of machinable materials that cannot be subjected to any thermal change during processing, electrochemical machining (ECM) is used.

In microsystem technology, because of the increased use of plastic injection molding and hot embossing there is a great need for tools made from metal. This need can be satisfied by a modified LIGA (LIGA is a German acronym for X-ray lithography (X-ray lithographie), electroplating (Galvanoformung)) process, where a cast made by employing lithographic or etching techniques is transferred to a tool, mostly from nickel, by means of electrochemical processes. These molds have quite a few disadvantages such as higher corrosiveness, lower hardness, and lower Young's modulus when compared to common steel molds. Furthermore, due to the process being used, their fabrication is quite time-consuming. Mechanical fabrication of the molds is a way out.

Because of the increasing need of and the progress in machine technology, the existing methods of mechanical precision manufacturing were adapted specifically to the demands of microtechnology, or were specifically developed for these demands.

1.13.2 Ultra-Precision Machining

Ultra-precision milling (UPM) is one way to fill the gap between conventional machining technologies and the semiconductor industry. UPM makes it possible to conform to the stringent requirements for optical surfaces. When manufacturing mold inserts for the mass production of micro-optical components, most conventional processing technologies reach their limits. On the other hand, technologies of the semiconductor industry offer no profitable way to generate free-form geometries (Brinksmeier and Gläbe 2002, Brinksmeier *et al.* 2002, Fleischer *et al.* 2004, Grimm *et al.* 2004, Ritzhaupt-Kleissl *et al.* 2005, Weck 2003).

1.13.2.1 Requirements of a UPM Machine

In order to realize surfaces with roughness less than 10 nm and structures with a precision higher than 100 nm, both the machine itself and its environment have to conform to high standards. The machine has to be set up in an air-conditioned room with a temperature of 20°C and constancy better than 0.5 K. Furthermore, care has to be taken that no environmental vibrations are transmitted to the machine. To meet this requirement, the machine should have a mass of about 6 tons and so-called self-leveling machine legs. In order to avoid vibrations during the machining process, such machines are set up using air-bearing milling spindles that can be fine balanced and that have engine speeds up to 150 000 rpm. All axes too use air bearings and are positioned using laser interferometers with nanometer precision. **Figure 1** shows a UPM machine manufactured by Fraunhofer Gesellschaft, IPT Aachen.

With the aid of a camera system, the whole machining process can be observed even from a remote distance. The UPM that is present at the chair has a large diameter and a 400-mm machining spindle, with a maximum engine speed of 3500 rpm.

Figure 1 Ultra-precision milling (UPM) machine.

It enables fixation of the workpiece as well as of the tool, depending on the machining technique. It therefore offers the possibility of turning and facing on the same machine. The milling process can be realized using high-frequency spindles that have an engine speed ranging from 1000 to 150 000 rpm (Table 1).

By means of this ultra–precision (UP) machine, highly precise 3D structures, free-form surfaces, and optical structures from nonferrous metals can be fabricated. Because UPM employs diamond tools, machining metals containing iron cannot be machined. The carbon from the diamond tool diffuses into the steel during processing, causing excessive wear of the tool. Figure 2 shows a diamond milling tool with a diameter of 250 μm. Since the clamping accuracy of such a milling cutter is about 5 μm, each tool has to be rotationally calibrated using the integrated tool gauging system in order to realize structures with the desired precision.

During UP machining, the surface quality of the tool is transferred directly to the workpiece. It is therefore necessary that the tool have a surface quality in the range of 10 nm. Cooperation with important tool suppliers guarantees the highest standard.

During machining of surfaces, standard cooling agents cannot be used. These fluids would flood the machine and damage the air bearings of the axles and the spindles. Fluids with high vapor pressures have to be vaporized onto the surface of the material that is to be milled. At the same time, excessive cooling of the workpiece and/or the tool has to be avoided since this could lead to dimensional deviations of up to several micrometers. Before machining, the whole setup as well as the workpiece has to acclimatize, as even handling of the workpiece induces thermal energy in the complete system.

During processing, the following machining techniques can be used in principle:

- Turning and facing on the large machining spindle
- UPM and fly cutting on the high-frequency spindle

The different machining techniques are described in greater detail below.

Table 1 Important process parameters for ultra-precision machining equipment

Application	Turning and milling, four-axis machining
Manufacturer	FhG-IPT
Resolution	10 nm
Rotational speed	Up to 150 000 rpm
Tools	>250 μm (diamond), >50 μm (carbide)
Material	Nonferrous metals, polymers
Surface quality	$R_a = 10$ nm
Precision	0.5 μm

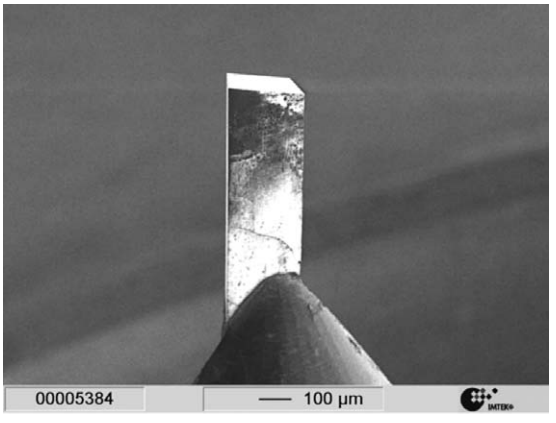

Figure 2 A single crystalline diamond tool.

1.13.2.1.1 Turning

During UP turning, the workpiece is fixed to the spindle. For smaller structures, this can be realized using vacuum as well as through mechanical clamping. Figure 3 shows a machining spindle with a tool holder placed in front. The holder can be adjusted in

Figure 3 Detailed view of the machining spindle.

height with micrometer precision so that for each tool, an optimized machining position can be arranged.

During turning, care has to be taken that the spindle, including the workpiece, is always properly balanced, since a slight unbalance can damage the spindle. By using this UP turning processing technique, rotationally symmetric structures with a precision in the range of 10 nm and having a diameter of up to 400 mm can be fabricated. Depending on the tool used, a wide variety of structures can be realized. The scope ranges from simple spherical and aspherical lenses to diffractive lenses such as a Fresnel lens. **Figures 4** and **5** show a UPM polymer lens with a diameter of 20 mm and a Fresnel lens with a diameter of 40 mm. Both structures have a surface quality less than 10 nm.

Table 2 lists typical process parameters for different materials with regard to turning. For UP machining as well, there is a difference between premachining and finishing. During premachining, a maximum feed depth of 50 µm can be achieved. For finishing, this is reduced to feed depths of 2 µm. In case the chip thickness falls below a material-dependent value, a continuous chip is no longer produced. This directly influences the surface quality. The machining parameters must be developed according to each material combination.

Table 2 Typical process parameters for different materials with regard to turning

Material	*Premachining*	*Finishing*
OFH-Copper	20–40 mm min^{-1}, 1000 rpm, 50 µm	3–5 mm min^{-1}, 1500 rpm, 5 µm
Brass	30–50 mm min^{-1}, 1000 rpm, 50 µm	3–5 mm min^{-1}, 1500 rpm, 5 µm
Red brass	30–50 mm min^{-1}, 1000 rpm, 50 µm	3–5 mm min^{-1}, 1500 rpm, 5 µm
Germanium	10–20 mm min^{-1}, 1000 rpm, 20 µm	1–2 mm min^{-1}, 1000 rpm, 2 µm
Silicon	10–20 mm min^{-1}, 1000 rpm, 20 µm	1–2 mm min^{-1}, 1000 rpm, 2 µm

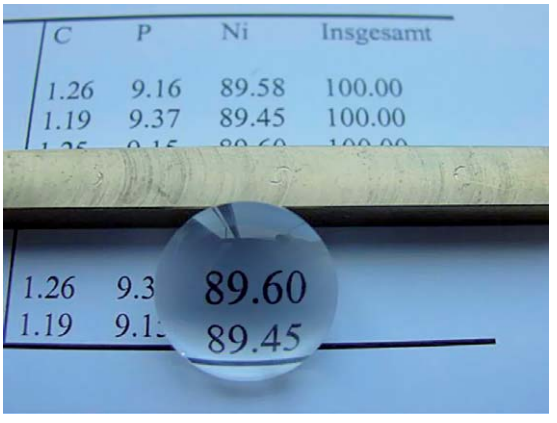

Figure 4 Example sphere in polycarbonate.

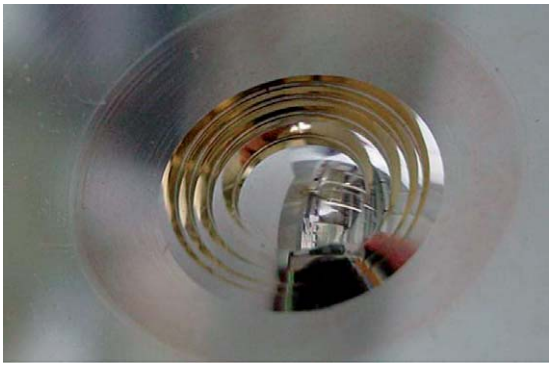

Figure 5 Example of Fresnel lens in brass.

1.13.2.1.2 Facing

During facing, a diamond tool with a relatively large radius of several millimeters is mounted on the spindle. For processing, the workpiece is moved in front of the spindle. This technique achieves parallelisms of less than 1 µm over a distance of 400 mm, with surface qualities less than 10 nm (**Figures 6** and **7**).

1.13.2.1.3 Ultra-precision milling

During UPM, standard tools made entirely from carbide steel and with a minimal diameter of 50 µm as well as diamond milling cutters with a minimal diameter of 250 mm can be used. By using diamond

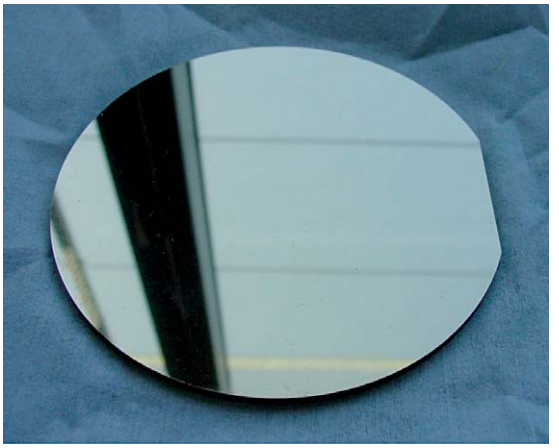

Figure 7 Surface quality after facing of a brass wafer.

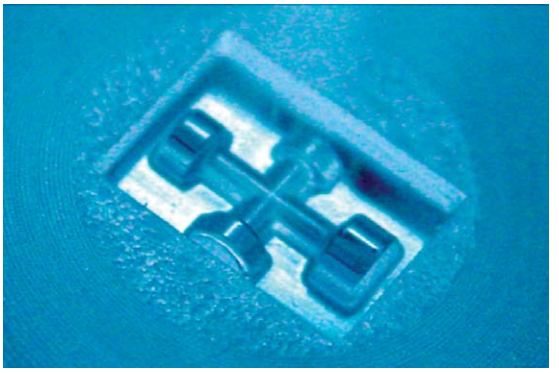

Figure 8 Ultra-precision (UP) machined free-form surface in polycarbonate.

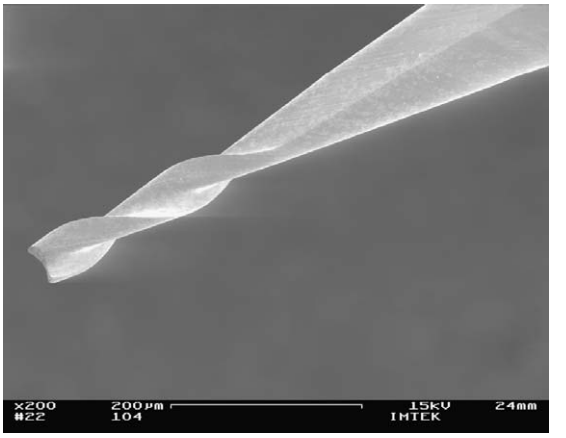

Figure 9 Carbide steel milling cutter with a diameter of 50 µm.

Table 3 Typical process parameters for ultra-precision milling

Material	*Premachining*	*Finishing*
OFH-Copper	50–100 mm min^{-1}, 50 000 rpm, 30–40 µm	20–50 mm min^{-1}, 50 000 rpm, 5 µm
Brass	50–100 mm min^{-1}, 50 000 rpm, 20 µm	10–50 mm min^{-1}, 50 000 rpm, 5 µm
Polymer, PMMA, PC	50–100 mm min^{-1}, 50 000 rpm, 20 µm	10–50 mm min^{-1}, 50 000 rpm, 5 µm

PC, polycarbonate; PMMA, polymethylmethacrylate.

milling cutters, free-form surfaces with optical surface quality can be fabricated. An example is given in Figure 8. The structure was worked in polycarbonate using a 250-µm-diameter diamond milling cutter.

With the aid of carbide steel milling cutters that are currently available with a diameter of 50 µm, microfluidic systems with minimal channel width of 50 µm can be fabricated directly in plastics (Becker *et al.* 1989). Direct machining of the polymer material offers a fast and economical way to transfer fluidic designs into functional structures for their efficient characterization. Figure 9 shows a 50-µm-diameter carbide steel milling cutter seen through a scanning electron microscope (SEM). By using a fourth axis, even complex 3D structures can be fabricated with a precision of 0.5 µm.

Table 3 lists typical processing parameters of UPM using a 500-µm-diameter diamond tool. As can be seen from the table, for such processing, engine speeds of 50 000 rpm are needed. If the tool diameter is reduced further, engine speeds of more than 100 000 rpm might become necessary in order to obtain the best possible machining results.

1.13.2.1.4 Fly cutting

When fly cutting, the tool does not rotate around its own axis but is eccentrically mounted, so that the tool blade follows a circular path. Figure 10 shows a typical setup used for fly cutting.

Fly cutting offers the possibility of fabricating parallel running structures with an extremely high sidewall quality. This technology also offers surface qualities up to 100 nm. In Figures 11 and 12, V-grooves with an angle of 90° machined into a brass foil are shown. This structure serves as the basis for a retro reflector that has been made keeping in mind the great precision required for the complete structure. By a smart arrangement of the single foils, the complete

geometry can be fabricated. By nickel electroplating, the mold insert for injection molding can be made from the brass master. In this application, the replicated parts have an angular deviation of less than 0.01°.

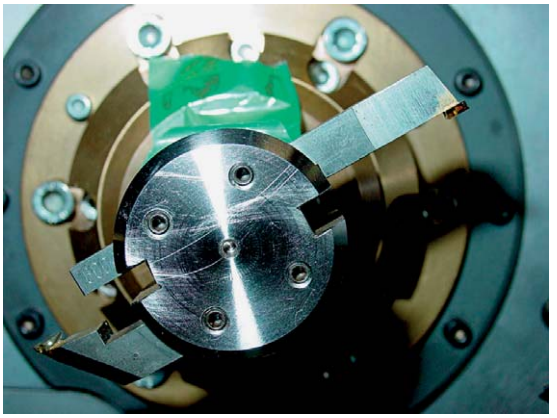

Figure 10 Spindle with tool for fly cutting.

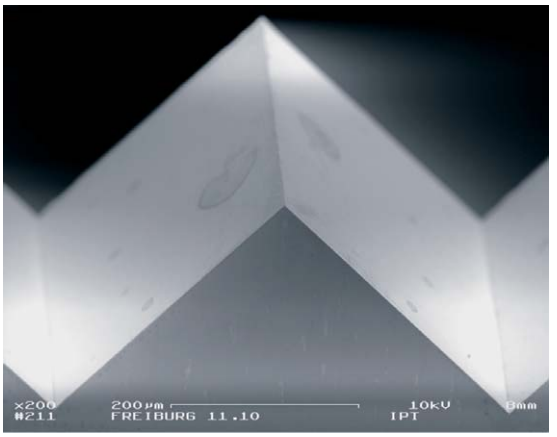

Figure 11 V-grooves, fabricated by fly cutting.

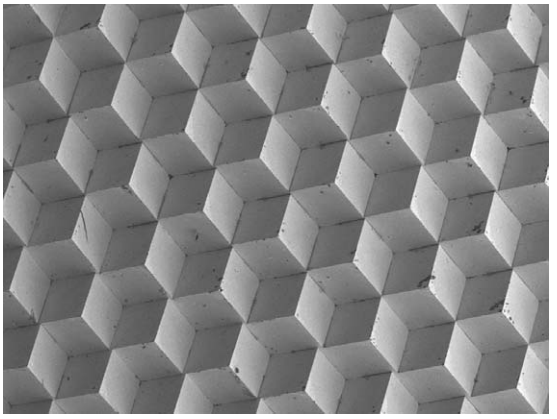

Figure 12 Mounted molding tool for the retro reflector.

Table 4 Typical process parameters for fly cutting

Material	*Premachining*	*Finishing*
Brass	25–30 mm min^{-1}, 1400 rpm, 15 µm	5 mm min^{-1}, 1400 rpm, 5 µm
Polymer, PMMA, PC	30–45 mm min^{-1}, 1400 rpm, 30 µm	5–10 mm min^{-1}, 1400 rpm, 5 µm

PC, polycarbonate; PMMA, polymethylmethacrylate.

Table 4 lists typical processing parameters for fly cutting. For this machining technique as well, a minimal chip size is mandatory, since otherwise no optimal machining is possible.

1.13.3 Electrodischarge Machining

1.13.3.1 Physical Principle

Electrodischarge machining (EDM or spark erosion machining) processes aid in material removal of electrically conductive materials through electric discharges (spark) in an electrically nonconducting liquid (dielectric). Spark erosion processing is characterized by successive, temporally separated, nonstationary electric discharges (sparks) taking place in a dielectric fluid (König 1990, N.N. 1975). Spark erosion is a shaping technology where the contour of the tool electrode is transferred into the workpiece by making use of an additional process gap (König 1990). Shaping of the workpiece electrode occurs through spatially and temporally separated, highly dynamic discharges of high frequency (Spur and Stöferle 1984). In a dielectric liquid, the workpiece and the tool electrode approach each other, so that a very small gap remains between them. When a voltage is applied, depending on the disruptive strength of the dielectric used, an energy-rich plasma channel can develop if the process gap is small enough. Because of the highly complex physical processes occurring during a spark discharge and the high discharge rate, these are hard to understand and describe. In order to understand the ablation mechanism of spark erosion and to enhance understanding of the process, experiments are often carried out using single discharges (König 1990, Nöthe 2001, Spur and Stöferle 1984, Wertheim 1975). The macroscopically visible ablation consists of the sum of the single microvolumes that are removed during every single discharge. The single discharge describes the processes that take place between the application of the voltage to the electrodes and the breakdown of the dielectric.

Generalizing the results given above is unfortunately not possible given that processing conditions in the process gap are very complex and several factors interfere with each other (Schönbeck 1992, Wertheim 1975). A great number of scientists came up with various theories about the mechanism of the ablation process for spark erosion processing. However, these often lead to inconsistent explanations of the processes running (Schoepf 2001, Spur and Stöferle 1984). The electrothermal erosion theory, developed by the Russian scientists Lazarenko and Zolotych, is the most commonly accepted (Lazarenko and Lazarenko 1944, Zolotych 1955). This theory proposes that because of the high temperatures in the discharge channel, melting and vaporization processes take place at the material surface of the electrodes in the proximity of the channel base points. For temperatures inside the discharge channel, values in the range of 2000–100 000 K are given by different authors. Material ablation at the workpiece is achieved by ejection of the molten metal. According to electrothermal erosion theory, a single discharge can be subdivided into three main phases: the buildup, the discharge, and the decomposition phase (Dauw 1985, van Dijck 1973, Mirnoff 1968).

Figure 13 shows the processes taking place during a single discharge between the anode and the cathode, along with the corresponding voltage and current curves.

1.13.3.1.1 Buildup phase

The processes necessary for the ionization of the discharge path and the development of the plasma channel are called the buildup or the ignition phase. In this phase, the ionization of the discharge path and the channel buildup take place up to the moment when a current breakthrough inside the discharge channel occurs (Spur and Stöferle 1984). The dielectric electrically insulates the two electrodes from each other. When a DC voltage is applied between the workpiece and the tool electrode, the highest electric field occurs at the smallest gap separating both. When the voltage inside the process gap exceeds the breakdown strength of the dielectric, a discharge channel forms (Förster 1979). The electrons expelled from the cathode are accelerated toward the anode under the

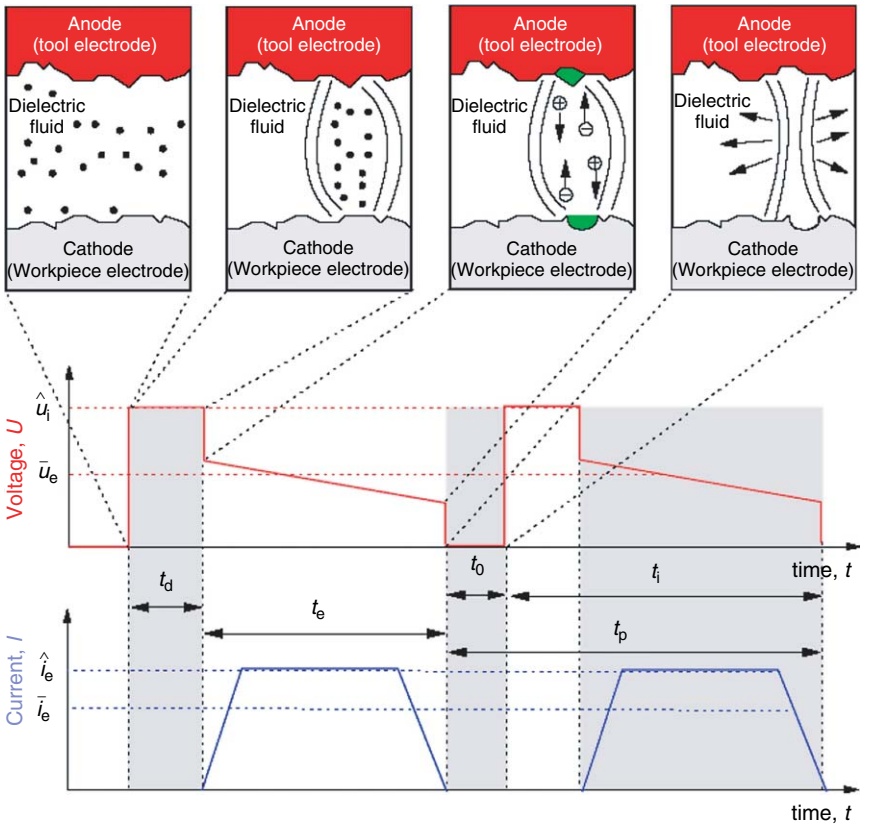

Figure 13 Electrodischarge machining (EDM) process.

influence of the electric field. Because of the ionization resulting from the collision of the molecules in the dielectric with the electrodes, the number of charge carriers increases greatly. Through formation of ions, an anode- as well as a cathode-directed plasma channel branch develops.

The electrons hit the anode considerably earlier than the positive ions hit the cathode (Finkenberg *et al.* 1956, Green 1987, Siebers 1993, Weitzel and Pompe 1949). The anode vaporizes partly due to the impact of the electrons just before the actual development of the plasma channel. However, the cathode mostly remains unaffected. In this phase, a large time-dependent current and voltage variation takes place (König 1990).

1.13.3.1.2 Discharge phase

During the subsequent phase – the discharge phase – current and voltage remain nearly constant. In this phase, according to the thermal erosion theory, material ablation takes place. In the discharge zone, electrical energy is converted into thermal energy.

Energy conversion is mainly affected by the physical characteristics (electrical and thermal conductivity, specific heat, melting and boiling temperature, and specific melting and vaporizing energy) of the tool electrode used (Jutzler 1982). The energy conversion in the discharge zone results in very high temperatures at the boundary of the plasma channel and the tool electrode. Consequently, these boundaries start to melt and the material partly vaporizes. Part evaporation of the material volume leads to a continuously growing gas bubble, which expands with an initial velocity of approximately $50\,\mathrm{m\,s^{-1}}$ (König 1990). When temperatures in the discharge channel are in a range far greater than 10 000 K, evaporation, dissociation, and ionization of all the components involved in the discharge process takes place. At very short discharge durations, up to 80% of the crater volume can vaporize. At longer discharge durations, melting processes use the greater energy part (Förster 1979, Jutzler 1982, Zolotych 1971). According to Förster (1979), local pressure can increase to 15 MPa. Hensgen (1984) found minimal discharge pressures of 50 MPa by experimenting on thin disks of lead. Using a self-developed model, Eubank *et al.* (1993) calculated pressures between 35 and 610 MPa and temperatures of 20 000–53 000 K for short discharge durations. Tsuchiya and Inoue (1982) determined by experiments and calculations a maximum pressure of 280 MPa and a maximum temperature of 87 000 K. For pressures of gaseous discharges inside the plasma channel, literature gives values of 100 MPa (Finkenberg *et al.* 1956).

1.13.3.1.3 Decomposition phase

During the third phase – the decomposition phase induced by the current shutdown – the plasma channel and the gas bubble collapse, and the melted and partly vaporized material is thrown out of the discharge zone (König 1990). After the ablated particles are washed out from the processing gap, the dielectric resolidifies. In order to enable the next discharge process, the working volume is deionized to a great extent by the fluid medium. The spark extinguishes after shutdown of the voltage, and the process can be repeated in another region (König 1990, Kurr 1972, Mirnoff 1965).

Material removal occurs mainly at both electrodes, although it should occur mainly at the workpiece electrode. An economical usage of spark erosive machining processing is possible only if the material ablation rates at the anode and at the cathode are different (König 1990, Lazarenko 1974, Lazarenko and Lazarenko 1944, Spur and Stöferle 1984, Zolotych 1955, 1957). At very short discharge durations, temperatures at the positive electrode are higher than at the negative electrode. Because of the high discharge rate of the electrons from the material's surface, there is a surplus of electrons at the beginning of the process. As ablation is stronger at the positive electrode, the tool is polarized negatively and the workpiece positively. At long discharge durations, approximately the same number of positive and negative particles are removed from the electrodes. Since a positively charged particle has a significantly larger mass than does a negatively charged one, the impact on the negative electrode results in higher temperatures and therefore in stronger ablation. Thus, long discharge durations result in positive polarization of the tool electrode and in negative polarization of the workpiece electrode (Schoepf 2001, N.N. 1985). By appropriate selection of the tool electrode's material and by varying the adjustable parameters, it is possible to achieve a strong asymmetry between ablation of workpiece and tool (König 1990, Spur and Stöferle 1984).

1.13.3.2 Process Parameters

The parameters for the description of the erosion process can be divided into electrical and technological ones.

1.13.3.2.1 Electric process parameters

The electrical processes during spark discharge at the discharge path are characterized by characteristic voltage and current progressions. The ones important for characterization and valuation of the process are defined as follows (König 1990, N.N. 1976):

The discharge duration t_e is the time interval of the current through the ignited discharge path. The ignition delay time t_d is the time between the switching on of the voltage pulse and the breakthrough of the discharge path, i.e., up to the increase in current. The pulse duration, or pulse width, t_i is the time when the voltage pulse is switched on. It is equal to the sum of discharge duration and the ignition delay time:

$$t_i = t_e + t_d \quad [1]$$

The pause duration t_0 is the time interval between two voltage pulses. The period duration t_p is the time between the switching on of a voltage pulse and the switching on of the following pulse. It corresponds to the sum of the pulse and the pause duration:

$$t_p = t_i + t_0 \quad [2]$$

The pulse frequency f_p is the number of voltage pulses per unit time. It is the reciprocal of the period duration:

$$f_p = \frac{1}{t_p} \quad [3]$$

The discharge frequency f_e is the number of actual ignited discharges inside the discharge path per unit time. The open-circuit voltage u acts as a peak value at the discharge path when no current flows. The discharge voltage u_e occurs at the discharge path, when the discharge has been ignited and current flows. The discharge current i_e flows during a discharge through the discharge path. The discharge energy W_e is the energy converted inside the discharge path during a discharge:

$$W_e = \int u_e(t) i_e(t) \mathrm{d}t \approx \bar{u}_e \bar{i}_e t_e \quad [4]$$

The duty cycle τ is the pulse width divided by the period duration:

$$\tau = \frac{t_i}{t_p} \quad [5]$$

The frequency λ is the discharge frequency divided by the pulse frequency:

$$\lambda = \frac{f_e}{f_p} \quad [6]$$

The electric parameters might indirectly comprise also the conductance and/or the specific resistance coefficient of the dielectric. By using water as a dielectric, its resistance coefficient can be adjusted to the processing task by continuous deionization. When hydrocarbons are used, a significant change in the processing task also makes a change of the dielectric necessary, as hydrocarbons have a constant coefficient of resistance that is not adjustable.

1.13.3.2.2 Technological process parameters

With the aid of the following technological process parameters, the quality of the erosion process can be described. The most important parameters for rating the efficiency of the erosion process, according to the VDI 3400 scale and König (König 1990, N.N. 1976, Stempel 1977), are as given below:

The ablation rate V_W is the workpiece volume removed per unit time. The wear rate V_E is the tool electrode volume removed per unit time. The relative wear λ is the wear rate divided by the ablation rate:

$$\lambda = \frac{V_E}{V_W} \quad [7]$$

The use of this parameter is recommended for gathering information about material-related behavior and for comparison with values from literature (Stempel 1977). Other technological parameters are the reproduction accuracy, the average of the cutting line, and various roughness parameters. The average cut track s_m is the average distance of the cut surfaces. They limit the minimum inner radius.

1.13.3.3 Procedure Variants

Spark erosion processing can be categorized as follows:

- Spark erosion by sinking with a shaped tooling electrode (spark erosion)
- Spark erosive cutting by running wire (wire erosion)
- Spark erosion by single tools (erosive milling and drilling)

Table 5 lists typical parameters and limits for EDM processes.

1.13.3.3.1 Spark erosion by sinking

Spark erosion by sinking is characterized by the simultaneous relative movement between tool

Table 5 Typical process parameters and limits for electrodischarge machining

Application	*Spark erosion*	*Wire erosion*
Applied voltage (V)	80–160	80–160
Precision (μm)	$\leq \pm 1$	$\leq \pm 1$
Roughness, R_a (nm)	200	100
Minimum structures (μm)	20 (lines), 20 (spaces)	20 (lines), 40 (spaces)
Maximum aspect ratio	15 (lines), 25 (spaces)	30 (lines), 80 (spaces)
Minimum inner radius (μm)	10	20
Minimum tool dimensions (μm)	10	30

electrode, workpiece, and feed movement. Movement of the tool electrode or of the workpiece can generate this relative movement. Furthermore, an additional movement can superimpose this relative movement (König 1990, N.N. 1976). The tool electrode represents the negative image of the body volume minus the process gap (N.N. 1976, Stempel 1977). Engraving can be seen as the simplest form of spark erosion by sinking, since the tool electrode is fed only in a single direction. By using this procedure, volumetric shapes are generated with the tool electrode representing the negative image of the volume to be removed, which copies itself into the workpiece with the additional process gap. According to Stempel (1977), matrices can be fabricated more economically by wire erosion. A significant enlargement of the field of application of spark erosion is the so-called planetary erosion. The conventional rectilinear sinking movement is overlapped by a spatial translation movement of the tool electrode. Further derivations of the sinking process are multiple-channel machining that is used for structuring large areas and the simultaneous processing of several components, by processing with rotating tool electrode and by processing the line of erosion (Behmer 1988, Kips 1960, König 1991, Kracht 1970, Staelens 1990).

All procedures described above can be used in principle for structuring tasks specific to microsystem engineering. The main areas of application of microspark erosion of sinking are the fabrication of air-cooling ducts in turbine blades, microreactors, injectors, ink-jet nozzles, tools for plastic molding, and punching tools for leadframes (Allen and Lecheleb 1996, Allen *et al.* 1999, Gruber 1999, Sato *et al.* 1985, Wolf 1997, Wolf *et al.* 1999).

1.13.3.3.2 Spark erosive cutting – wire EDM

The term spark erosive cutting comprises all processes where workpieces are separated and cut in or out (N.N. 1974). Normally, care has to be taken to work with as small a process gap as possible, in order to enable production of very small geometries with high accuracy. As an independent procedure variant, spark erosive cutting with wire electrode has been developed. Besides separating workpieces, this technique enables the fabrication of highly complex recesses and complex components and is used in prototyping, in tool and mold construction, as well as in series production (König 1990, Schumacher 1975, Stempel 1977).

By cutting with an uncoiling wire electrode, the desired geometry is generated by a numerically controlled relative movement between the tool electrode (uncoiling wire) and the workpiece electrode. This shaping process can realize only those geometries that correspond to the movement of a straight line in space, i.e., only regular forms (Bronstein 1999, Schönbeck 1992). **Figure 14** shows the work area of the five-axis wire erosion machine Charmilles Robofil 2020SI, from the company Charmilles Technologies SA, Geneva, Switzerland, with its most important components. By moving the upper wire duct in the direction of the axes v and u, conical shapes can be produced. With this process variant it is possible to fabricate stamps and matrices for tool construction without division of molds. Tool wear

Figure 14 Work area of a spark erosive wire erosion machine.

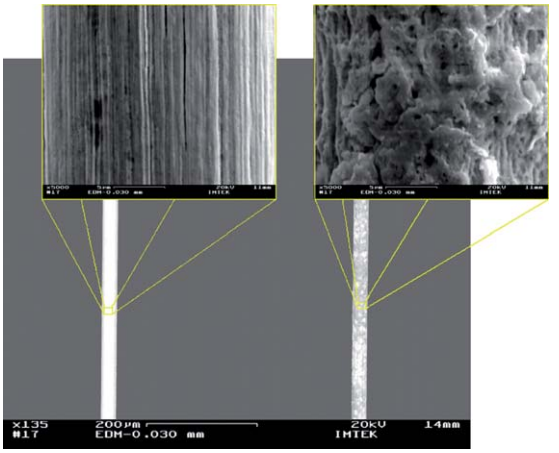

Figure 15 Comparison of unused (*left*) and used wire (*right*) (30 µm wire diameter).

during wire erosion is relatively large; however, the effect on the process is almost negligible, since the wire is renewed permanently (König 1990, Spur and Stöferle 1984). **Figure 15** (*left*) shows a tungsten wire with a diameter of 30 µm in its delivery status, and **Figure 15** (*right*) shows the wire in the state after processing. The discharge craters can clearly be identified on the surface of the wire. Because of the relatively great wear, the wire can be used only once.

1.13.3.3.3 Wire EDM with thin wires – microwire erosion

In the early 1980s a multitude of products and components from several industries required wires with diameters that are significantly thinner than the diameters of standard wires (100–250 µm). **Figure 16** shows the common standard wires and, in comparison, recently developed and used microwires. It can be seen that by using these wires a great number of new problems arise, particularly in wire handling. This is particularly the case in tool and mold construction (drawing profiles, cutting tools), in the watch and the clock industry, and in the textile industry (manufacturing of spinnerets) (Christmann 1999, Gruber 1999).

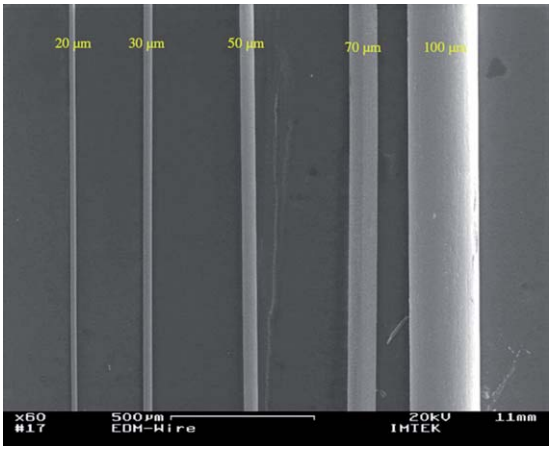

Figure 16 Comparison of different wires (20–100 µm).

By developing process energy sources and controls further and by acquiring greater expertise with regard to the EDM process itself, surface roughness in the range of $R_a = 0.1$ µm can be achieved. The best reproduction accuracies are in the range of a few micrometers (Dauw and Coppennolle 1995, Gruber 1999, Wolf *et al.* 1999).

Another very successful variation of EDM methods was done in the 1990s by Masuzawa (1990, 1998). He described a technology for manufacturing a rotationally symmetric electrode by electrowire grinding. The electrode is used as a sinking electrode in an additional manufacturing step. This technology is called wire electrodischarge grinding (WEDG) and by using this technology 3D microstructures made by EDM became possible.

1.13.3.3.4 Electrodischarge milling and drilling

Micro-EDM milling is an improvement on EDM; like numerically controlled milling, it uses a universal tool electrode of simple shape (e.g., spherical or cylindrical) that moves along a complex path to machine hard materials like tools. EDM is a machining technique that removes a small amount of workpiece material continuously by controlling the discharge energy applied between the tool electrode and the workpiece. Both electrodes are immersed through a side flushing in a dielectric fluid (e.g., deionized water or oil) that electrically insulates and cools the electrodes as well as removes the particles out of the gap. For this work, a micro-EDM milling machine (e.g., SX-100 (Sarix SA, Switzerland)) that integrates a 3D micro-EDM milling CAM concept, enabling computer-aided manufacturing, and a multiaxis motion that allows for contour-controlled machining according to a preprogrammed path in directions x, y, and z simultaneously can be used. It thereby achieves a high-precision positioning accuracy of up to ±2 µm and a resolution of 0.1 µm. By using standard tool electrodes with a simple shape, the tool manufacturing costs are reduced to a minimum; additionally, the degree

of automation is increased and simplified process planning is enhanced. The machining speed and surface finish can be adjusted by properly controlling the micromilling and discharge strategies (shape pulse, energy).

The overall fabrication sequence for creating a mold insert with microfluidic structures is illustrated schematically in **Figure 17**. Initially, a semifinished part is fabricated by CNC (computer numerical control) milling and a subsequent polishing step in order to get a surface quality of about 15 nm. The micro-EDM milling process is divided into two steps. First, a carbide electrode with a diameter of 340 µm for machining large areas is used. Next, the details are structured by fine machining with an electrode having a diameter of 45 µm. This electrode size is prepared automatically by using a built-in microwire EDM device (WEDG unit). The fine machining process operates using a new additional microfine pulse shape generator (SX-MFPS) in order to make small, deep, and precise round-shaped holes as well as channels. **Figure 18** is a SEM micrograph of the microstructure as part of a mold insert. It shows the structured geometry that results in reservoirs and microchannels after the replication process. The SEM micrograph in **Figure 18** shows a detailed view of the bend region of the microstructure.

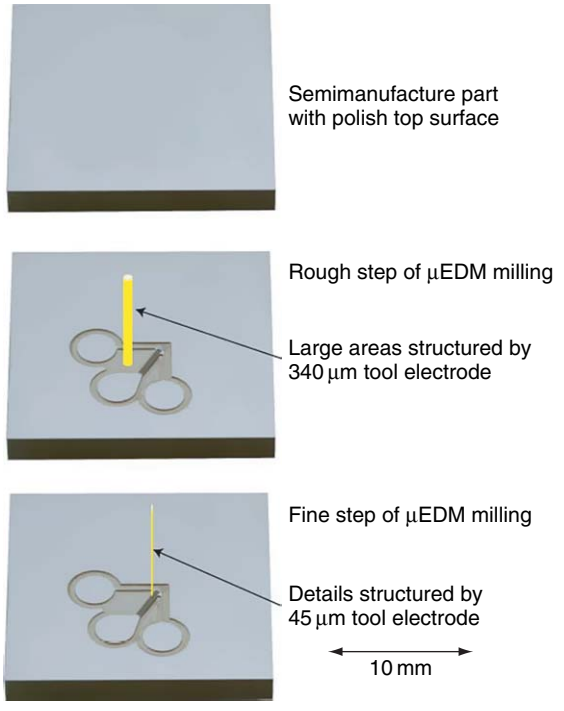

Figure 17 Schematic process of tool fabrication.

1.13.4 Electrochemical Machining

1.13.4.1 Principles

In 1930, Gusseff patented electrochemical metal dissolution for the production of boreholes and profile recesses. Further development and the increasing use of high-strength and high-temperature-resistant materials, initially in the aerospace industry, eliminated a number of problems in commonly used processes that mainly used machining. Because of the extremely high tool wear, the efficiency of the machining processes is restricted by the mechanical properties of the material to be machined (Kubeth 1965, Heitmann 1966). From the 1960s and 1970s up to the mid-1980s, a great number of investigations on and articles about the application of the ECM technique in almost all fields of the metal-working industry were published. The strongest driver for the rapid development was the increasing demand for the materials being used, since they could not be machined or proved expensive to machine with the commonly used material cutting techniques (Stanek 1970). Because of the further development of other manufacturing processes and the increased focus on ecological subjects, the ECM technique lost importance within industrial practice and did not reach the high level of usage once predicted in industrial production. Today, ECM processing techniques are still being used to a relatively large extent in the aircraft industry and in the defense industry and in stationary gas turbine construction. Because ECM makes it possible to structure highly loaded materials with no regard to their mechanical properties, ECM sinking provides very interesting possibilities in microsystem engineering: the company PEM Technologiegesellschaft für elektrochemische Fertigung mbH, Dillingen/Saar, utilized this feature in an ECM sinking process that makes use of an oscillating tool electrode. This technique became known under the brand name PEM (precise electrochemical machining). This electrochemical process can be described as a sinking process with an oscillating tool electrode. Publications about ECM processing mainly deal with investigations on the process of anodic metal dissolution, the workability of different materials, the processing rates, the achievable removal rates, the electrode correction factors, and the different electrolytes. Against the many advantages that ECM manufacturing processes offer are a number of very complex problems that make a reliable control of the process and predictions

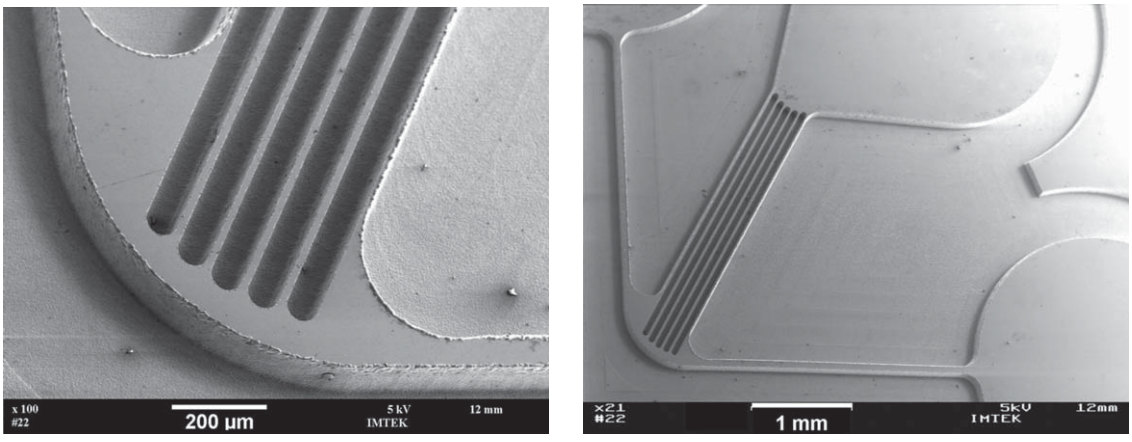

Figure 18 Detailed view of the bend region of the microstructure (*left*) and top view of the microstructure (*right*).

of the work results difficult. The great number of parameters do require the user of this technique to carry out extensive empirical investigations in order to find optimal process parameters for the desired work results.

ECM processes are a type of separation process. A primary characteristic of these manufacturing processes is nonmechanical material removal. ECM processes (**Figure 19**), i.e., the processes occurring in the working gap and the basics of the electrochemical removal process, are explained below:

The ECM process is based on the anodic dissolution of a material in an electrically conductive medium. In an electrochemical cell, a DC voltage of 5–20 V is applied. The positive pole (anode) of the power source is connected to the workpiece. The negative pole (cathode) is connected to the tool electrode. An electrically conductive medium – the electrolyte – is present between both the electrodes. The applied voltage drops across the electrolyte solution in the process gap between the tool and the workpiece electrode. The applied voltage U, according to Ohm's law, is:

$$U = U_A(j) + U_C(j) + U_{Ely}(j) \quad [8]$$

The voltage drop across the electrolyte solution is:

$$U_{Ely} = AR(j)j \quad [9]$$

By measuring the change in the galvanic voltage across the local barrier layer, the voltage drop across the anode (U_A) and the cathode (U_C) can be calculated (Forker 1966). The electrical resistance of the electrolyte solution can be determined from the specific electric conductivity χ of the electrolyte, the electrode distance s, and the electrode surface A, using the following equation (Forker 1968, Schwabe 1974):

$$R = \frac{s}{\chi}A \quad [10]$$

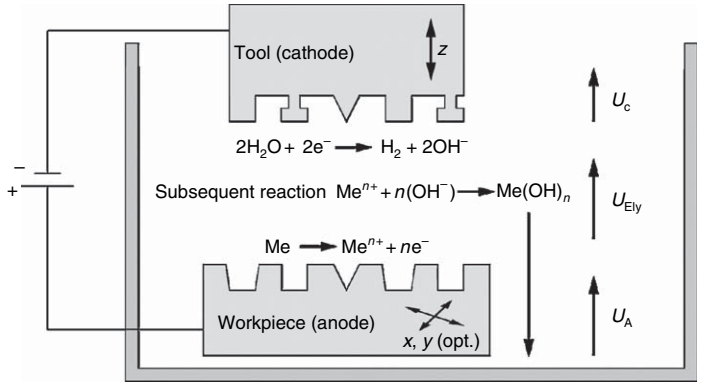

Figure 19 Electrochemical machining processes in the working gap.

If $U_D = U_A + U_C$ is substituted in eqn [8], from eqns [9] and [10] we get:

$$U = U_D + U_{Ely} = U_D + \frac{s}{\chi} j \qquad [11]$$

The current density j is given by:

$$j = (U - U_D)\frac{\chi}{s} \qquad [12]$$

The term U_D depends on the material–electrolyte combination of the anode and also on the material of the cathode (Degner 1984).

1.13.4.1.1 Anodic metal dissolution

In an electrochemical cell, two electrodes are connected to a power source and immersed in an aqueous solution. In the electrolyte, the salt disassociates completely and is present as separated cations K^{in+} and anions Sr^{in-}. Furthermore, the water is, to a small extent, dissociated into H^+ and OH^- ions. During electrolysis, the cations (K^{in+}, H^+) migrate to the cathode and the anions (Sr^{in-}, OH^-) to the anode. The following phenomena can be observed:

- At the tool electrode (anode), metal ablation takes place, which can be determined by weighing the electrode before and after the processing.
- At the workpiece electrode (cathode), depending on the electrolyte used, hydrogen might be produced.
- At the bottom of the cell, a brown coating is deposited, which on chemical analysis reveals metal hydroxide.

These observations can be described by the following chemical reactions:

At the anode, metal ions dissolute by the emission of electrons:

$$Me \rightarrow Me^{n+} + ne^- \qquad [I]$$

At the cathode, hydrogen and hydroxide are formed by the acceptance of electrons:

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \qquad [II]$$

In a subsequent reaction, metal hydroxide is formed, which can be precipitated depending on the electrolyte used:

$$Me^{n+} + nOH^- \rightarrow Me(OH)_n \qquad [III]$$

Eqns [I]–[III] depend on the electrolyte used and on the material that has to be machined. If, for example, sodium chloride is used as an electrolyte and only pure iron is machined, eqn [I] becomes:

$$Fe \rightarrow Fe^{2+} + 2e^- \qquad [IV]$$

From eqns [II] and [IV] we get:

$$2H_2O + Fe \rightarrow Fe(OH)_2 + H_2 \qquad [V]$$

In this case, only water, but no electrolyte, is consumed. This may not be the case for other electrolytes. For example, for so-called STEM (shaped tube electrochemical machining) drilling of cooling holes in turbine blades, sulfuric acid is used. For the reactions at the anode and the cathode, eqns [II] and [IV] are valid; however, the equation for the reaction becomes:

$$H_2SO_4 + Fe \rightarrow FeSO_4 + H_2 \qquad [VI]$$

So the formation of insoluble ferrous hydroxide is suppressed because of the formation of soluble iron sulfate. Thus, the electrolyte wears itself out and must therefore be continuously monitored and replenished if necessary. For sodium nitrate, the electrolyte most often used in practice, further peculiarities exist: At the anode, the rate of oxygen production depends on the current density, as given by the following equation:

$$2H_2O \rightarrow 4H^+ + 4e^- + O_2 \qquad [VII]$$

The anodic metal dissolution, as given in eqn [I], starts only for higher current densities. The Fe^{2+} ions reduce; however, the NO_3^- oxidize Fe^{3+} ions that then precipitate as hardly soluble iron (III) hydroxide.

$$4Fe^{2+} + 2NO_3^- + 4H_2O + 2e^- \rightarrow 2NO_2^- + 4Fe^{3+} + 6OH^- + H_2 \qquad [VIII]$$

At the cathode, no or insignificant hydrogen is produced. The main reaction that takes place is the reduction of the nitrate ion to the ammonium ion.

$$NO_3^- + 7H_2O + 8e^- \rightarrow NH_4^+ + 10OH^- \qquad [IX]$$

If oxygen and hydrogen production is ignored, the complete reaction when sodium nitrate is used as an electrolyte is as given:

$$4Fe + 3NO_3^- + 11H_2O \rightarrow NH_4^+ + 4Fe(OH)_3 + 2NO_2^- + 4OH^- + H_2 \qquad [X]$$

Because of the hydroxide ions formed, the electrolyte becomes more alkaline during the process; in

addition, ammonia is formed (Degner 1984). These basic equations represent machining only for a pure material, in this case iron. For materials used in industrial practice – mostly alloys from several elements, i.e., material mixtures – the chemical reaction is very complex; sometimes the reaction is not even possible, as is evident from the attempts that have been made to directly draw a material sample from the working gap to observe the reactions, which have not succeeded. In order to learn about the reactions taking place during the machining process, one can refer to many preliminary works on analytical electrochemistry. However, only quasi-stationary processes are considered there; furthermore, mostly pure materials are examined. Thus, knowledge of process behavior of alloys and the optimal process parameters for the corresponding materials can only be gained by investigations.

1.13.4.1.2 Quantitative description of anodic metal dissolution

For the calculation of the theoretically possible specific ablation volume V_{spez}, Faraday's law

$$m = \frac{M}{zF} I t_B \qquad [13]$$

is used under the condition that at the tool electrode, only electrochemical dissolution of the anode material takes place. In eqn [13], m represents the ablated mass (g), M the molar mass (g mol^{-1}), I the current (A), t_B the machining time (s), z the electrochemical valence, and F the Faraday constant.

If reactions that are not conducive for ablation take place, as described in eqn [VII], the energy input is not completely converted for metal dissolution. If the density of the workpiece, $\rho = m/V$, is included, the equation for the ablation volume becomes:

$$V_{spez} = \frac{A_r}{z} F \rho_{Wst} \qquad [14]$$

For the calculation of the ablation volume of an alloy, eqn [14] can also be used. If the n alloying elements ($i = 1, 2, \ldots, n$) are present in the alloy in the proportion p_i, the following equation is obtained:

$$V_{spezLeg} = \frac{100}{F \rho_{Leg} \sum (p_i (z_i / A_{ri}))} \qquad [15]$$

It can be seen from eqns [14] and [15] that the valency change z greatly influences the result. Since elements with different valencies can be in a dissolved state, the determination of z for an alloy often involves extremely high cost, or is even impossible. Because determination of the electrochemical valency of alloys is often difficult, and because it cannot always be guaranteed that the energy introduced into the process is transformed completely into removal–effective reactions, the real value of the material ablation V_{Abreal} must be determined experimentally and, furthermore, must be compared to the theoretical value of the specific ablation volume, in accordance with eqns [14] and/or [15]. This quotient is referred to as the current efficiency η_j, and can be calculated using the following equation:

$$\eta_j = \frac{V_{Abreal}}{V_{spez}} \qquad [16]$$

1.13.4.1.3 Passivation

According to the principle of anodic metal dissolution, all metallic materials except for some noble metals can be dissolved, provided that suitable electrolyte solutions are used and a sufficient current density is available (Degner and Boettger 1979, König and Klocke 1997). However, for specific electrode potentials, surface (anode) oxides can develop on the workpiece, which hinders the transition of the metal ions in the electrolyte (Vetter 1961). The movement of the coreactants is also impeded or comes to a complete stop. This phenomenon is known as passivity. The development of these coatings, which are also referred to as passive layers, is influenced by the type of electrolyte, the process conditions, and the anode material. A passive layer can cause removal–ineffective reactions and therefore reduce the efficiency of the process, which is expressed through a poor current efficiency. By assuming a current density potential, the passivity can be measured by various techniques (Hoar 1967, 1968, König and Klocke 1997, Schwabe *et al.* 1958, Vetter 1958). The current density increases with increasing anode potential until it reaches a potential barrier. This potential barrier is called Flade potential after its discoverer Flade (Hensler *et al.* 1958, König and Klocke 1997). When the potential barrier is reached, the current density decreases to the level of the corrosion current density. With higher anode potentials, the dissolution of the anode starts and the current density increases once again.

For the quantitative determination of passivity, current density potential characteristics are recorded. The characteristics depend on the material

electrolyte combination used. In the lower potential range, the current density increases with increasing voltage, then declines steeply when the passivation current density is reached because of the formation of nonporous oxide layers. Because of acid electrolytes, the current flowing in the passive field is rather small and is probably used for renewal of the oxide film (Evans 1965). It is virtually independent of the potential since dissolution is a chemical process.

In the transpassive field, the development of gaseous oxygen becomes thermodynamically possible because of the discharge of hydroxide ions. However, an electron-conducting coating layer should be available (Degenhardt 1972). The passive layer gets dissolved locally, which is characterized by a pitting mechanism at the cover layer, and the current increases again (Datta and Landolt 1980). According to the conductivity of the cover layer, the metals can be categorized as electron-conducting, cover layer building, and ion-conducing cover layer-building materials (Hamann and Vielstich 1998, Hoar 1968, Schwabe 1966). For iron, nickel, chrome, and, apparently, cobalt, the effect of electron conductivity is stronger than the effect of the passive layers that are built up during the stationary passive state, such that, for a further voltage increase, oxygen is generated from a higher-valence metal oxide. For other materials (aluminum, tantalum, titanium, and zirconium), metal ions are transported through the passive layer to the dissolution side due to the poor electron conductivity of their oxides. The cover layer grows there subsequent to hydrolysis. The current does not increase if the voltage rises until disruptive discharge occurs. Because these materials are capable of charge storage, they are also referred to as condenser metals. For metals with an ion-conducting passive layer, a high overvoltage, together with the dissolution of the passive layer, is therefore necessary in order to induce an oxidation–reduction reaction (Degenhardt 1972). Degenhardt (1972) gives an overview of the properties of coatings of different metals. For the metals of this group, the dissolution of the passive layer begins at about 20 V. For the development of an oxide layer, oxygen is necessary; during electrochemical processing this must be bound in a sufficient amount to the electrolyte. This is the case only for basic solutions of neutral salts. Development of passive layers can be counteracted by lowering the pH value (Enke 1982, McGeough 1974). Generally, passive layers are more stable in alkaline solutions. From the Pourbaix diagrams, the corrosion resistance of a material for specific combinations of pH value and potential can be determined (Bargel and Schulze 1978). Furthermore, such diagrams provide information on whether a material can be passivated. Pourbaix diagrams have been drawn for many elements. However, they describe only reactions between the metal and its oxides, its hydroxides, and water. For alloys, Pourbaix diagrams can be drawn only occasionally. The passivation behavior of single material–electrolyte systems can furthermore be influenced by temperature and concentration of the electrolyte. When using passivating electrolyte systems, for example, sodium nitrate, the stability of the coatings increases with temperature and the decreasing concentration of the electrolyte (Enke 1982, Pahl 1969).

1.13.4.1.4 Gap

From eqn [10] and according to Ohm's law, we get the following equation:

$$I = U\chi\frac{A}{s} \qquad [17]$$

By rearranging and substituting the current density j, the following equation is obtained for the gap width:

$$s = U\frac{\chi}{j} \qquad [18]$$

The gap width can be decreased by decreasing the specific electric conductivity χ of the electrolyte solution, by decreasing the operating voltage U, and by increasing the current density j, resulting in an increase in the achievable reproduction accuracy.

1.13.4.1.5 Electrolyte solutions

During electrochemical processing the following processes should be possible in electrolyte solutions (Degner 1984, König and Klocke 1997):

- Conduction of electric current (transportation of charge carriers)
- Anodic metal dissolution
- Removal of particles and reaction products
- Conduction of the process heat

Furthermore, for selecting electrolytes the following are next in importance to process-relevant properties:

- Physiological harmlessness
- Ecological neutrality (wastewater)
- Corrosive effect on the processing installation and its environment

- Economical requests (price, availability)
- Chemical stability
- Universal applicability

Aqueous solutions of neutral salts such as sodium chloride, sodium chlorate, sodium nitrate, potassium nitrate are mainly used, partly by adding complexing agents such as citric acid, in order to keep the ablation products in a dissolved state. For special applications (e.g., electrochemical drilling), sulfuric acid and caustic soda are used. Furthermore, a number of electrolyte mixtures are used, partly under organic additions, in order to reduce corrosion or to improve surface quality. For the machining of multiphase materials that show a different solution behavior, electrolyte mixtures are used. Applications of such mixtures have been described by Enke (1982) for nickel base alloys and by DeBarr (1968) for tungsten carbide. The characteristics of the electrolyte that must be taken into account are specific electric conductivity, concentration, temperature, pressure, and pH value. In literature, electrolytes are categorized as passivating and nonpassivating electrolytes. However, the distinction between passivating (e.g., sodium nitrate) and nonpassivating (sodium chloride) electrolytes is only valid for iron and nickel, since other metals such as aluminum, copper, and titanium show similar polarization behavior in both electrolyte types (Datta 1993, Walsch 1979). For most anode materials, the choice of the electrolyte determines whether the dissolution of the metal takes place in the active or in the passive region (Walsch 1979). For dissolution of passive layers on ferrous metals, halogen ions can be used since they have a corroding effect (Schwabe 1966). Here, the dissolution of the passive layers occurs above a critical potential by the entry of anions in the passive layer. In most cases, adsorbed water dipoles or sorbed oxygen are exchanged against the anions in question (Schwabe 1966). These processes mostly occur where the crystal structure is disordered, as, for example, at grain boundaries and dislocations (Hoar 1968). The ions with the smallest radius penetrate the passive layer fastest. Hoar arranged these ions according to their effectiveness: Cl^-, Br^-, I^-, CN^-, NO_3^-, and ClO_4^-.

The halogen anions Cl^-, Br^-, and I^- are absorbed by the surface atoms of the metal at a much more negative potential than the oxidation potential of the metal lets one expect. The passivation therefore does not occur when halogen-containing electrolytes are used (Evans 1965). Highest ablation rates are achieved by the use of Cl^- ions due to their high chemical aggressivity when penetrating passive layers. DeBarr (1968) considers sodium chloride as a common and widespread electrolyte for electrochemical processing of steels and nickel base alloys because of its relatively low acquisition costs. Chloride-containing electrolytes lead, however, to pitting corrosion and development of grooves and dimples at the surface. These defects have a negative impact on the mechanical and corrosion properties of the components (Effertz 1977, La Boda *et al.* 1971, Powers and Wilfore 1970). Effertz observed that pitting corrosion occurs at very small sodium chloride concentrations on heat-treated steel X20Cr13. For the processing with sodium chloride, Mao (1971) found a current efficiency of 100% when the solution is saturated with $FeOH_2$. In industrial practice, sodium chloride-containing electrolyte is used solely for the processing of titanium.

During processing with sodium nitrate, metal ablation occurs only at higher current densities. When the minimal necessary current density $\mathcal{J}_{min}$ is reached, a passive layer can dissolve locally. When sodium nitrate is used as an electrolyte, oxygen is produced at the anode, small or insignificant hydrogen is produced at the cathode, and the current efficiency is poorer (Mao 1971). Below a current density of 12 A cm^{-2}, almost the entire current is used for producing oxygen at the anode. According to Mao (1971) the current efficiency increases with increase in the concentration of the electrolytes and the current density. This observation is confirmed by Yu (1981). Mixed electrolytes are described by Enke and DeBarr for materials that show an opposite solution behavior for sodium chloride and nitrate solutions, as, for example, for nickel base alloys and tungsten carbide (DeBarr 1968, Enke 1982). A high number of experiments were conducted by Thornton (1992) for mixed electrolyte titanium processing. Bemelmans (1970) carried out basic investigations on titanium using different electrolyte mixtures that contained sodium chloride and/or sodium chlorate. Experiments with chloride/nitrate combinations did not increase the ablation rate when compared to processing with pure sodium nitrate (Mao 1973). Other authors too have provided information on different complexing agents. Typical complexing agents are oxalate, tartrate, citrate, and ethylenediaminetetraacetate anions (Bemelmans 1970). Complexing agents prevent precipitation of metallic salts and therefore the development of passive layers in the transpassive region. Since the solubility of these materials is limited, dissolved metals will be deposited onto the cathode in the case of saturation. Such electrolyte mixtures must be monitored continuously and

replenished frequently (Bannard 1997, Kubeth 1965, McGeough 1974). Yu (1981) tested different electrolyte combinations for the ECM of the titanium alloy TC4, for which he could not achieve any increase in the ablation rate.

1.13.4.1.6 Characteristics of electrolyte solutions

For describing the properties of electrolytes, a number of parameters, which are explained in detail in the following sections, are used.

1.13.4.1.7 Specific electric conductivity of the electrolyte solution

As mentioned above, the main task of the electrolyte is conduction of charge and/or ions. The ability to fulfill this task is expressed through the specific electric conductivity χ of the electrolytes. The specific electric conductivity is the reciprocal of the Ohm's resistance:

$$\chi = \frac{1}{R} \qquad [19]$$

For achieving high ablation rates, the conductivity of the electrolyte must be high. The specific electric conductivity of an electrolyte solution depends on its concentration and its temperature. According to Bemelmans (1970), the typical specific electric conductivity for electrolyte solutions is between 0.05 and 0.3 $S\,cm^{-1}$. Warming of the electrolyte can cause gas bubbles to develop, resulting in a decrease in the electrical conductivity. Increased contamination by reaction products and a resulting increase in viscosity cause a minor decrease in the electrical conductivity (Bemelmans 1970, Kubeth 1965, McGeough 1974). When the electrical conductivity decreases, the working gap decreases as well, and the accuracy of the process increases. That is why nitrogen is added to the electrolyte (Degenhardt 1972). The gas concentration and the conductivity are inversely proportional (Heitmann 1966, Hopenfeld and Cole 1966). However, this admixture might also lead to short circuits and nonuniform dissolution of the working materials (Landolt 1970).

1.13.4.1.8 pH value of the electrolyte solution

The pH value is a measure of the H^+ ion concentration in a solution and is calculated according to the following equation:

$$\mathrm{pH} = -\log_{10} C_{\mathrm{H}} \qquad [20]$$

An electrolyte with a pH value of 1 therefore has a high H^+ ion concentration and is strongly acidic. A strong base has a pH value of 14 at a small H^+ ion concentration. For ECM processes, neutral salts with pH values of around 7 are mainly used. When compared to strongly acidic or strongly basic electrolytes, the disadvantage of neutral electrolytes is that they have poor conductivity (DeBarr 1968, Kleiner 1963). The formation of hydrogen at the cathode has negative effects on the machining process. On the one hand, the formation of hydrogen through H^+ ion revocation reduces conductivity of the electrolyte solution; on the other hand, an increasing pH value promotes unwanted deposition of metal on the cathode surface (DeBarr 1968). According to Faraday's law, a dynamic balance is established during the machining process. Eventually, the pH value levels out in a range where the insoluble metal hydroxides precipitate and can be filtered out in a relatively easy manner (Walsch 1979).

1.13.4.1.9 Concentration of the electrolyte solution

The specification of the concentration of an electrolyte solution is mostly given in mass percent and is calculated using the following equation:

$$C_{\mathrm{Ely}} = \frac{m_{\mathrm{salt}} \times 100\%}{m_{\mathrm{Salz}} + m_{\mathrm{Wasser}}} \qquad [21]$$

An increase in electrolyte concentration during electrochemical processing generally results in an increase in the number of charge carriers within the electrolyte solutions, and therefore in a higher specific electric conductivity (McGeough 1974). Pahl and Degenhardt found a concentration dependency of the ablation rate only by usage of sodium nitrate when processing 41Cr4 and 56NiCrMoV7, but not for the usage of sodium chloride. For C45, Kubeth showed an increase in the ablation rate when sodium chloride was used due to the increase in the specific electric conductivity (Degenhardt 1972, Kubeth 1965, Pahl 1969). Klocke's viewpoint, however, contradicts that of Pahl and Degenhardt. He machined 56NiCrMoV7 with sodium chloride and determined the concentration dependence for this process (Klocke and Sparrer 1998).

1.13.4.1.10 Temperature of the electrolyte solution

Ions are mass-bound corpuscles that move under the influence of the working voltage in an electrolyte solution. Because of frictional heat, the temperature

of the solution increases (DeBarr 1968, Heitmann 1966). The conductivity of ionic conductors increases because of the increase in temperature since the mobility of the ions increases. On the other hand, gas bubbles form because of warming and subsequent overheating of the electrolyte. The occurrence of gas bubbles, in turn, leads to a decrease in the electrical conductivity (Bemelmans 1970, Kubeth 1965, McGeough 1974). Heitmann showed that with increasing temperature the increase in conductivity outweighs the decrease in conductivity (Heitmann 1966, Landolt 1970). However, a further temperature rise can lead to the boiling of water-soluble electrolytes (Heitmann 1966, Hopenfeld and Cole 1966). In this case, water vaporizes and the electrolyte crystallizes, which results in a short circuit between the anode and the cathode (Heitmann 1966, Pahl 1969). The large quantity of heat produced at high current densities must be removed from the processing volume (DeBarr 1968). Next to good thermal conductivity, a high specific heat capacity of the electrolyte is mandatory. A strong warming of the tool electrode can lead to deformations and therefore a decrease in the mapping accuracy.

1.13.4.1.11 Pressure of the electrolyte solution

For a higher pressure, the volume flow of the electrolyte and therefore the electrical conductivity increases. The temperature of the electrolyte solution decreases, as a larger amount of heat can be removed. Kawafune (1967) showed that for the processing of unalloyed steel using a 20% sodium chloride electrolyte solution, the current density increases with increasing electrolyte velocity. This statement was confirmed by Neubauer (1984). However, for the material X15CrMo13 and when using a sodium chloride solution, Kubeth (1965) found only a minor dependence of the specific ablation volume on the flow velocity. Clark reduced the flow velocity of sodium chloride electrolytes and detected a temperature rise up to the boiling point (Clark and McGeough 1977).

1.13.4.2 Materials

1.13.4.2.1 Irons, iron alloys, and steels

The idea for the ECM process was based on the use of a homogeneous working material consisting of a single metal. From that emanates a uniform metal dissolution in the feed direction. However, industrially used materials consist of several elements with different potentials. If several elements are present in a working material, the element that is less noble dissolves more quickly than the more noble one does. For example, iron (standard potential of –0.44 V) dissolves faster than nickel (standard potential of –0.25 V) (Lindenlauf 1977, Neubauer 1984). Neighboring structural domains with differing electrochemical properties lead to inhomogeneous current density distributions and therefore to locally differing ablation rates.

If the current density is increased further, potential differences that arise from structural inhomogeneities, together with the equidirectionally increasing electrode potential, loose their influence on the current density distribution, and therefore on the ablation behavior of the different material regions (Lindenlauf 1977, Neubauer 1984). Concentration of the current paths occurs in the region of the less noble structure phase. These phases dissolve faster than the more noble structure phases (Wilson 1971). Lindenlauf (1977) proved that the ferrite phase (Fe + C) dissolves faster than does the perlite phase (Fe + Fe_3C). When coarsely grained perlite phase exists in a ferrite matrix, whole grains can be rinsed out and eroded. These processes can then result in current efficiencies of more than 100%.

Neubauer (1984) observed that during the processing with sodium nitrate there was an increase in the specific ablation volume with increasing ferrite content in the structure. Fukunaga (1981) and McGeough (1974) obtained the same results. It is assumed that by heat treatment, the structure phases are distributed more uniformly. Pramanik examined the influence of an initial heat treatment on the ablation rate and the surface quality. He found that annealing after hardening increases the ablation rate; in the same way, the ablation rate should increase with increasing grain size (Pramanik 1975). Kops obtained different results from his investigations. He observed an increase in the current density and the metal ablation rate for reduced grain size. This observation can be explained by viewing the grain boundaries as surface defects. The atoms at the grain boundaries dissolve more easily from the surrounding material structure due to the different orientation of the bordering grains. The atoms of a grain, therefore, represent areas of increased chemical activity. The more the grain boundaries that are available at the surface, the better are the conditions for dissolution. By reduction of the grain size, the absolute grain border length and also the material ablation increases (Förster 2004, Kops 1976).

1.13.4.2.2 Titanium and titanium alloys

Titanium has a very high affinity for oxygen. Because of its position in the electrochemical series, it is a very basic metal. In oxidizing environments, oxide layers develop, which stick very firmly to the titanium surface and are chemically very inert. These oxide layers are the reason for the excellent corrosion resistance of titanium and titanium alloys. The properties of the oxide layers complicate the electrochemical workability of titanium. In order to carry out the processing, the oxide layer must be removed. This is often done using chemically aggressive electrolytes, which results in frequent surface defects (Thornton 1992). Dimples form in the immediate vicinity of the electrochemically ablated faces (Powers and Wilfore 1970). For high current densities, these dimples are so close to each other that they are not always recognizable as such. Bemelmans (1970) carried out basic investigations on titanium with different electrolyte mixtures that contained sodium chloride and/or sodium chlorate. Degenhardt (1972) concluded that for processing of titanium, there is no difference between a sodium nitrate and a sodium chloride electrolyte. This is contrary to the investigations of Bemelmans (1970) and many others. Thornton examined sodium bromide solutions for the electrochemical processing of titanium. He also used electrolyte mixtures of sodium fluoride, sodium bromide, and sodium nitrate (Thornton 1992). There are doubts regarding the toxic properties of these electrolytes; these electrolytes are hard to handle in industrial practice since they must be monitored and replaced where appropriate. Sauschkin *et al.* (1995) suggests the use of watery organic electrolytes for electrochemical processing of titanium, in order to avoid hydrogen saturation of the titanium surface and to avoid the resulting deterioration in the mechanical properties of the material. The disadvantages of these electrolyte solutions are the high costs, the poor conductivity, a low boiling point, and the danger of explosion of these solutions.

1.13.4.2.3 Hard metals

Hard metals represent a challenge for electrochemical processing as they consist of very different structural components that, electrochemically, behave differently; for example, by processing tungsten carbide, insoluble tungsten trioxide is produced, which prevents metallic dissolution (Bemelmans 1970, Kunert and Schwieger 1977). By short-term conversion of the polarity, where the workpiece is poled as cathode, coatings can be dissolved specifically. The hydrogen that develops on the workpiece surface reduces the passive layer, thereby lowering the valency of oxides or hydroxides, and as such oxides and hydroxides becomes more soluble (Bemelmans 1970).

However, material ablation takes place on the now anodically poled tool electrode. This tool wear leads to a deterioration in the accuracy. It is dependent on the current density, the duration of the polarity reversion, the type of hard metal that is to be depassivated, the electrode material, and the type of the electrochemical reaction that takes place in the electrolyte at the anode (Kunert and Schwieger 1977).

1.13.4.3 Procedure Variants for Microsystem Engineering

1.13.4.3.1 Electrochemical microdrilling

An activity that is increasingly gaining attention in the field of microsystem engineering is the manufacturing of small boreholes with the highest possible aspect ratios. Next to applications in turbine construction (air-cooling ducts), small boreholes in high-temperature materials have a high potential particularly in the automotive industry (injection systems) (Adam 1998). Also, in tool and mold construction, there is a need for small drillings, which are used for the evacuation and ventilation of molds during injection molding. A spindle can be mounted on the z-axis of the electrochemical processing machine. Besides external rinsing, the rotation spindle enables rinsing through the electrode. The rotational speed of the spindle can vary from 0 to 20 000 rpm. However, the construction has not yielded satisfactory results. **Figure 20** shows some boreholes produced during the pretests. The large sloping angle and the relatively large feed opening radius are clearly visible. When compared to boreholes that are fabricated by traditional electrochemical drilling procedures, such as STEM drilling, electrostream triplet drilling (ESD), electrochemical precision drilling (ECF), and electrojet (EJ) drilling, the boreholes fabricated by electrochemical microdrilling are still of limited application. There is an urgent need for further investigations, especially with regard to the effects of the rotational speed, the circumferential speed of the tool, and rinsing.

Another possibility, in particular for the parallel fabrication of a great number of drillings, consists in the sinking of thin pen or needle arrays. Another interesting application of the electrochemical sinking

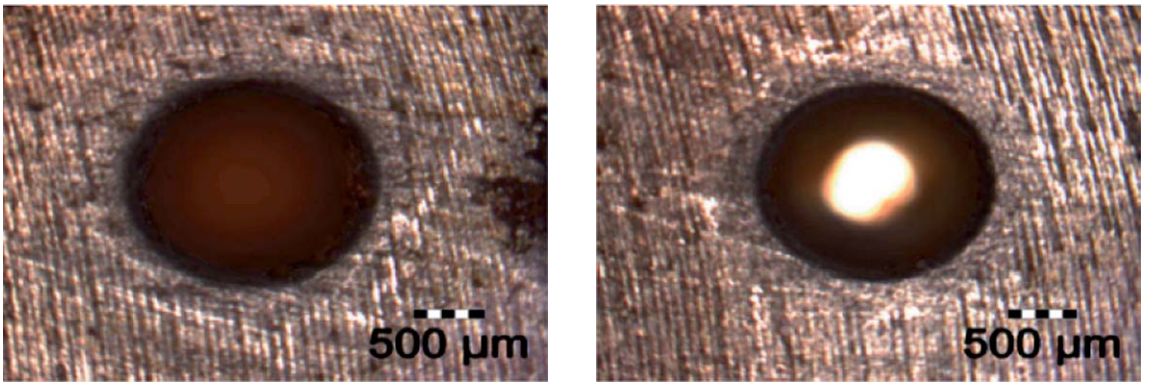

Figure 20 Holes produced by electrochemical microdrilling.

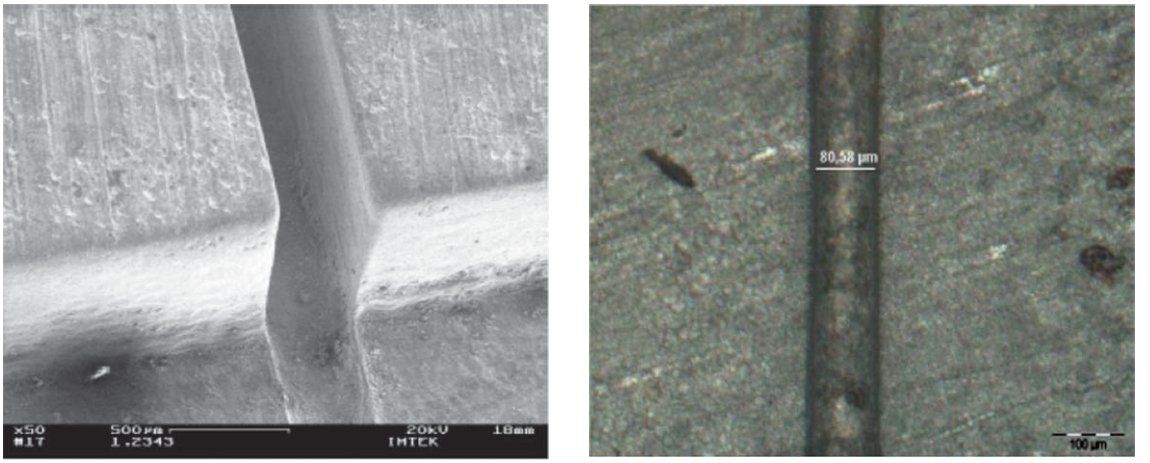

Figure 21 Structures made by electrochemical (EC) wire cutting.

process that uses an oscillating tool electrode is in the production of tools for micropunching with very filigree structures. Advantages result particularly because of the absence of process forces and because of the possibility to structure materials independently of their mechanical properties.

1.13.4.3.2 Electrochemical microwire cutting

The height of structures that can be manufactured with microwire EDM cutting is still limited. To overcome these limits, ECM was used to produce such structures.

Figure 21 shows such structures. The SEM picture clearly shows the very good sidewall angle of the structures produced. The smallest channels that have been manufactured with this process variant have a width of about 80 µm. These structures feature a length of about 15 mm and were manufactured with a 20-µm diameter tungsten wire.

1.13.4.3.3 Electrochemical micromilling

For the fabrication of micropatterns by mapping a negative of the structure to be produced, the fabrication of the negative by using electrochemical sinking of the tool electrode is also a technical challenge. One way of minimizing the relatively high manufacturing costs in the production of tool electrodes is by using a simple rotationally symmetric tool electrode. This tool electrode is fed along the desired shape of the workpiece, as in a traditional milling process. For this application, several controlled axes are necessary in the equipment.

Biographies

Holger Reinecke was born in 1964 in Bad Harzburg. From 1983 to 1988, he studied chemistry at the Technical University at Clausthal-Zellerfeld. From 1988 to 1990, he was scientific assistant at the Institute for Inorganic and Analytical Chemistry, and graduated in the field of electrochemical analytics in 1990.

In August 1990, Mr. Holger Reinecke started as a scientific assistant at the company microParts GmbH in the electroplating group, which he became head of in 1991. From 1993, he took over the department of chemical process technology, and the complete department of process technology in 1995. During this time, he developed, qualified, and established processes for the fabrication of microstructured components and tools. Among other things, lithographical, electrochemical, vacuum, or laser technical methods were implemented. Furthermore, he has established complete process chains for mass production of silicon-based medical products as well as for cleaning and surface coating of polymeric components. These components were used in medical devices. These processes were designed, installed, validated, and operated according to medico-technical and pharmaceutical requirements of European and US-American approval authorities. In 1999, as an area manager Mr. Reinecke additionally became head of the product branches microfluidics and microoptics. Since November 2004, Holger Reinecke is Head of the Chair of Process Technology at the Institute for Microsystem Technology (IMTEK) at the Freiburg Albert Ludwigs University. Since May 2005, Holger Reinecke is also Speaker of the Executive Board of the HSG-IMIT in Villingen-Schwenningen.

Claas Müller studied physics from 1986 to 1991 at the University of Karlsruhe. Following the physics diploma, he earned his doctorate in 1994 at the Forschungszentrum Karlsruhe, Institute for Microstructure Technology, for his work on a miniaturized spectrometer system, fabricated by LIGA technology. Meanwhile, the micro spectrometer is introduced to a broad range of industrial applications by the company microParts. At the Forschungszentrum, the prerequisites for a small-scale production were achieved. As a responsible project manager, Claas Müller was considerably involved in these activities. Since 1996, he is a graduate council at the Chair of Process Technology of the IMTEK. In 1999, he was appointed substitutional manager, and in 2004, the managing director of the Chair of Process Technology.

1.14 Self-Assembly

Jiandong Fang and Karl F Böhringer, University of Washington, Seattle, WA, USA

1.14.1 Introduction and Motivation

1.14.1.1 The Growing Need for Assembly

Microassembly is a technique for producing complex microstructures and systems by integrating microcomponents made in separate manufacturing processes. Two-dimensional microassembly mounts components on a flat substrate, and 3D microassembly produces structures with a more intricate spatial geometry.

Both 2D and 3D microassemblies are needed for mass production of microdevices. For example, a radio frequency identification (RFID) tag consists of a silicon microchip and an antenna. The antenna powers the tag and exchanges data between the chip and a neighboring RFID reader. The key to efficient

fabrication of RFID tags lies in the rapid replacement of the small, more expensive silicon microchips with the larger, cheaper antenna substrate (Silicon Chip Online 2006). Another example for a microassembly is smart dust, i.e., collections of tiny distributed nodes that integrate sensing capabilities with signal processing and can organize into a communications network (Warneke *et al.* 2001). These systems are emerging as commercial products, and microassembly techniques play a very important role in mass production of such microscale devices.

1.14.1.2 Monolithic Fabrication vs. Hybrid Integration

Monolithic fabrication constructs a whole device step by step from a single substrate. Hybrid integration constructs a device by combining various components from different techniques or processes. For devices with simple structures, monolithic fabrication has advantages such as compact layout and easy encapsulation. But many fabrication processes and materials are not compatible with one another, and thus microdevices having complex functionalities or structures must be constructed by hybrid integration of multiple units from several different fabrication processes.

Additionally, hybrid integration has another significant advantage for product developers. A complex microsystem can be broken down into multiple distinct units. Each unit is then assigned to a separate process engineer or group. Each unit can be separately optimized in design and fully characterized before integration. Units of the same type can be fabricated at the highest spatial density on a single substrate to save fabrication costs.

1.14.1.3 Packaging: Die Level vs. Wafer Level

Typically, packaging of microdevices involves three process steps:

(1) Placement of microdevices with correct face and in-plane orientations on receptor sites
(2) Permanent bonding of microdevices with electrical interconnections to the substrate
(3) Encapsulation of the bonded device components for protection from the environment

The choice of bonding method depends on the placement of microdevices: flip chip bonding is used for microdevices with electrical interconnects facing the substrate and wire bonding is used for microdevices with electrical interconnects facing the same direction as their counterparts on the substrate. A flip chip bonding process achieves electrical and mechanical connections simultaneously, and the electrical connections are established in parallel. A wire bonding process attaches a microdevice to the substrate to form mechanical connections before serial establishment of electrical connections. Die-level packaging assembles individual microcomponents after they are diced from a wafer. Wafer-level packaging simultaneously assembles all the devices on the same substrate before they are diced into individual devices, i.e., wafer-level packaging process is parallel assembly whereas die-level packaging is serial assembly.

1.14.2 State of the Art in Microassembly

1.14.2.1 Deterministic vs. Stochastic

Microassembly approaches, aimed at achieving highly efficient assembly of a very large number of microcomponents, can be classified into two major categories: deterministic and stochastic (**Figure 1**). In a deterministic assembly process, each part is assigned to a specific receptor site, e.g., as in wafer-to-wafer transfer of microstructures. In a stochastic assembly process, each part can be attached to any of the specifically designed identical receptor sites. The term self-assembly usually describes such stochastic assembly approaches, owing to the property that the assembly takes place in a spontaneous manner with components of a specific design. Self-assembly processes are discussed in detail in the remaining sections.

1.14.2.2 Serial vs. Parallel

The number of parts assembled at a time on a single platform defines the property of an assembly process: serial or parallel. In a serial assembly process, only one part is assembled at each time, for example, as in robotic pick-and-place assembly methods. In a parallel assembly process, multiple parts are assembled simultaneously, which can achieve a higher throughput. Both wafer-to-wafer transfer of microcomponents and self-assembly are parallel processes.

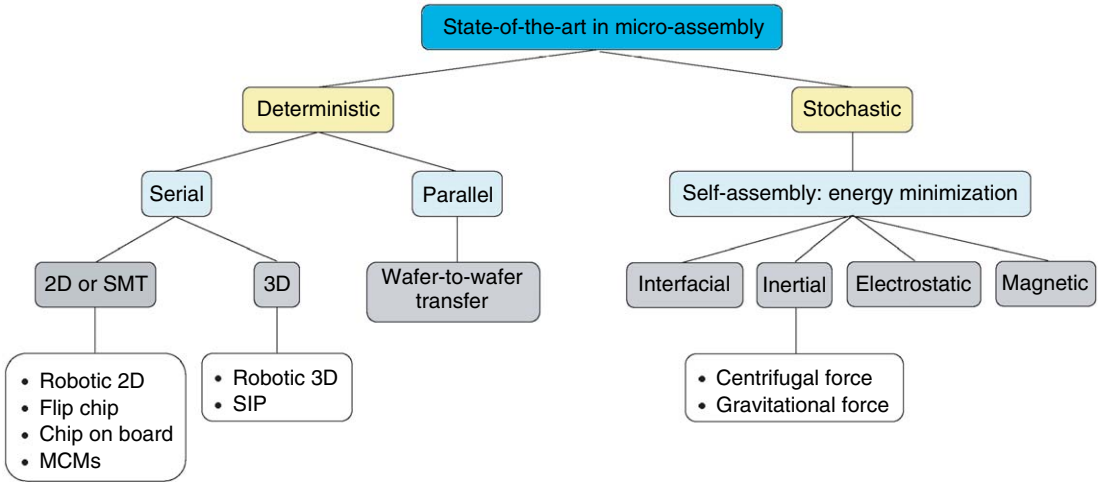

Figure 1 Categories of state-of-the-art microassembly techniques. MCM, multichip module; SIP, system in package.

1.14.2.3 Surface Mount vs. 3D Assembly

Surface mount technology (SMT) was fully established in the 1980s, when circuits became more and more complex so that through-hole component-mounting techniques were no longer economically or technologically feasible. The limitations in conventional printed circuit (PC) board technology motivated circuit design engineers to develop SMT. SMT keeps components and their interconnecting leads on one PC board surface, rather than feeding the component leads through the circuit board. SMT employs a solder to provide electrical and mechanical connections between components and PC boards. Compared with conventional through-hole mounting techniques, SMT possesses many prominent benefits such as reduced component size, increased circuit density, reduced PC board size, reduced weight, increased interconnecting leads density, and improved high-frequency performance. No single electronic assembly technology is perfect for satisfying all circuit design constraints. Current SMT also has some significant limitations such as poor heat dissipation, thermal mismatch, and decreased mechanical bonding strength of solder. SMT has a wide range of applications in packaging IC or microelectromechanical systems (MEMS) components, e.g., chip-on-board (COB) and multichip modules (MCMs).

Robotic assembly is a serial deterministic method widely used in industry to assemble a variety of components. This assembly approach has three major steps:

(1) Feed parts
(2) Pick and place parts
(3) Affix parts in specified position and orientation

During a typical part feeding step, randomly agitated components move through a series of mechanical filters so that finally they show appropriate face and in-plane orientations. Then robotic grippers pick up these components and transfer them to targeted sites to complete the assembly. This is a serial assembly process. Different part feeding mechanisms are required by various types (geometry or material fragility) of components. Zyvex Corporation has constructed small semiautomated robotic systems for microscopic and nanoscopic assemblies (Skidmore *et al.* 2000). Flat silicon microcomponents are a big challenge for part feeding since they are symmetrical except for negligible differences in geometric features on some surfaces, such as interconnecting pads. Depending on the degrees of freedom of the gripper, robotic assemblies can achieve 2D surface mount or 3D assembly.

A system in package (SIP) comprises multiple components integrated into a single package. In a typical SIP, components can be stacked vertically with 3D electrical interconnections; thus SIPs tend to be compact with much less parasitic capacitance and inductance.

1.14.3 Self-Assembly

Self-assembly techniques for component-to-substrate assembly are mainly based on energy minimization (**Figure 2**). A substrate is patterned with an array of energy traps. The types of energy traps include inertial, interfacial, electrostatic, and magnetic energies. On an assembly substrate, agitated

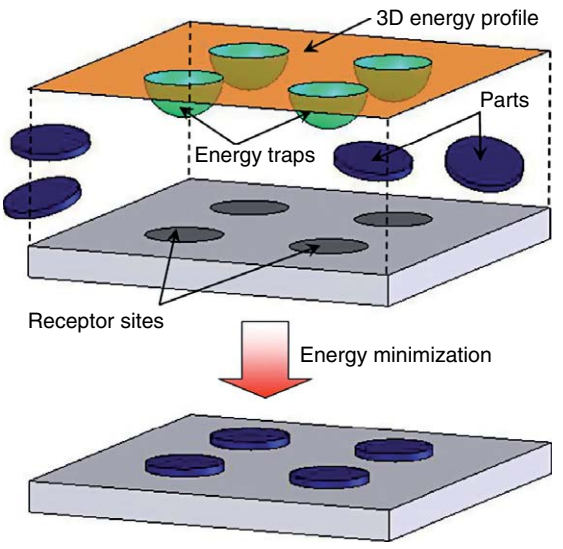

Figure 2 Schematic diagrams showing a typical self-assembly process based on energy minimization: on a substrate, patterned receptor sites are energy traps to attract the surrounding agitated microcomponents.

components are attracted to these energy traps and then permanently attached. Thus, components self-assemble to receptor trap sites on the substrate.

Compared with SMT and robotic pick-and-place assembly methods, self-assembly techniques have several major advantages such as easy handling of components with size in microdomains, fast parallel assembly, and self-alignment with high accuracy.

1.14.3.1 2D-Conformal-3D

A 2D conformal self-assembly process positions microcomponents on a rigid or flexible substrate, and the flat components attach directly to the substrate, i.e., assembled components are conformal with the substrate surface. This is the most common type of self-assembly, since patterning of energy traps on a substrate is straightforward with current microfabrication and surface modification techniques.

Three-dimensional self-assembly of microcomponents poses more challenges to currently available microfabrication techniques than does 2D self-assembly. Some simple 3D microstructures have been constructed by self-assembly processes based on shape matching and interfacial energy minimization (Gracias *et al.* 2000, Zheng *et al.* 2004), but this bottom-up fabrication method for complicated 3D microstructures still requires more breakthrough innovations in microfabrication techniques and assembly mechanisms.

1.14.3.2 Hard-Coded vs. Programmed

Depending on whether the probability for parts to attach to receptor sites can be adjusted by varying conditions, self-assembly processes can be categorized into hard-coded or programmed types. In a hard-coded assembly process, each receptor site has a constant probability to attach a part at any time. In a programmable assembly process, a receptor site has different affinities for a part under different conditions such as assembly environment and surface hydrophobicity, i.e., a receptor site can be turned on (an energy trap) or off (at the same energy level as its background or even higher). A typical usage of programmed self-assembly is to integrate different types of microcomponents on an array of receptor sites patterned by a single fabrication process.

1.14.3.3 Electrostatic and Electromagnetic Self-Assembly

1.14.3.3.1 Electrostatic 2D assembly

Electrostatic 2D assembly is based on the electrostatic attraction of microcomponents, and the electrostatic attraction is due to the polarization of the microcomponents in electrical fields. According to Coulomb's law, electrostatic force is inversely proportional to the square of the distance between charges, and thus it is a short-range interaction. Patterned surface areas with charges or localized electrical fields can be binding sites for microcomponents, and the binding strength increases with surface charge density or electrical field intensity.

Tien *et al.* (1997) exploited electrostatic interactions for direct patterning of 10-μm diameter gold disks on functionalized substrate surfaces. They fabricated the small charged gold disks by electroplating gold into photoresist molds and derivatizing these disks with charged self-assembled monolayers (SAMs), and patterned the planar or curved substrate with surface charges by microcontact printing or photolithography. By agitation, the charged gold disks aggregated on the regions with the opposite charges. Finally, they obtained selective and dense assembly in solutions such as methanol, ethanol, IPA, and dioxane (**Figure 3**).

Cohn *et al.* (1995) demonstrated a self-assembly process with alignment capabilities over electrostatic traps. The experiment was performed in an aqueous environment. The electrostatic traps were fabricated on a silicon substrate: a layer of 2-μm low-temperature oxide (LTO) was first deposited

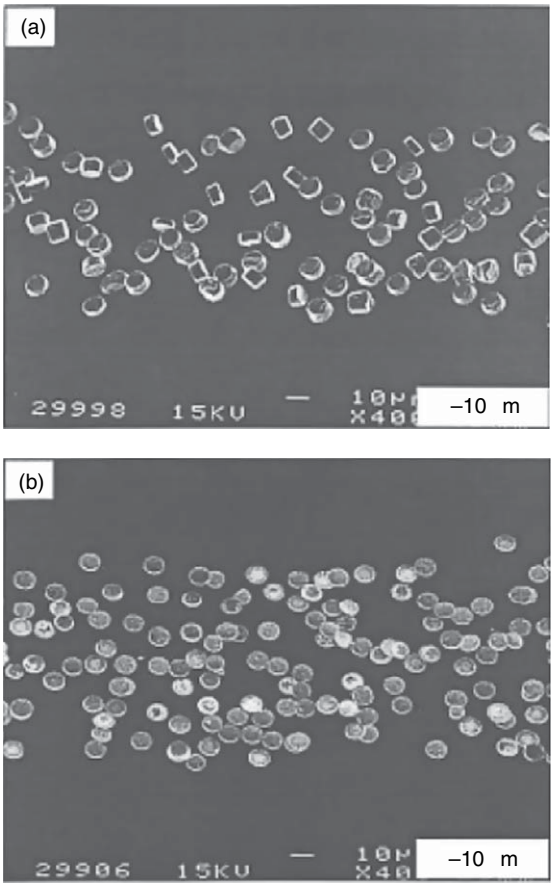

Figure 3 Scanning electron micrographs (SEMs) of PO_3H-terminated gold disks assembled on patterned gold. Gold wafers were patterned with HS-$(CH_2)_{15}$COOH and washed with 1 mM $HS(CH_2)_{11}NMe^{3+}$ and 1% HCl/EtOH. (a) Disks with an aspect ratio near 1:1 did not overlap each other. (b) Disks with an aspect ratio of 1:15 overlapped occasionally. (Photo courtesy: Tien J, Terfort A, Whitesides G M 1997 Microfabrication through electrostatic self-assembly. *Langmuir* **13**, 5349–55.)

as a dielectric layer by using low-pressure chemical vapor deposition (LPCVD), and then a layer of Au was deposited and patterned with an array of apertures (in the size ranges from 2 to 100 μm). The silicon substrate and the Au layer acted as two driving electrodes, which resulted in fringing electric fields from the patterned apertures in the Au layer. If the microcomponents stick to the substrate or to each other, there is no way to distribute or to assemble them to the specified binding sites or to the electrostatic traps on the substrate. They demonstrated a method to avoid such sticking phenomena by levitating the microcomponents a short distance (0–100 μm) above the target electrostatic traps before letting them settle, and thus accurate placement and orientation of the microcomponents with respect to the binding traps became feasible with a relatively low applied field of $\sim 10\,V\,\mu m^{-1}$. Each microcomponent (a SiO_2–*p*-Si–SiO_2 sandwich) had an average dielectric constant of 10, and the assembly liquid environment was hexane with a relatively low permittivity; therefore, microcomponents were easily attracted to the charged electrodes. The levitation of microcomponents was achieved by adding a small amount of a more polar solvent (acetone, with a relatively high dielectric constant of ~20), i.e., acetone shielded the electric field from the microcomponents and prevented contact of microcomponents with the binding sites. When all trap sites were occupied with floating microcomponents, the polar solvent was titrated out to lower the microcomponents to contact the trap sites. Finally, permanent bonding could be accomplished with sintering metals.

Fringing electric fields out of patterned apertures on a substrate can be exploited for assembling microparts in an air environment (Böhringer *et al.* 1998). The experimental setup is shown schematically in **Figure 4**. A glass substrate was coated with a layer of Cr/Au and the Cr/Au was patterned with an array of square holes to expose the glass underneath. The glass substrate was mounted on an aluminum vibratory platform driven by a piezoelectric actuator. Bulk parts were placed on the glass substrate. For effective agitation of these parts (initially parts tended to stick to the substrate and to each other because of the combination of electrostatic interaction and capillary and van der Waals forces), the vibrating frequency was chosen in the 20-kHz range. A DC voltage was applied on the aluminum platform and the Au electrode, and the resulting fringing electric field from the apertures in the upper electrode induced polarization in neutral parts and caused them to be attracted to the apertures. When a part covered an upper electrode aperture, the fringing electric field was significantly reduced, which prevented attraction of more parts to this occupied site. Assembly experiments were performed in both air and low vacuum, and the results indicated that the vibrating energy required to overcome adhesive forces decreased with air pressure, probably due to squeeze film effects (Fearing 1995) and due to the vacuum created between the flat-part bottom surface and the substrate when operated at ultrasonic frequencies.

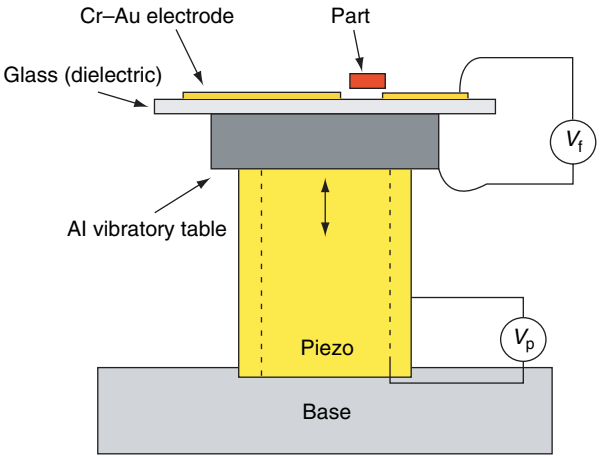

Figure 4 Schematic experimental setup for self-assembly with electrostatic traps: a vibratory table with a gold-covered dielectric is attached to a piezoelectric actuator. The aperture in the upper electrode creates a fringing field that causes polarization in the part. The part is attracted to the aperture. (Source: Böhringer, K F, Goldberg K, Cohn M, Howe R T, Pisano A 1998 Parallel microassembly with electrostatic force fields. *Proc. Int. Conf. Robotics and Automation (ICRA)*, Leuven, Belgium, pp. 1204–11.)

1.14.3.3.2 Toward 3D by triboelectricity

Kaajakari and Lal (2001) demonstrated a method based on triboelectricity for batch assembly of polysilicon hinged structures (**Figure 5**). Triboelectricity on hinged plates and the substrate was achieved by use of ultrasonic vibrations generated with an attached piezoelectric actuator to vibrate polysilicon plates on silicon nitride or polysilicon substrate surfaces. Such contact electrification charges resulted in hinged flaps being stabilized vertically on the substrate. Furthermore, they also observed a memory effect in which assembly occurred even without further ultrasonic vibration after the initial ultrasonic assembly.

1.14.3.3.3 Magnetic assembly

Magnetic force is a type of short-range interaction, and it can be utilized to attach microcomponents to magnetized sites on a substrate. Perkins *et al.* (2002) developed a new assembly approach called magnetically assisted statistical assembly (MASA): the compound semiconductor device heterostructures, 'nanopills' covered with a soft magnetic material, were trapped in the shallow recesses patterned into the surface of an integrated circuit wafer, and the short-range magnetic attractive forces kept the parts in the recesses (**Figure 6**). The 'nanopills' were agitated by liquid flow. **Figure 7** shows the

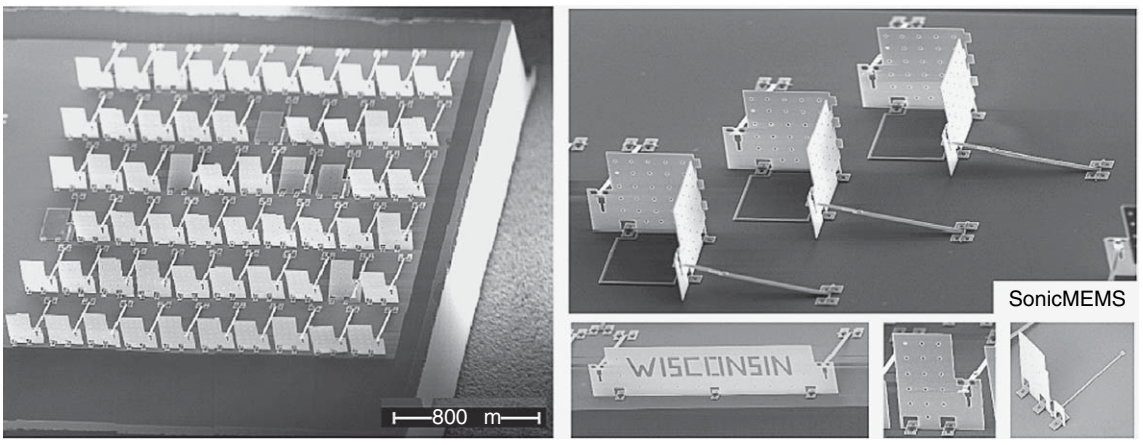

Figure 5 Examples of devices assembled with triboelectricity: array of assembled micromachined flaps, polysilicon corner cube reflectors (200 μm × 200 μm) with lock-in structure, and micro-art Wisconsin banner. Lower right shows a flap with a retaining spring latch anchored to the substrate. relationship between the magnetic force per unit area and the separation between a part's permalloy surface and the magnetized Co–Pt stripes at the bottom of a recess.

Magnetic fields can also be exploited to construct 3D microstructures. Iwase *et al.* demonstrated a sequential batch assembly method (Iwase and Shimoyama 2005) based on the magnetic field-assisted self-assembly (**Figure 8**): an external magnetic field perpendicular to the substrate was used to lift the hinged ferromagnetic microstructures, and the magnetic field was increased gradually so that the plate with softer hinges was lifted first. The softness of a plate's hinge can be controlled by adjusting the length and the number of hinge beams.

1.14.3.4 Shape Matching

1.14.3.4.1 Fluidic self-assembly

Fluidic self-assembly relies on shape matching between microcomponents and recessed receptor sites (Yeh and Smith 1994). Bulk microcomponents are agitated by liquid flow until they fall into receptor holes. GaAs vertical cavity surface-emitting laser (VCSEL) components were demonstrated to be integrated on a silicon substrate. The silicon host substrate was patterned with etched holes of trapezoidal shape, and the GaAs light-emitting diode (LED) components were also of the same trapezoidal shape. Carrier fluid containing the GaAs microcomponents was dispensed over the host silicon substrate. Because of the trapezoidal shape design, the GaAs blocks fit preferentially into the holes in the desired face orientation. Random mechanical vibration was performed to enable the precise positioning of a large number of microparts in the recessed receptor sites. More than 90% of the etched holes on the substrate were correctly filled with the GaAs blocks before the carrier fluid evaporated.

Alien Technology Corporation has commercialized this fluidic self-assembly technique (**Figure 9**). Fluidic self-assembly can work on either rigid (glass or plastic) or flexible (polyester, polyimide, polycarbonate, etc.) substrates. They have been using fully automated in-line reel-to-reel (web) processing on a continuous flexible substrate. Fluidic self-assembly and web processing offer many advantages over conventional processing on rigid substrates, such as those given below:

(1) Reduced manufacturing facility investment
(2) Reduced material and manufacturing costs
(3) Increased manufacturing throughput

Stauth *et al.* also used a fluidic self-assembly technique to integrate silicon microcomponents on a plastic substrate (Stauth and Parviz 2005). Receptor

Micro Electromechanical Systems*, pp. 588–91.)

wells on the plastic substrate were formed with a lithographically patterned thick SU8. At the bottom of these receptor wells, electrical terminals were coated with low-temperature melting solder. Interconnect pads on silicon microcomponents are patterned Au areas with high solder-wetting capability. In a hot and acidic aqueous environment, microcomponents slid on the tilted substrate and fell into receptor wells, and then the microcomponents were anchored when their interconnect Au pads contacted melting solder droplets in the wells.

1.14.3.4.2 Dry self-assembly

Shape matching can also take place in a dry assembly environment such as air or vacuum. Dry assembly environments avoid potential physical damage to or chemical erosion of microcomponents. Fragile structures on a microcomponent, for example, cantilever beams, can be easily immobilized or even broken by surface tension forces of liquid residue from a wet assembly environment. Dry self-assembly techniques based on shape matching are discussed in Section 1.14.3.7.

1.14.3.5 Centrifugal Force-Driven Self-Assembly and toward 3D

For microscale components, inertial forces, for example, gravity, are usually neglected when compared with surface forces such as surface tension and electrostatic forces. As an inertial force, a centrifugal force can be increased to overcome surface forces because it is proportional to the square of the rotating speed.

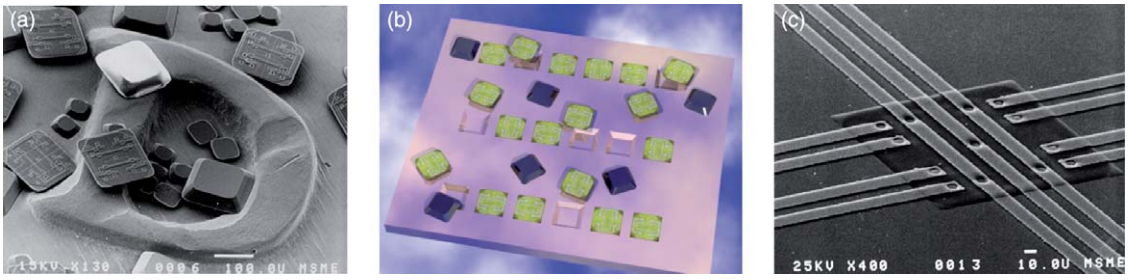

Figure 9 Fluidic self-assembly technique commercialized by Alien Technology: (a) microphotograph of individual nanoblocks on the surface of a dime; (b) artist's rendition of nanoblocks falling into substrate holes; (c) microphotograph of a passivated metallized nanoblock. (Photo courtesy: Lai K W C, Hui A P, Li W J 2002 Non-contact batch micro-assembly by centrifugal force. *Proc. IEEE Conf. Micro Electro Mechanical System*, pp. 184–7.)

Lai *et al.* (2002) demonstrated noncontact batch assembly of 3D microstructures by centrifugal force. Hinged microstructures fabricated in a multi-user MEMS process (MUMPs) were assembled with the help of latching features by centrifugal forces (**Figure 10**).

1.14.3.6 Capillary Self-Assembly

1.14.3.6.1 Toward 3D with solder/photoresist reflow

In microdomains, surface tension forces dominate over gravitational forces, and they have been explored and exploited by some researchers to lift hinged plates for constructing 3D structures (Syms *et al.* 2003). To achieve this type of 3D assembly, a thick layer of solder or photoresist is usually deposited and patterned at the joint of hinged structures. When the solder or photoresist is reflown, it changes into a spherical shape to minimize interfacial energies (a spherical shape has the minimum surface-to-volume ratio), and thus the hinged plate attached to the reflowed droplet rotates. With appropriate latching features, some complex 3D microstructures can be constructed (**Figure 11**).

Yang *et al.* (2006) developed a method to achieve local assembly by reflowing solder with magnetic induction welding. The heating temperature depends on the area of the magnetic film underneath the solder, and thus different heating temperature regions on a substrate can be photolithographically defined (the magnetic field is assumed to be uniform across the substrate). They demonstrated this technique by separating Ni plates from Ti plates (**Figure 12**).

Zheng *et al.* (2004) used a low-temperature melting solder to construct functional circuits that consisted of 3D structures including a LED component, a chip carrier with solder bumps, and an encapsulation body with solder bumps. The assembly sequence was as follows (**Figure 13**):

(1) LED components and chip carrier components were put in a hot and acidic liquid environment, where tumbling agitation caused each LED component to attach to a chip carrier component. Finally, the attached components with the solder bonding were sorted out.

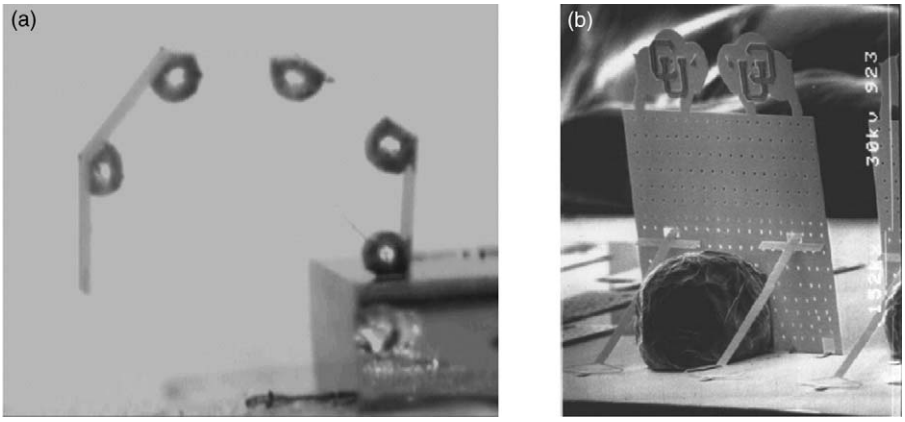

Figure 11 Optical graphs of some 3D self-assembled structures by reflowed solder: (a) 5-bar multiple link assembly. (2) The attached components from the previous step were placed in a hot and acidic liquid environment together with encapsulation components for another batch assembly.

1.14.3.6.2 Parallel 2D assembly

In capillary-driven 2D self-assembly processes, agitated flat microcomponents contact and attach to adhesive liquid droplets on receptor sites, and then self-align to receptor sites to minimize interfacial energies. Depending on the assembly environment, capillary-driven self-assembly processes can be classified into two types: in an aqueous environment and in an air environment. Different adhesive liquids require different hydrophilicity or surface coatings for the receptor sites. For an acrylate-based adhesive liquid, receptor sites should be hydrophobic for aqueous assembly environments and hydrophilic for air assembly environments (**Figure 14**). For low-temperature melting solder, receptor sites should be thin film metals with good solder-wetting capability, e.g., copper and gold.

Low-temperature melting solder can be used to assemble flat microcomponents with both electrical and mechanical connections on a substrate. Jacobs *et al.* (2002) developed a self-assembly process to mount LED arrays on flexible cylindrical templates by using a low-temperature melting solder. The assembly template was patterned with copper squares, and a simple dip coating process left melting solder on these copper squares since copper has very good wetting capability for solder. The dip coating process was performed in an acidic aqueous

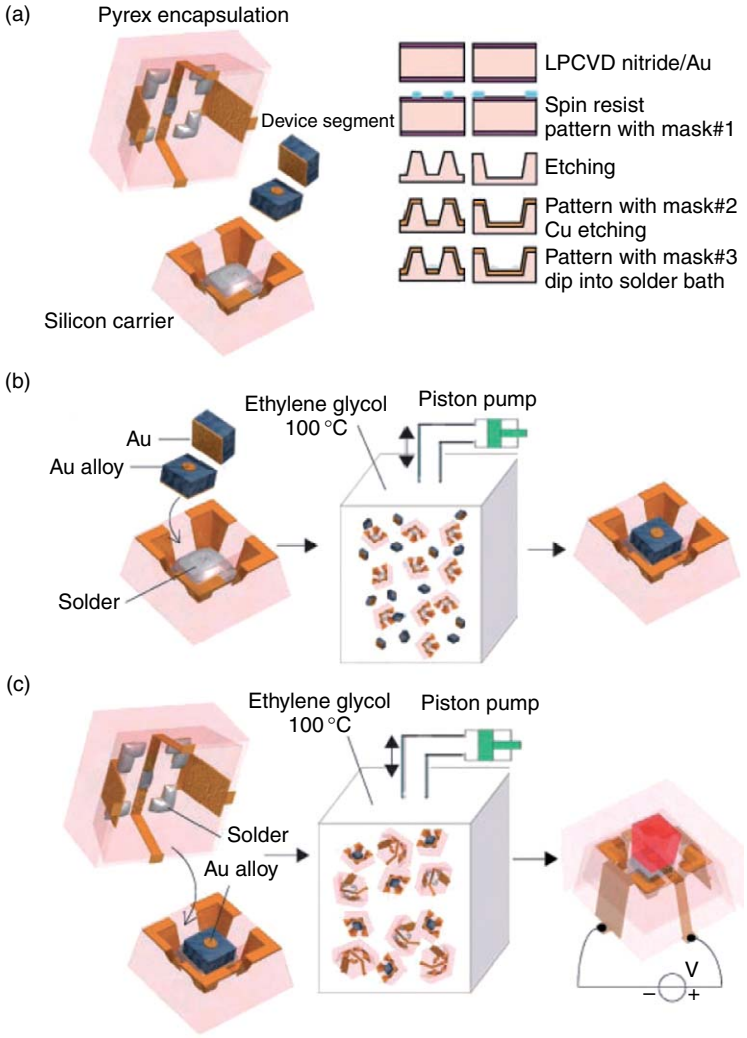

Figure 13 Schematic overview of the solder-directed 3D assembly of LED components. (a) Layouts of carrier, device, and encapsulation components fabricated by surface micromachining and etching. The illustrated device segment is a LED that has two contacts: a small circular anode on the front, and a large square cathode covering the back. The silicon carrier has a solder-coated area in a tapered opening to host a single semiconductor device segment. The encapsulation unit has five solder-coated copper areas inside a tapered opening to connect to corresponding contact pads on the device and the carrier. (b) Chip-on-carrier assembly and (c) chip encapsulation in an ethylene glycol solution at 100 °C, where the solder is melted. The components, agitated by using a piston pump, self-assemble and form a 3D circuit path between device layers that allows testing in a surface mount device configuration. (Photo courtesy: Zheng W, Buhlmann P, Jacobs H O 2004 Sequential shape-and-solder-directed self-assembly of functional microsystems. *Proc. Natl. Acad. Sci. USA* **101**, 12814–17.)

environment to avoid oxidation of the melting solder. Since a LED segment has electrical polarity, i.e., it can be lit only with an appropriate positive DC bias, two electrodes on either side of each LED segment should be distinguished with some pattern: the gold covered the whole bottom surface and 1/9th of the top surface. Hundreds of LED components and a flexible assembly template were placed inside a vial filled with water at a temperature above the melting point of the solder. The LED components were tumbled inside the vial, and then they were attracted, aligned, and bonded to the receptor sites on the template by the surface tension forces of the melting solder. By controlling the agitation intensity, only the bottom surfaces 100% covered gold instead of the top surface with 1/9 covered gold were bonded to solder droplets because the adhesion is roughly proportional to the gold-covering area on the LED segments. Therefore, the LED components self-assembled with unique face orientations. Gold pads

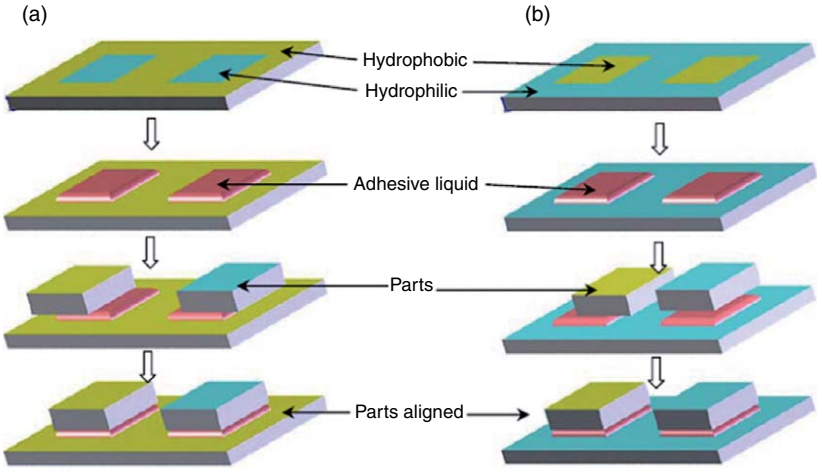

Figure 14 Schematic process overviews of capillary-driven self-assembly of flat microcomponents: (a) in an aqueous environment and (b) in an air environment.

on the top surfaces of the bonded LED components were coated with melting solder by another dip coating. As a final assembly step, a flexible transparent film patterned with electrical circuits and solder bumps was roughly and manually aligned to the assembly template, i.e., a wafer-level flip chip bonding process, and the film was aligned with high accuracy to the assembly template by surface tension of the melting solder. Thus, the electrical connections to the top electrodes of the LED segments were established. Assembly was successful by testing with a low defect rate of ~2% (**Figure 15**).

Srinivasan *et al.* (2001) developed and demonstrated another fluidic self-assembly technique. They patterned a substrate with an array of hydrophobic thiolated Au binding sites. When the substrate was inserted into water through a film of hydrophobic adhesive floating on the water surface, the adhesive covered only the hydrophobic binding sites. Then they introduced microparts fabricated from silicon-on-insulator wafers through a pipette to the substrate in the water. When the hydrophobic pattern on the microparts came in contact with the adhesive, shape matching occurred spontaneously due to interfacial energy minimization. Finally, the adhesive was polymerized by heat or UV light depending on the type of the adhesive, so that the bonding became permanent. Binding sites of shapes with in-plane rotational symmetries such as squares gave alignment yields up to 100% (**Figure 16(a)**). The translational and rotational misalignments were <0.2 μm and within ~0.3°, respectively. Binding sites without in-plane rotational symmetries (aimed at a

(Source: Srinivasan U, Liepmann D, Howe R T 2001 Microstructure to substrate self-assembly using capillary forces. *J. Microelectromech. Syst.* **10**, 17–24.)

uniquely oriented alignment) such as semicircles and commas gave alignment yields of approximately 30–40% (**Figure 16(b)**).

To achieve self-assembly with unique in-plane orientations, Liang *et al.* (2004) designed and demonstrated a capillary-driven self-assembly process with special geometrical designs for binding sites. Both the parts and the binding sites are of an offset ring shape, which provides a unique global interfacial energy minimum (**Figure 17**): the energy calculation is based on the assumption that the interfacial energy has an approximately linear relationship with the overlap area between a part and the binding site (Böhringer *et al.* 2001).

Capillary-driven self-assembly can also proceed in an air environment as long as the receptor sites are coated with liquid droplets that act as a medium to attach flat microcomponents. Fang *et al.* (2006) have demonstrated a capillary-driven self-assembly method to surface mount PZT (lead zirconate titanate) actuators for microfluidic devices. The hydrophilic receptor sites are precisely recessed wells with an opening smaller than the PZT actuators, and the bonding face of each PZT actuator has a hydrophilic area of identical size at the center as the recess's opening. All the surfaces except the receptor wells and the bonding areas on the PZT actuators are hydrophobic. A simple dip coating process left adhesive droplets only in receptor wells. When PZT actuators were attached to these adhesive droplets, they self-aligned to minimize interfacial energies. Then, the aligned PZT actuators were pressed down such that their rims touched the substrate with excess adhesive squeezed out, and the electrically insulated adhesive was polymerized by heating to form permanent bonds. Electrical and mechanical connections were established at the rim and at the center, respectively, of the PZT actuators.

To introduce bulk microcomponents to receptor sites during dry assembly, Liang *et al.* (2005) developed a method using an agitated diaphragm to bounce microcomponents until some were caught by water droplets on the receptor sites on the downward-facing assembly substrate (**Figure 18**). This process demonstrated fast assembly (<30 s) and high yields (>90%), and fast recycling of redundant components. The glass substrate was coated with hydrophobic thiolated Au, which was patterned with an array of openings (exposure of the glass substrate). The exposed glass receptor sites were hydrophilic and covered with water droplets after a dip coating process. The capillary-driven alignment was a subsecond process (**Figure 19**).

1.14.3.6.3 Multibatch assembly

Xiong *et al.* demonstrated a method for controlled multibatch self-assembly, based on the fluidic self-assembly technique developed by Srinivasan *et al.*, of microparts by capillary force. They patterned an

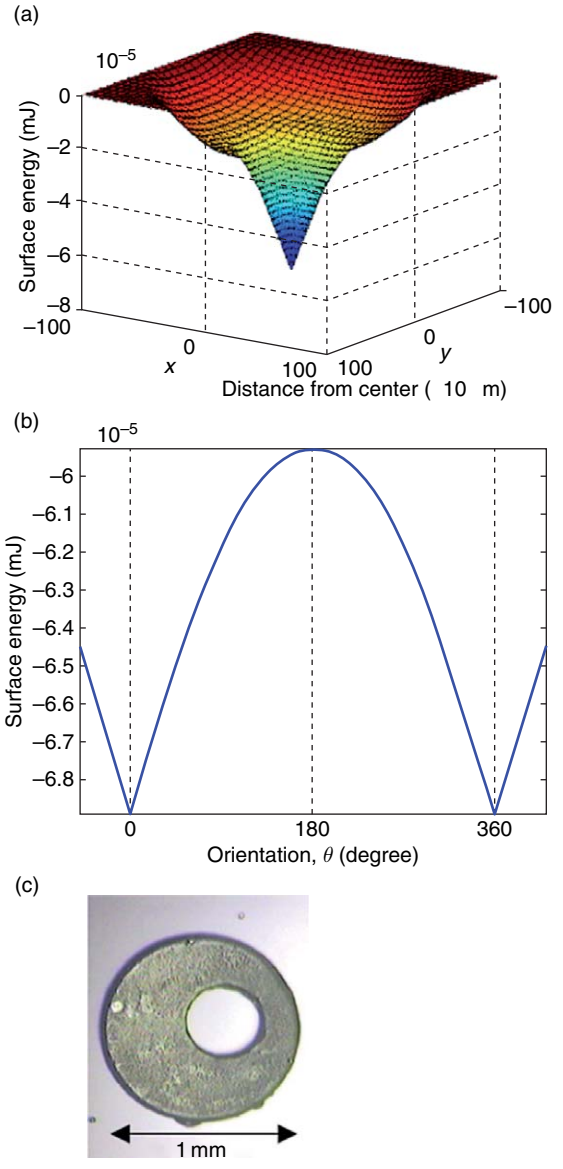

Figure 17 Energy profiles for an offset ring design: (a) the part with the correct in-plane orientation moves in a translational way across the binding site; (b) the part rotates about its center, which coincides with the binding site's center; and (c) an experimental result shows exact alignment of the silicon part over the thiolated gold binding site in water. (Photo courtesy: Liang S, Xiong X, Böhringer K F 2004 Towards optimal designs for self-alignment in surface-tension driven micro-assembly. *Proc. IEEE Conf. Micro Electro Mechanical Systems (MEMS)*, Maastricht, The Netherlands, pp. 9–12.)

oxidized silicon substrate with an array of gold binding sites, and these hydrophilic gold binding sites became hydrophobic after adsorbing a SAM. To be active, i.e., to adsorb an adhesive lubricant droplet for later

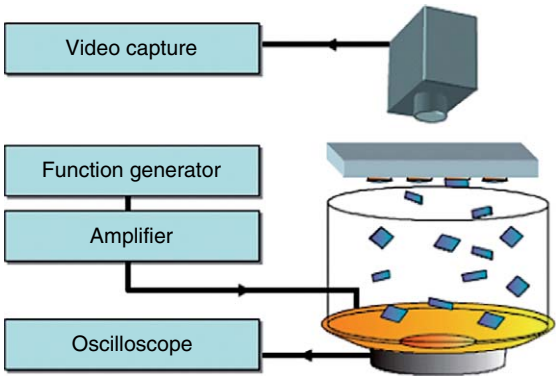

Figure 18 Schematic experimental setup: a sinusoidal wave signal from a function generator drives the speaker diaphragm to bounce microcomponents up until they make contact with the binding sites of the downward-facing assembly substrate. anchoring of parts, a binding site should be hydrophobic. They demonstrated an electrochemical method to desorb the SAM from the gold binding sites: an appropriate electrochemical potential was applied between the gold binding sites and an aqueous environment. Before the first batch assembly, some binding sites were selectively deactivated by SAM desorption, to be reactivated for the next batch assembly. An array of commercial LED components was assembled on the substrate with the heat polymerizable adhesive, and the electrical connections between the substrate and the LED components were established by solder electroplating (**Figure 20**).

1.14.3.7 Multistage Self-Assembly

1.14.3.7.1 Semidry, uniquely orienting, self-organizing parallel assembly

Fang and Böhringer have developed a semi-DUO-SPASS (dry, uniquely orienting, self-organizing parallel assembly) process for batch assembly of flat microcomponents. This semidry assembly process, based on the assembly strategy shown in **Figure 21**, includes two wet process steps followed by two dry process steps.

The parts used in demonstration were dummy flat silicon components with dimensions of 2 mm × 2 mm × 0.5 mm. Each part had a circular peg (ϕ 0.3 mm) located offset from the center of mass. The part surface opposite to the peg was the only hydrophobic face coated with thiolated gold (**Figure 22(a)**). Correspondingly, each

receptor site on an assembly substrate had a circular well with a large diameter for easy adoption of a peg, but the well's diameter should have an upper limit to ensure that one well adopts exactly one peg (**Figure 22(b)**).

The first wet process step is to uniquely face-orient bulk silicon parts. An agitated water surface was exploited to selectively float silicon components with only their hydrophobic faces upward. For floating parts, the other two poses, horizontal with the hydrophilic face upward and vertical, are not stable due to surface tension forces. It was observed that the uniquely face-oriented floating parts stayed together in a single layer after agitation was turned off for several minutes, and this monolayer assembly phenomenon is driven by potential energy minimization.

A hydrophobic carrier wafer was employed to transfer the uniquely face-oriented floating parts. When the hydrophobic carrier wafer entered water vertically, the water surface curved downward near the hydrophobic surface to approach a contact angle $>90^\circ$. Such downward-curving surface resulted in a water valley near the carrier wafer surface, and this valley attracted the nearby floating

Micro Electro Mechanical Systems*, Miami, FL, USA, pp. 12–15.)

parts to minimize their potential energies (**Figure 23(a)**). As the carrier wafer continued to enter water, floating parts started to adhere to the carrier wafer and be submerged in water. The adhering of parts is due to significant capillary forces introduced by trapped air bubbles between the parts and the carrier wafer (**Figure 24**). After all the floating parts adhered to the carrier wafer, the carrier wafer was withdrawn from water, and more than ~98% parts stayed attached. The final step to transfer these parts was to bring the carrier wafer approximately parallel to an alignment template on a 120 °C hotplate (**Figure 23(b)**), and these parts were then released to touch the alignment template with their pegs when water evaporated.

The next process step for the assembly sequence is to distribute the palletized silicon parts to an array of receptor sites on the alignment template. Orbital shaking was utilized to drive the parts to move until their pegs were trapped to receptor sites. Since orbital shaking provides a centrifugal force field, which is uniform in both magnitude and direction, and since the force direction is rotating in phase with the orbital shaker's rotating arms, parts are randomly moving locally instead of unidirectionally. Therefore, each unoccupied trap has an equal chance to have some parts to pass by, i.e., have a chance to trap the moving parts. Our trapping experiments with varying part redundancies gave yield–time curves shown in **Figure 25**.

The last process step was achieved by gravitationally driven self-alignment of anchored parts. When the alignment template was tilted in an appropriate orientation, gravitational forces drove the parts to rotate about their anchoring pegs to approach the equilibrium position with the lowest potential energies as a simple pendulum does (**Figure 26(a)** and **26(b)**). Kinetic frictional forces became smaller when the slope of the alignment template increased. Some parts can get stuck due to dust contamination or adsorbed moisture from the environment. A slight agitation at the edge of the alignment template (the impacting force must be in the plane of the alignment template) can break the sticking and free the parts to rotate. If the tilting orientation of the alignment template is precisely controlled, high accuracy of alignment can be achieved. Without good control of

Micro Electro Mechanical Systems*, Miami, FL, USA, pp. 12–15.)

the template tilting, an additional wet fine alignment step was used: steam condensate was introduced into the parts and the template where steam formed film-wise and droplet-wise condensation on hydrophilic and hydrophobic surface areas, respectively. The receptor sites were hydrophilic with a hydrophobic background. The capillary gaps underneath the parts attracted steam condensation, so that parts self-aligned

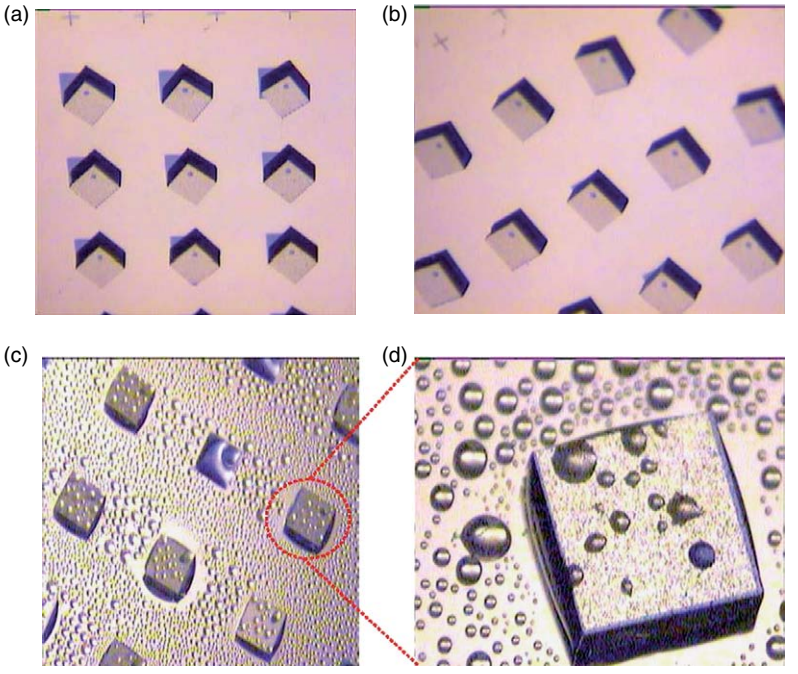

Figure 26 Uniquely aligning of 2-mm square silicon parts: (a) parts roughly aligned by gravity on a tilted alignment template; (b) parts roughly aligned to the receptor sites on an appropriately tilted alignment template; (c) misalignment corrected by capillary-driven self-alignment when water steam is introduced to condense on the alignment template and parts surface; and (d) a zoom view of a part with water condensate. Micro Electro Mechanical Systems*, Miami, FL, USA, pp. 12–15.)

to receptor sites by minimizing interfacial energies (**Figure 26(c)** and **26(d)**). After the parts were self-aligned, the water was evaporated by slow heating (rapid heating can cause nonuniform capillary stress on parts and can result in misalignment) to leave a dry aligned array of parts on the alignment template (**Figure 27**). At this stage, the aligned parts are ready to be transferred to a chip carrier template (CCT) via wafer-level flip chip bonding, and then dicing separates these simultaneously assembled or packaged devices.

1.14.3.7.2 Dry, uniquely orienting, self-organizing parallel assembly

To avoid aqueous assembly environments for microcomponents with released microstructures that can be easily immobilized or even broken by surface tension forces, Fang and Böhringer (2006b) developed a completely dry assembly process called DUO-SPASS. A schematic overview of this assembly process is shown in **Figure 28**. The main mechanism for this dry assembly is two-stage shape recognition: each part has one tall circular peg (CP) and one low cross peg (XP); each receptor site has correspondingly a circular trap (CT) and a cross trap (XT); the first stage assembly is achieved by anchoring a CP into a CT; the second stage assembly fixes the part in a specific in-plane orientation when its XP falls into an XT.

The pegs can be fabricated with either an additive or a subtractive method. A possible additive pattern

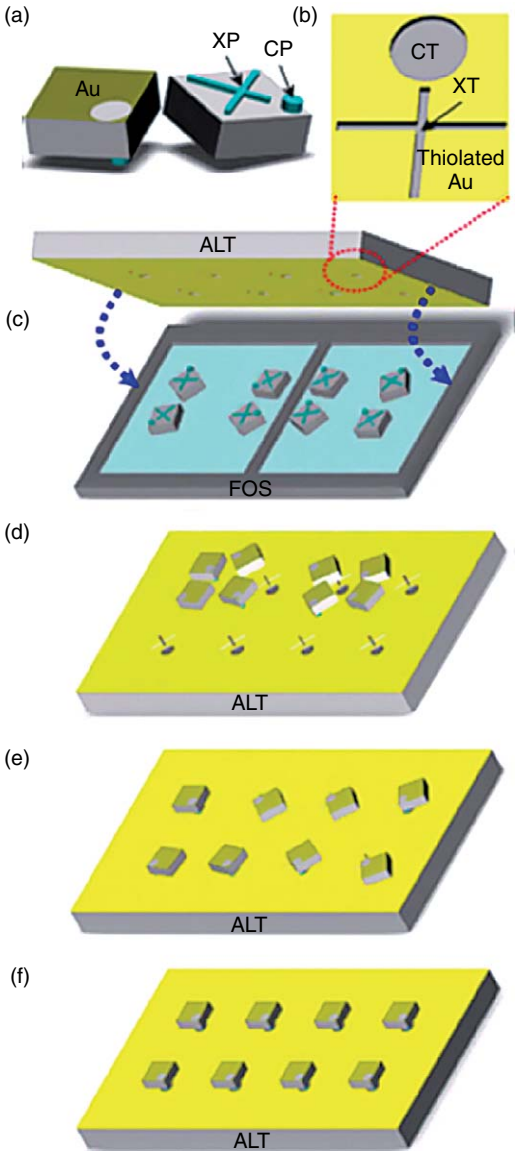

Figure 28 Schematic overview of the dry process to parallel assemble square microparts: (a) top and bottom views of a silicon part (the bottom face has a CP and an XP, and the CP has twice the height of the XP; the top face is coated with gold, and the opening in the gold layer marks the position of the CP); (b) trenches of a receptor site on the alignment template; (c) bulk parts face-oriented on an orbital shaken face-orienting substrate and then sandwiched by adding an alignment template; (d) parts palletized to the alignment template with their peg sides facing downward; (e) parts one-to-one anchored to receptor sites by orbital shaking: the CPs fall into the CTs (the first shape recognition); (f) parts rotated by orbital shaking introduce torques until their XPs fall into the XTs (the second shape recognition). (Source: Fang J, Böhringer K F 2006 Wafer-level packaging based on uniquely orienting self-assembly (the DUO-SPASS processes). *ASME/IEEE J. Microelectromech. Syst.* **15**, 531–40.)

method consists of double-layer SU8 casting (**Figure 29**), and a subtractive method is deep reactive ion etching (DRIE). The traps are fabricated with DRIE, with the depth of the traps being greater than that of the circular peg for stable anchoring.

A unique face orientation of bulk parts based on an asymmetry in dynamic stability was achieved. On an orbitally shaken plate, it is much more stable to rest bulk parts on their flat surfaces than on the pegs, and thus bulk parts are uniquely face-oriented to point upward with their pegs. Uniquely face-oriented parts are then transferred to an alignment template by the method shown in **Figure 28(c)** and **28(d)**.

Centrifugal forces generated by orbital shaking drive the parts to move until they are anchored to the circular traps (the first shape recognition). Since the anchored circular peg is located offset from the center of mass, a torque is exerted on each anchored part. The torque rotates each part until the second shape recognition is achieved: the cross peg falls into a cross trap. During this two-stage shape recognition, parts should move without flipping over, which can be achieved by the following:

(1) Lower orbital shaking speeds (~110 rpm for 1-mm square silicon parts)
(2) Thiolated gold coating on the alignment template for lower sliding friction
(3) An ultrasonic vibrating stage attached to the alignment template to reduce sticking effects and sliding friction.

Assembly results for 1-mm square silicon dummy parts are shown in **Figure 30**.

1.14.3.7.3 Parallel component-to-substrate assembly with controlled poses

Most of the reported parallel microassembly techniques had flat microcomponents assembled in only one pose: horizontal mounting on a substrate with the largest possible footprint. In some special cases, such as radio frequency MEMS (with MEMS = microelectromechanical system) and optical MEMS components, vertical mounting can benefit in the following ways:

(1) Less footprints and higher spatial density
(2) Functional surfaces (assuming to be the large flat surfaces) perpendicular to the assembly substrate.

Especially for VCSEL components, vertical mounting can direct a laser beam parallel to the substrate,

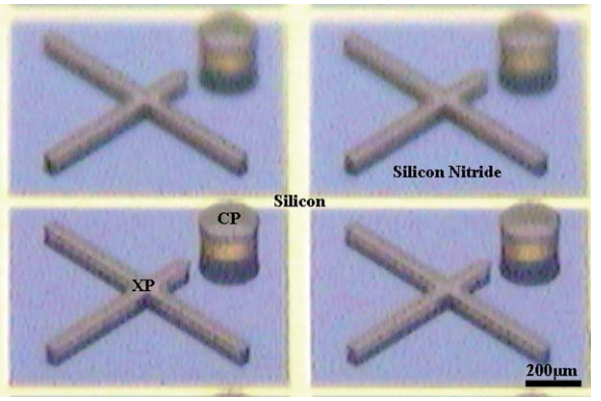

Figure 29 An optical microscope image of a 2 × 2 section of an array with SU8-2025 pegs on a 3″ silicon substrate, before dicing into individual parts. (Source: Fang J, Böhringer K F 2006 Wafer-level packaging based on uniquely orienting self-assembly (the DUO-SPASS processes). *ASME/IEEE J. Microelectromech. Syst.* **15**, 531–40.)

which enables the construction of free-space micro-optical systems and optical detectors for lab-on-chip microsystems.

A strategy to mount flat microcomponents parallelly on a substrate with either vertical or horizontal poses is shown schematically in **Figure 31**. Only a vertical pose is allowed for trapped components in the apertures due to geometrical constraints (**Figure 31(a)**). The surface tension of water is exploited to transfer the trapped vertically standing components onto a palletizing plate having an array of water-covered receptor sites (**Figure 31(b)** and **31(d)**). The transfer process leaves components vertically attached to the palletizing plate, i.e., components are assembled with vertical poses.

Assembly with a horizontal pose for a flat-edge component can be achieved by surface tension torques. The component has one hydrophobic surface, and the opposite surface is hydrophilic. After attaching to a water droplet, the component has more water on its hydrophilic face than does the other faces. The water droplets on the palletizing plate are formed by dip coating, and thus their volumes are limited by the dynamic contact angle of water and the receptor site area. For a 790 μm × 790 μm × 330 μm silicon component, the volume of a dip-coated water droplet cannot introduce enough surface tension torque on the hydrophilic surface to lay down the component. Steam condensation can introduce more water to increase the surface tension torque on the hydrophilic surface, and then the component will lie down on its hydrophilic surface as shown in **Figure 31(d)**. Optical images of an assembly process are shown in **Figure 32**.

1.14.4 Theoretical Aspects of Self-Assembly

The purpose of modeling, as discussed in this section, is twofold:

(1) To develop a theoretical understanding of the physical processes that are essential to self-assembly.
(2) To develop design tools that can help us to optimize engineered self-assembly processes and to establish the theoretical and practical bounds on their performance. The model presented here is very general. It simply assumes the existence of reaction rate constants that specify the speed at which components organize into aggregate structures, and assumes that this speed is proportional to the number of available parts and/or binding sites. Thus, it is applicable to all self-assembly approaches described in this review. However, the rate constants are highly dependent on the specific technique chosen, and they vary significantly with particular system parameters such as, for example, materials properties and scale of the components. Determining these rate constants can be achieved empirically by performing systematic sets of experiments. Alternatively, they can be derived from first principles; because of the complex interplay between the numerous effects that may influence a typical self-assembly process, such an *ab initio* approach remains a challenging task.

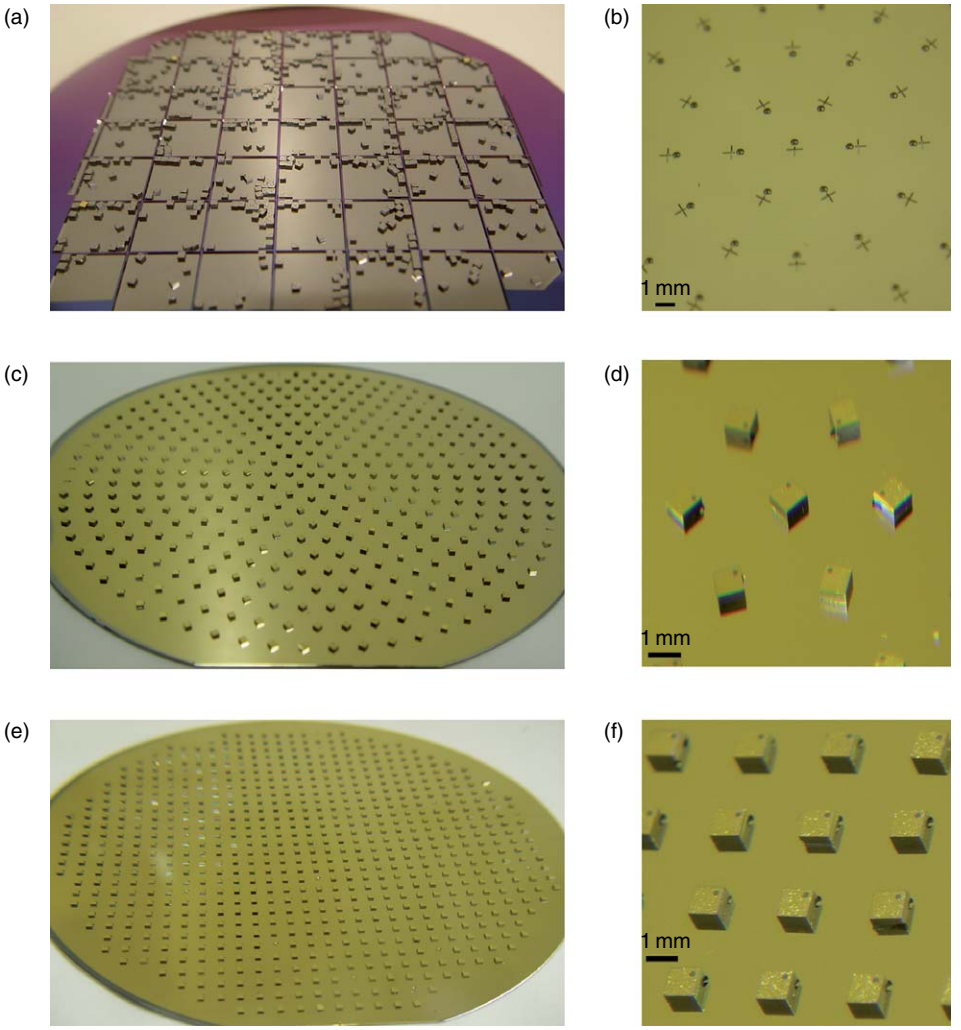

Figure 30 Optical photographs of templates and assembly results: (a) after 1 min of orbital shaking, almost all parts come to rest on their flat faces on the ϕ100-mm face-orienting substrate; (b) a partial view of an alignment template with a polar array of receptor sites; (c) 388 silicon parts assembled on the ϕ100-mm alignment template with a polar array of 397 receptor sites; (d) zoom-in view of the center of the alignment template; (e) 710 silicon parts assembled on the ϕ100-mm alignment template with an orthogonal array of 720 receptor sites; (f) zoom-in view of a 3×3 section of the array of receptor sites. 1.14.4.1 Modeling

1.14.4.1.1 Parallels to chemical kinetics

A self-assembly process is, in principle, very similar to a chemical reaction. Typically, a large but finite number of reactants are available to interact and form bonds with each other. In chemistry, these reactants are atoms or molecules; in microscale self-assembly, they are, for example, silicon chips or hydrophobic binding sites. In either case, the reaction is of a stochastic nature and driven by energy minimization; however, the energy minimization for a microscale self-assembly relies on a wide range of possible sources, as described in Section 1.14.3. The equivalent of temperature is usually provided by some kind of mechanical agitation, such as the orbital shaker in the DUO-SPASS process described in Sections 1.14.3.7.1 and 1.14.3.7.2. Hosokawa *et al.* (1994) illustrated this connection to chemical kinetics with assemblies of tiles with moving permanent magnets that provided the binding force. A more detailed investigation followed in Cohn's (1997) Ph.D. thesis.

Whether or not a reaction takes place depends not only on the energy difference between the

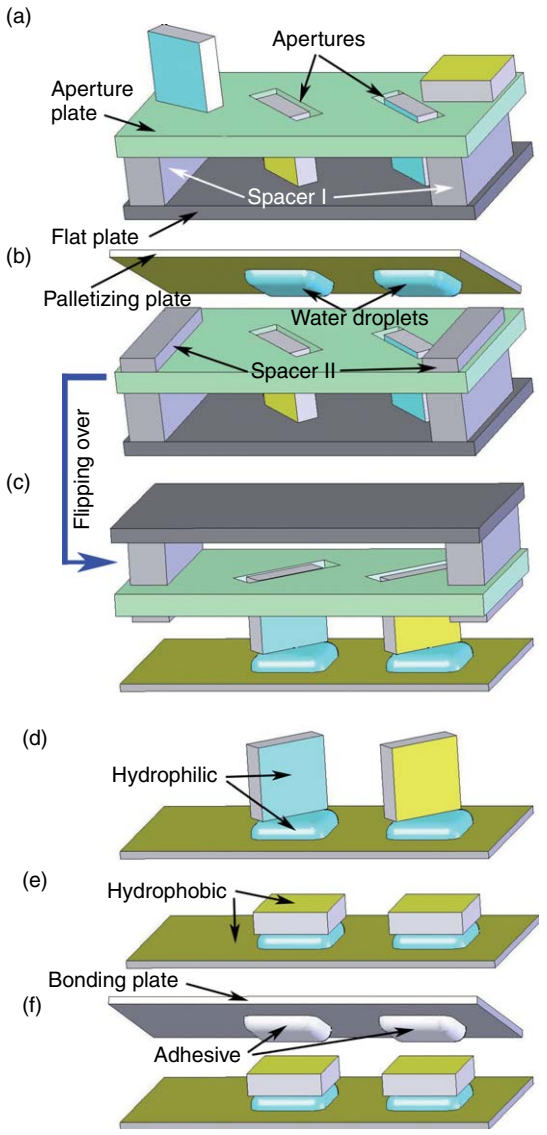

Figure 31 Schematic overview of the assembly process: (a) bulk parts fall into apertures vertically; (b) a palletizing plate carrying water droplets is aligned with the aperture plate; (c) the plates are flipped over to transfer parts on water droplets; (d) parts stand on receptor sites; (e) parts rotate to adhere to the palletizing plate with their hydrophilic oxide faces; (f) parts are permanently bonded to a bonding plate via wafer-level flip chip bonding. (Source: Fang J, Böhringer K F 2006 Parallel micro component-to-substrate assembly with controlled poses and high surface coverage. *IOP J. Micromech. Microeng.* **16**, 721–30.)

unassembled and the assembled states, but also on the activation energy and the overall temperature of the system. Stiction between parts and substrates is a typical example of an energy barrier that has to be overcome either with careful engineering of the self-assembly system (e.g., nonstick hydrophobic surfaces and low humidity conditions) or with activation energy (e.g., vibration). This activation energy can be understood as the temperature of the system, and agitation with a piezoactuator or an orbital shaker is the analog of Brownian motion.

Consider the semi-DUO-SPASS self-assembly system described in Section 1.14.3.7.1 as an example. Here, gravity provides the potential energy difference that causes the parts to assemble in the cavities. If we have n binding sites and rn parts ($r \geq 1$ is the

part redundancy) we can initially expect a forward reaction rate of $K_f rn^2$, where K_f is the rate constant of the forward reaction. As parts are consumed and binding sites fill up, this rate changes to $K_f(rn-x)(n-x)$ with x being the number of already occupied sites. We can thus express x through a differential equation: $dx/dt = K_f(rn-x)(n-x)$. This equation has a closed-form solution

$$x(t) = \frac{rn(1-\exp(-K_f(r-1)nt))}{r-\exp(-K_f(r-1)nt)} \quad [1]$$

and x approaches 100% as t goes toward infinity. In **Figure 33**, the rate constant is set to $K_f = 1$ part per time unit and $r = 1.1$, 1.2, and 1.3.

In practice, 100% yield is difficult to achieve because (a) assembly has to be terminated in a finite – and usually short – amount of time and (b) there may also exist a nonzero reaction in the reverse direction that causes occasional breakup of already assembled parts. Let K_r be the rate constant for the reverse reaction, and we expect that usually $K_r < K_f$. Then eqn [1] needs to be updated to include the reverse reaction whose rate is $K_r x$. Note that here x is a linear term and not a quadratic term as in the forward reaction. This is due to the combinatorics of this particular self-assembly system, where the number of free part–free binding site combinations is quadratic in x but the number of occupied sites is linear in x. Thus we obtain a new differential equation $dx/dt = K_f(rn-x)(n-x) - K_r x$. This equation, again, can be solved exactly, and we can derive the equilibrium equation

$$x = \frac{K_{rf} + (r+1)n}{2} - \sqrt{\left(\frac{K_{rf} + (r+1)n}{2}\right)^2 - rn^2} \quad [2]$$

where K_{rf} stands for K_r/K_f. For $K_{rf} = 0.1$ and $r = 1.1$, 1.2, and 1.3, we now obtain equilibria at 97.0%, 98.2%, and 98.7%, respectively (**Figure 34**).

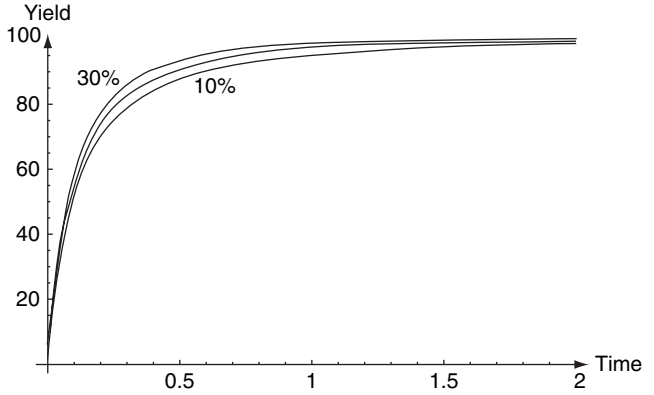

Figure 33 Theoretically determined yield of a self-assembly process described by eqn [1] as a function of time, with part redundancy at 10%, 20%, and 30%.

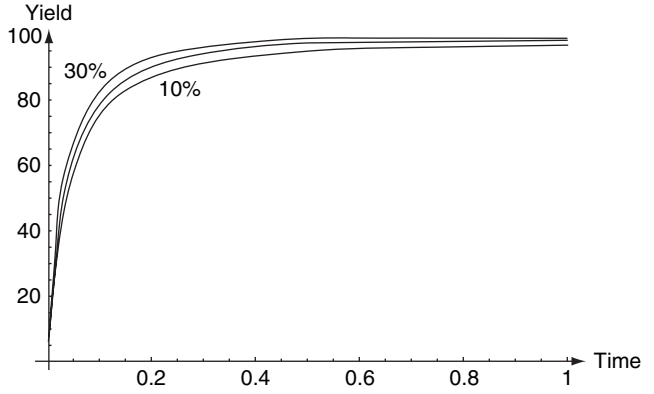

Figure 34 Theoretically determined yield of a self-assembly process that takes into account forward reaction rate $K_f = 1$ and reverse reaction rate $K_r = 0.1$. Again, part redundancy is 10%, 20%, and 30%. The self-assembly processes reach a yield of 97.0%, 98.2%, and 98.7%, respectively.

This analysis could be further refined in many ways. For example, note that eqns [1] and [2] assume a reaction-limited process. In practice, this means that parts are sufficiently mobile to reach all binding sites. If instead a diffusion-limited process is chosen (i.e., the parts' mobility is more constrained such that only parts in the immediate vicinity of a binding site can react) then the equation must be adjusted again. Another limitation of eqns [1] and [2] is the application of a continuous equation to a discrete system. Alternatively, one can express the assembly in terms of discrete states, and each reaction corresponds to a state transition. Such a system can be represented by a directed graph where each node represents a state and each edge a (probabilistic) transition. The theory of Markov processes provides a powerful and well-developed foundation for this approach.

1.14.4.1.2 Predicting and optimizing performance

When describing a self-assembly system, we can distinguish between process parameters and performance parameters. Process parameters describe the physical conditions under which the system operates: geometry, material properties, environmental conditions, part counts, etc. Performance parameters provide a metric to evaluate the self-assembly process: yield, assembly time, accuracy, wear on parts, etc.

The model equations in Section 1.14.4.1.1 indicate process parameters that influence specific performance parameters. If our objective is to maximize the number of assemblies x in a given time t, then intuitively we would choose a large part redundancy r and a large ratio between the rate constants K_f and K_r. The equations confirm this strategy but also give bounds on the yield, which we can expect from a practical experimental setup.

Calculating exact values for the rate constants K_f and K_r for self-assembly processes from first principles is difficult in general. The challenge lies in the usually complex interplay of different phenomena (gravity, capillarity, van der Waals forces, etc.) and in the difficulty to find the equivalent of temperature (i.e., kT) in reaction kinetics. Further research is needed in this area to establish a generally applicable theory of microscale self-assembly.

1.14.4.2 Parallels between Assembly and Computation

Another fascinating aspect of self-assembly is its close relationship to computation. Adleman's seminal paper showed that nondeterministic polynomial time (NP)-hard problems can be encoded into DNA molecules (Adleman 1994). Moreover, it is well-known that self-assembly systems consisting of simple 2D tiles can implement a Turing machine, and thus can perform (in principle) any computation (Grünbaum and Shephard 1986, Wang 1963). This result may not lead to practical computers based on self-assembly, but it indicates that virtually arbitrarily complex structures could be created via self-assembly, given a sufficiently sophisticated program that guides the assembly toward the desired product. Real-time error correction is essential because, as we have seen throughout Section 1.14.3, stochastic processes cannot be expected to produce perfect yield. To date, biological growth in nature remains by far the best proof of principle for successful self-assembly.

1.14.5 Discussion and Outlook

Self-assembly techniques enable rapid and parallel construction processes for MEMS devices. With appropriate driving forces, self-assembly techniques can assemble components ranging from submicrons to millimeters or larger scales, while conventional robotic pick-and-place assembly methods face mounting difficulties below 500 μm due to sticking effects between grippers and components. The following research directions are worthy of efforts to further extend the capabilities of self-assembly techniques.

In the previous sections, several major self-assembly techniques driven by inertial, electrical, magnetic, and interfacial energy minimization have been discussed. Each of these self-assembly techniques can achieve both 2D and 3D assemblies with appropriate structure designs. Current and potential applications of these self-assembly techniques are given in **Table 1**.

Three-dimensional self-assembly methods will most likely play a key role in building MEMS devices with more complicated architectures. Most of the currently available self-assembly techniques mount microcomponents on a substrate surface, i.e., a 2D assembly process. To achieve multiple functions or stand-alone applications, a MEMS device can be integrated with various components such as MEMS sensing units, MEMS actuating units, or complementary metal oxide semiconductor (CMOS) signal processing units. Three-dimensional assembly

Table 1 Current and potential applications of each self-assembly technique

Inertial	2D	• Mass fabrication of RFID tags by fluidic self-assembly • Self-assembly of microcomponents by single- or double-stage shape recognition
	3D	• Construction of 3D structures by centrifugal forces driving hinged structures • Potential construction of 3D structures by feature mating
Interfacial	2D	• Patterning and aligning of microcomponents on a substrate by capillary forces of melting solder or other liquids
	3D	• Integration of different types of microcomponents to form a hybrid composite component • Construction of 3D structures by reflowing solder or photoresist deposited at hinges
Electrical	2D	• Patterning of micro- and nanoscale components on a substrate • Programmable assembly of hybrid components
	3D	• Construction of 3D structures by triboelectricity • Potential aligning of nanowires in desired orientations
Magnetic	2D	• Integration of semiconductor components to recessed sites with magnetized strips on a substrate • Potential programmable assembly of heterogeneous components
	3D	• Construction of 3D frames by sequential pricking up of hinged structures • Potential building of 3D structures by attaching components of specific geometric design

enables dense packaging of these components, which can greatly reduce environmental disturbances and signal transmission losses among different functional units.

Assembly programmability will greatly widen the application range of self-assembly techniques and enable construction of more versatile MEMS devices. This programmability can indicate several situations such as the following:

(1) Integration of different types of components by multiple batches of self-assembly
(2) Self-assembly of same types of components into various patterns in different batches
(3) Selective disassembly of some components by breaking up their bonds to receptor sites
(4) Assembly of multiple components in appropriate sequences to form 3D structures

A consequence of the stochastic nature of self-assembly is that in most cases, perfect yields of 100% cannot be expected. As a remedy, redundancy could be incorporated into the assembly, for example, by including more than the minimum required amount of components. Intentional disassembly of incorrectly placed components is also a possibility, but it would require binding sites that can be deactivated even after assembly has already taken place. Finally, a precision robotic assembly step could also be employed to place any remaining defects.

Assembly process automation enables running the self-assembly process continuously for maximum throughput. To this end, one needs to consider how the process can be integrated into the overall production flow, including parts feeding, redundant parts recycling, assembly defect recognition, and recovery. The high capital investment and specialized equipment used in prior and subsequent processing steps should not be affected by the introduction of a new process step. Thus, ideally, the inputs and outputs of the self-assembly process module should be identical with the conventional assembly module that it replaces. This may imply additional constraints on how the substrate and parts are delivered to and from the self-assembly module.

Acknowledgments

Biographies

Jiandong Fang received his Bachelor's degree in Physics from the University of Science and Technology of China in 1999 and his Master's degree in Physics and the Ph.D. degree in Electrical Engineering from the University of Washington (Seattle, WA) in 2001 and 2006, respectively. From September 2006, he worked as a postdoc research fellow at the School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, GA.

His current research is mainly focused on self-assembly of microcomponents, design, fabrication, and packaging of microelectromechanical systems (MEMS) such as fluidic pumps, scanning mirrors, biochemical sensors, and piezoelectrically driven MEMS resonators.

Karl F. Böhringer received his Dipl.-Inform. degree from the University of Karlsruhe, Germany, in 1990 and his MS/Ph.D. degrees in Computer Science from Cornell University, Ithaca, NY, in 1993/1997.

He was a Visiting Scholar at Stanford University in 1994–1995 and a Postdoctoral Researcher at the University of California, Berkeley from 1996 to 1998. He joined the Electrical Engineering department at the University of Washington in Seattle, WA, in 1998, where he is currently Associate Professor. He also held visiting faculty positions at the Universities of Tohoku, Tokyo, Kyoto (Japan), and São Paulo (Brazil). His research interests include microelectromechanical systems (MEMS), manipulation and assembly from macro- to nanoscales, microfluidic systems for the life sciences, and microrobotics. He has created, among others, multibatch self-assembling systems, massively parallel microactuator arrays, and a walking microrobot.

Karl F. Böhringer is a member of the Society for Nanoscale Science, Computing and Engineering (ISNSCE), the American Society for Engineering Education (ASEE), and the German Society for Information Sciences (GI). He was awarded a Long-Term Invitational Fellowship for Research in Japan by the Japan Society for the Promotion of Science (JSPS) in 2004, an IEEE Robotics & Automation Society Academic Early Career Award in 2004, an NSF CAREER Award in 1999, and an NSF Postdoctoral Associateship in 1997. His work was listed among the Top 100 Science Stories of 2002 in *Discover* magazine. He is an associate editor of ASME/IEEE Journal of Microelectromechanical Systems and IEEE Transactions on Automation Science and Engineering and has served, among others, on technical program committees for the IEEE MEMS and Transducers conferences.

1.15.1 Introduction

Packaging is one of the most important aspects in microsystem development. It is typically a major cost component, regularly exceeding the common 30% for integrated circuit (IC) packages, and ultimately determines the reliability and long-term stability of the microsystem. Therefore, an excellent packaging concept is crucial for a successful microsystem product. Nevertheless, packaging is often considered far too late in the development cycle of a microsystem. A simple search on the engineering and sciences publication database INSPEC reveals roughly 20 000 publications for the keyword search *microsystem* or *MEMS* (microelectromechanical systems) (as of November 2006), but only about 2600 publications or less than 15% if the keywords *package* or *packaging* are added to the above search string. The reader might argue that packaging is the job of the companies, not of academia, and companies generally do not publish their results. This is certainly true, but there is more to it. Packaging research is typically time-consuming, requiring long-term testing, and generally does not yield a publication as easily as a new device or a new fabrication process. Nevertheless, the importance of packaging has been widely acknowledged in recent years and several books (Gilleo 2005, Hsu 2003, Spangler 2007) and book chapters (e.g., Bright *et al.* 2004, Monajemi *et al.* 2007) have been dedicated exclusively to this topic.

The goal of the present chapter is not a comprehensive review of all packaging work done in the microsystems area (this would be a very challenging task, looking at roughly 2500 publications published over the past 25 years), but rather to provide an overview on common packaging concepts. The chapter starts with a summary of microelectronics packaging, highlighting the concept of different packaging levels, chip interconnection techniques, and standard IC packages. Section 1.15.2 concludes with a comparison of microelectronics and microsystems packaging requirements. Section 1.15.3 covers zero-level packaging concepts, i.e., wafer-level packaging (WLP) processes, which encapsulate the fragile MEMS/microsystem components before the dicing step. Section 1.15.4 is dedicated to first-level packages, covering dicing, die attach and interconnect, and various concepts for nonelectrical feedthroughs. This section is enriched with a number of microsystem examples, which utilize ceramic packages, metal packages, plastic packages, or chip-on-board (COB) technologies. Based on the background of the author, the focus is on the packaging of microelectromechanical components and topics like the packaging of optoelectronic components are not covered.

1.15.2 Microelectronics Packaging

Microsystems packaging strongly borrows from designs and processes originally developed for the microelectronics industry. The purpose of this section is to provide a brief overview on chip interconnection technologies and packages used to encapsulate ICs. For more detailed treatments of microelectronics packaging, the reader is referred to one of the many handbooks in this area (e.g., Harper 2004, Lau *et al.* 1995, 1998, 2000, Tummala 2001, Tummala and Rymaszewski 1989, 1997, Ulrich and Brown 2006). It should be noted that the microelectronics packaging industry, just as the microelectronics field in general, is developing fast, with a constant flow of new package types and packaging processes. Therefore, most up-to-date information on the latest developments is likely to be found on the web pages of major microelectronic packaging companies, such as Amkor Technologies (http://www.amkor.com).

1.15.2.1 Packaging Hierarchy

The package for an electronic system has four major functions, namely power distribution, signal distribution, heat dissipation, and circuit protection (Tummala and Rymaszewski 1989). As electronic systems can be rather complex, they typically involve several levels of packaging, often referred to as a packaging hierarchy. Figure 1 illustrates such a packaging hierarchy: the encapsulation of single IC chips is widely considered the first level of packaging. It should be noted that modern first-level packages might not only contain one but several IC chips and are then referred to as multichip modules (MCM). Single-chip modules and MCM are assembled together with other components, such as resistors and capacitors, on multilayer cards. Typically, the components are soldered onto a printed circuit board (PCB), but the cards may also have sockets to plug-in additional components. These cards make up the second level of packaging. In case of a personal computer as an example of an electronic system, second-level packages include the processor card (if not directly mounted onto the motherboard), random access memory (RAM) modules, or a graphics card. Most simple electronic systems typically only comprise first- and second-level packages, i.e., consist of a PCB with attached, encapsulated ICs and passive components. In the example of the personal computer, the motherboard, again a multilayer circuit board, constitutes the third level of packaging, providing sockets for various cards to be plugged in, but also incorporating single-chip packages and other components.

Not surprisingly, the traditional packaging hierarchy is not hammered into stone and many variations are found in today's microelectronic

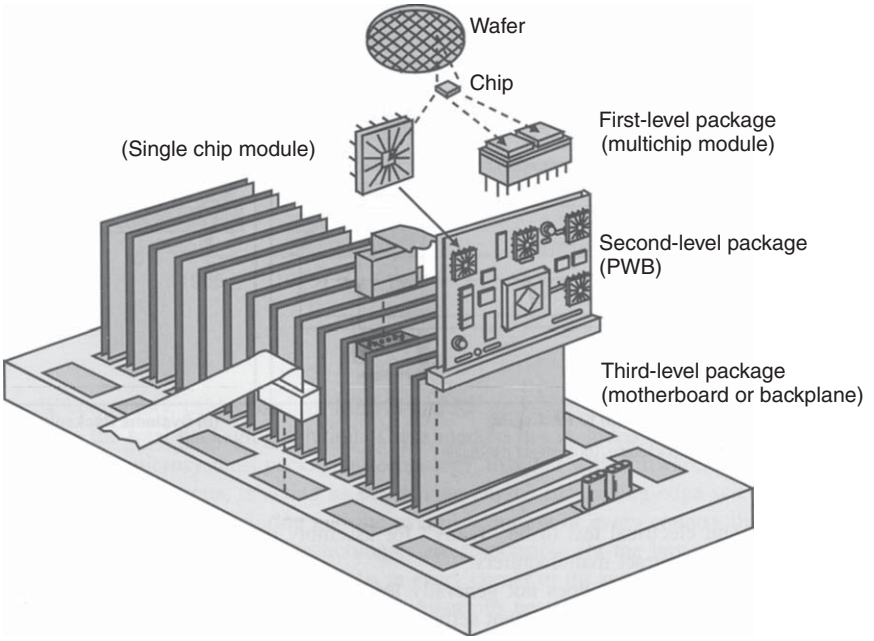

Figure 1 Schematic of microelectronic packaging hierarchy with first-, second-, and third-level packages. (Source: Tummala R R 2001 *Fundamentals of Microsystems Packaging*. McGraw-Hill, NewYork. Copyright: The McGraw-Hill Companies, Inc.)

systems to accommodate the customer's needs. For low-cost consumer applications, bare silicon chips are directly mounted onto PCBs, effectively skipping the first-level package. On the other hand, systems on a chip (SOC) or systems in a package (SIP) refer to systems where all necessary components for their operation are incorporated onto a single chip and into a single package, respectively (Brand 2006), thus combining first- and second-level packaging functions into a first-level package.

To protect the fragile mechanical structures of today's MEMS, special fabrication processes have been developed to cap these parts on a wafer level. This is often referred to as zero-level packaging and will be discussed in detail in Section 1.15.3. For the remainder of this chapter, we are now focusing on zero- and first-level packages.

1.15.2.2 Chip Interconnection Techniques

Electrical connections between chip and package are commonly performed by wire bonding, flip chip bonding, or tape-automated bonding (TAB) (Baldwin 2001). Even though wire bonding is a serial process, i.e., one interconnect is formed after the other, it is still today the most common chip interconnect technology. In case of flip chip bonding and TAB, all interconnects are formed at once (referred to as gang bonding), which constitutes a tremendous advantage for microsystems with very large input/output (I/O) count. To understand the advantages and disadvantages of these three chip interconnection technologies for the purpose of microsystem packaging, they are briefly reviewed in the following subsections.

Comparing the three chip interconnection technologies (**Figure 2**), the main advantages of wire bonding are its wide installation base and its process flexibility. With current bond speeds (>15 bonds s^{-1}), the wire bonding process is cost competitive even for chips with several hundred I/Os (Baldwin 2001). One of the key advantages of the flip chip technology are the better electrical characteristics of the interconnects with lower interconnect resistances, capacitances, and inductances. This can be decisive for high-frequency applications including radiofrequency (RF)-MEMS. Flip chip packages can be made smaller than wire-bonded packages, because no lateral space is needed for the fanout of the wires and no extra vertical space is needed to accommodate the wire loops.

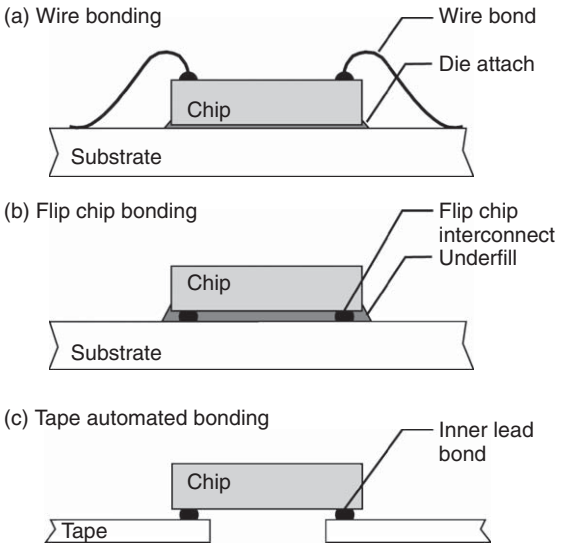

Figure 2 Comparison of chip interconnection technologies: (a) wire bonding, (b) flip chip bonding and (c) tape-automated bonding.

1.15.2.2.1 Wire bonding

Wire bonding always requires a preceding die attachment process to mount the die onto the substrate, such as a leadframe or multilayer substrate. One distinguishes polymer die bonding, solder die bonding, and glass die bonding (Tummala and Rymaszewski 1989, 1997), with polymer die bonding being the most common method. In case of polymer die bonding, an adhesive, commonly an epoxy, a polyimide or a silicone, is used to attach the chip to the substrate. The characteristics of the adhesive, namely its rheological, mechanical, electrical, and thermal properties, can be controlled by the polymer matrix itself, but also by adding filler materials, such as gold, silver, alumina (Al_2O_3), or boron nitride particles. The die attach process is typically highly automated: a die bonder feeds the substrates, dispenses the die attach adhesive, picks the chip from a carrier, and attaches it to the substrate. Subsequently, the polymer is cured and the assembly is ready for wire bonding. The advantages of polymer die bonding are its flexibility with respect to material properties, the low process temperature, and the relatively low cost. Many MEMS are sensitive to packaging-induced stresses and soft die attach adhesives are widely used to minimize the stress acting on the sensor chip (see Section 1.15.4). Solder and glass die bonding generally form a more rigid interface between chip and substrate and typically require

higher process temperatures. In solder die bonding, different solder systems, such as AuSi (eutectic), AuGe, PbSn, AuSn, and PbAgIn, are used to attach the chip to the substrate. The solder can be applied by dispensing from a hot nozzle, by dispensing and printing solder pastes or by applying solder performs. Typical process temperatures range from 200°C to 400°C. Solder die attach provides an excellent thermal conductivity, high-temperature stability in case of hard solders, and is typically used in conjunction with metal and ceramic packages. Glass die bonding uses a glass frit material, which is either screen/stencil printed or dispensed onto the substrate (see also glass frit bonding in Section 1.15.3.1). Typical process temperatures are around 400°C, which limits its application mainly to ceramic packages.

After the die attach, thin metal wires are bonded, one after the other, from the chip's bond pads to the substrate pads. One distinguishes two wire bonding sequences, ball–wedge bonding and wedge–wedge bonding, and three basic bonding processes, ultrasonic (US), thermosonic (TS), and thermocompression (TC) bonding (Baldwin 2001). In case of ball–wedge bonding, the bonding wire is fed through a capillary; in case of wedge–wedge bonding it is fed through a bonding wedge. The ball–wedge bonding sequence (**Figure 3(a)**) starts with the formation of a ball at the end of the bonding wire, e.g., with a high-voltage electric discharge (electronic flame off). The first bond of a bonding cycle is achieved by pressing the ball onto the bonding pad on the chip surface, while applying either heat only (TC bonding) or a combination of heat and US energy (TS bonding). This initial bond is referred to as the ball bond. Along a programmed trajectory, the wire is now looped to the location of the second bond on the substrate (loop formation). The second bond, a wedge bond, is performed by pressing the capillary onto the package pad, applying either thermal energy only or thermal energy and US excitation to assist bond formation. While raising the bonding tool after the second bond, the wire tail is

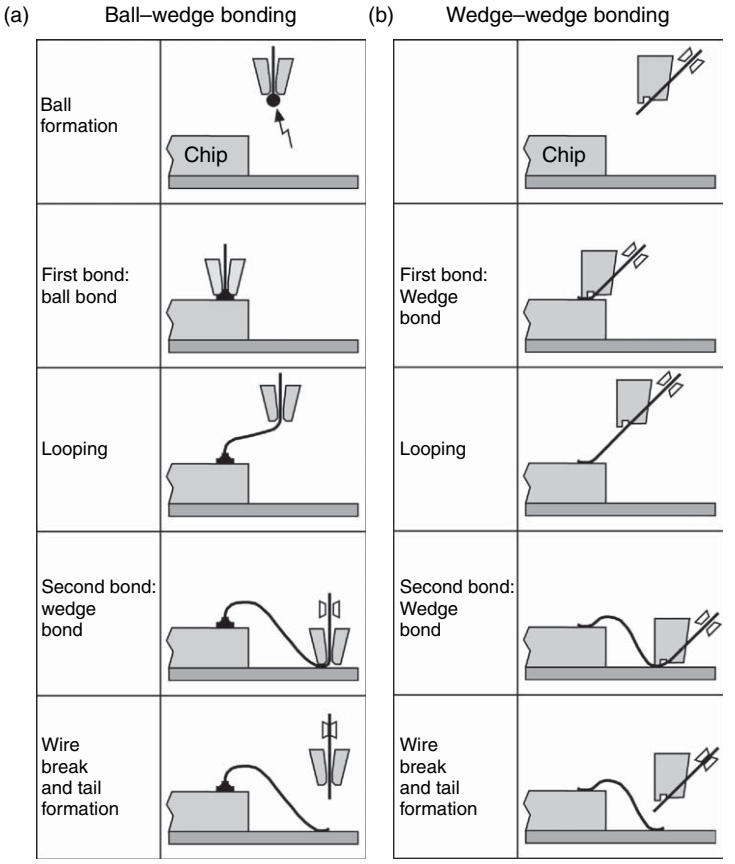

Figure 3 Schematics of (a) ball–wedge and (b) wedge–wedge bonding cycles; for clarity, only the tips of the bonding tools and a schematic of the wire clamp are shown.

broken off and the next bonding cycle can start with the formation of a new ball. Because of the circular symmetry of the first ball bond and the bonding capillary, the bond head can move in any direction during loop formation, i.e., no rotation of the substrate holder or bond head is required to bond all the wires along the perimeter of a chip. This allows for very high bond speeds and automatic ball–wedge bonders can execute between 10 and 20 bond cycles per second (see, e.g., Oerlikon ESEC Semiconductor, Cham, Switzerland, http://www.esec.com). Gold wires with a typical diameter of 25 µm are widely used for ball–wedge bonding. In fine-pitch applications, 15-µm gold wires enable high-speed wire bonding with a pad pitch of only 35 µm. To be able to bond ICs with advanced copper metallization, ball–wedge bonding processes based on copper wires have been developed in recent years.

In case of wedge–wedge bonding, both bonds of a bonding cycle are wedge bonds (**Figure 3(b)**). In contrast to the ball–wedge bonding, the wedge–wedge process is unidirectional, i.e., the direction of the looping must be along the centerline of symmetry of the first bond. This generally requires the rotation of the substrate holder for each wire bond. Using aluminum wires, wedge–wedge bonding can be done at room temperature by applying a vertical bond force and US energy only (US bonding). However, TS and TC bonding are possible as well. Because of the dimensions of the first wedge bond, wedge–wedge bonding generally enables smaller bonding pitches. Wedge–wedge bonding is especially popular in laboratory and prototyping environments, where manual bonders enable unsurpassed process flexibility in terms of substrate choice, pad layout, and wire material. In microsystem applications, gold wires are often preferred over aluminum wires because of their superior corrosion resistance.

1.15.2.2.2 Flip chip bonding

In flip chip bonding, the chip is flipped before being attached, and solder or conductive polymer bumps between chip and substrate serve as both an electrical and a mechanical interconnection. The original technology, known as Controlled Collapse Chip Connection or C4, has been demonstrated in the late 1960s by IBM. Main drivers for this process are ultrahigh I/O counts and the ever-increasing electrical performance requirements for high-frequency applications. Today, customers can choose between a growing number of different flip chip interconnection systems depending on their particular application (Lau 1995, 2000, Oppermann *et al.* 2000). Flip chip services are offered by a number of companies, including FlipChip International (http://www.flipchip.com) and PacTech (http://www.pactech.de). Flip chip connections can be made to ceramic and polymer substrates using either solder or adhesive interconnection systems. The basic flip chip interconnection can be subdivided into four functional areas (Baldwin 2001):

(1) the underbump metallization (UBM),
(2) the IC bump and bond material,
(3) the substrate metallization, and
(4) the encapsulant.

The UBM is a compatible metal sandwich connecting the chip metallization (usually aluminum or copper) to the bump metallization, and generally consists of an adhesion layer, a barrier layer, a wetting layer, and an antioxidation barrier. Depending on the application and the actual interconnection system, various UBMs are available. For solder systems, an electroless nickel–gold UBM is a frequently used low-cost option: the aluminum metallization of the chip is activated with a zincate layer (adhesion layer); subsequently, a nickel bump (typically 5 µm) is formed by electroless plating (barrier and wetting layer), and finally, a thin gold film (typically 50 nm) is deposited as an antioxidation barrier. In case of a solder interconnect system, the IC bump and bond material consist of a controlled amount of solder per interconnect, deposited by evaporation, electroplating, stencil printing, or solder jetting. Alternatively, the solder balls can be placed and reflown with a Laser Solder Ball Jet System (see PacTech, Nauen, Germany; http://www.pactech.com). The chosen solder system again depends on the application: if the flip chip packaged die requires withstanding a subsequent soldering step (e.g., in case of a surface-mountable package with a flip chip die), a higher melting temperature solder is needed for the flip chip attachment. If, on the other hand, the flip chip die is mounted onto a laminate substrate together with other surface-mount device (SMD) components, a low melting temperature solder might be preferable to form all interconnects on the board simultaneously.

For adhesive flip chip interconnection systems, nonoxidizing gold is widely used as bump material and combined with, e.g., a titanium–tungsten UBM. Thereby, the gold bump is either electroplated or provided by a ball wire bonder in the form of a so-called stud bump (i.e., a ball bond with short wire tail). The adhesives are either isotropically or anisotropically conductive. Isotropic conductive adhesives, such

as epoxies filled with silver flake particles, are printed or dip-transferred to either the IC bumps or the substrate bond pads. After assembly and curing, the isotropically conducting adhesive forms a mechanical bond between the substrate and the IC bump. This is in contrast to the generally more reliable solder system, where a metallurgical bond is formed. Anisotropic conducting adhesives consist of a polymer matrix with embedded conducting spheres and are applied not only to the contacts but also to the complete chip area as a paste or a film. While pressing the chip onto the substrate, the conducting spheres are compressed and captured between the IC bump and the substrate pad, making a reliable interconnect upon curing the polymer. The advantage of anisotropic conductive adhesives is that they serve as an underfill at the same time. Most of the other flip chip interconnection systems require the application of a polymer underfill material between chip and substrate to reduce the thermomechanical stress acting on the interconnects, caused by differences in thermal expansion coefficient between chip and substrate. The underfill is dispensed along one or several edges of the chip and drawn into the volume between chip and substrate by capillary forces (Baldwin 2001).

1.15.2.2.3 Tape-automated bonding

TAB is an interconnection process based on mounting and bonding an IC to a flexible conductor tape, either a single-layer metallic tape or a multilayer polymer/metal sandwich. Like in flip chip bonding, all interconnects are formed at the same time (gang bonding). To prepare for the bonding process, the bond pads on the chip are coated with a UBM and a metal bump, e.g., an electroplated gold bump. Alternatively, the tape instead of the chip can be bumped. The so-called inner lead bonding forms the actual interconnects between inner metal leads on the tape and the chip, using either TC (e.g., Au–Au) or solder bonding (e.g., eutectic Au–Sn) as the bonding process. After the inner lead bonding, the chip and interconnects are encapsulated by dispensing and curing a polymer, followed by an optional burn-in and test. Before assembly, the TAB packages are singulated and the outer leads are formed. Finally, the outer leads are boded to the substrate (outer lead bonding).

1.15.2.3 Standard IC Packages

The goal of this section is to provide an overview of first-level packages for ICs. Keeping in mind that the overall chapter concentrates on microsystem packaging, the focus is more directed toward low pin count packages. Single-chip packages can be categorized by a number of criteria, such as package material (plastic, ceramic, or metal), interconnect arrangement (peripheral or area array interconnects), assembly technology (through-hole or surface-mount technology (SMT)), or package type. Thereby, an industry-wide body, the Joint Electronic Devices Engineering Council (JEDEC, http://www.jedec.org), establishes standard package designators and geometries. In the following, the basic single-chip package types (**Figure 4**) are briefly discussed (Tummala 2001, Tummala *et al.* 1997).

Single in line packages: Single in line packages (SIPs) are less common than the dual in line packages (DIPs) and have pins for through-hole assembly only

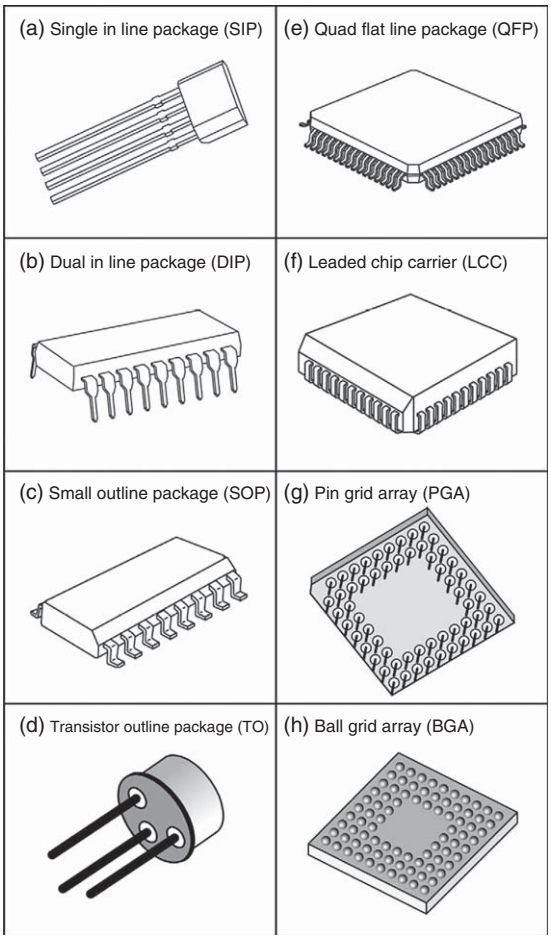

Figure 4 Overview of common single-chip package types used for integrated circuit packaging. (Images (a), (b), (c), (e), and (f) courtesy of: Allegro® MicroSystems Inc., Worcester, MA, USA.)

along one side of the package. SIPs are generally plastic packages with a pin count up to 48 and a pin pitch of 2.54 mm.

Dual in line packages: DIPs come in either plastic or ceramic versions and have two rows of interconnects along two opposite sides of the package. The DIP is a commodity through-hole package with up to 84 pins and a most common lead pitch of 2.54 mm (1.78 and 1.27 mm are less common). Ceramic DIPs are frequently used for testing MEMS/microsystem prototypes.

Small outline packages: The small outline package (SOP) is the most common package type for low pin count ICs. It is a leadframe-based plastic package with leads on two sides of the body and pin counts ranging from 8 to 84. The original lead pitch is 1.27 mm (SOP or SOIC (small outline integrated circuit)), but shrink small outline packages (SSOP) with smaller pitches of 0.8, 0.635, and 0.5 mm are available as well. Fully encapsulated SOP with a total package height of less than 1 mm are often termed thin small outline packages (TSOP).

Quad flat packages: Quad flat packages (QFPs) are available as ceramic (CQFP) or leadframe-based molded plastic (PQFP) packages with up to 356 peripheral leads. The surface-mountable QFP has leads on all four sides of the package and lead pitches ranging from 1 mm down to 0.3 mm. QFPs with overall thickness equal or below 1 mm are termed thin QFP or TQFP.

Chip carriers: Chip carriers (CCs) are, like QFPs, surface-mountable packages with peripheral leads on all four sides of the body. In contrast to the QFP with its gullwing leads, CCs feature either J-leads or no leads at all. Leadless chip carriers (LCCs or LLCCs) have a laminated ceramic substrate, leaded chip carriers (LDCCs) with J-leads are either leadframe-based molded plastic packages (PLCCs) or utilize ceramic substrates. CCs are often mounted in dedicated sockets and have I/O counts of less than 120 and typical interconnect pitches of 1.27 and 1.0 mm.

Pin grid arrays: Pin grid arrays (PGAs) are through-hole packages with an area array of interconnect pins using either laminated ceramic (CPGA) or laminated plastic (PPGA) substrates. Pin counts up to 750 are available with pin pitch of either 2.54 or 1.27 mm. CPGA packages are available in cavity-up or cavity-down configurations, i.e., the cavity for the IC is on the opposite or the same side, respectively, as the pin array. Several generations of Intel microprocessors have been packaged using PGAs. More recent versions use a land grid array (LGA), a package similar to the PGA (and BGA (ball grid array)), but having interconnect pads instead of pins.

Ball grid arrays: BGAs are the surface-mountable versions of the PGA with an area array of interconnects with attached solder balls. Plastic BGAs (PBGAs) based on laminated multilayer plastic substrates and ceramic BGAs (CBGAs) based on multilayer ceramic substrates are available. The chip interconnection is accomplished either by wire bonding or by flip chip bonding. Conventional BGAs have a solder ball pitch ranging from 1.0 to 1.5 mm and I/O counts up to 1100 (2600 for flip chip PBGA). Novel chip scale versions of BGA packages, such as Tessera's μBGA (http://www.tessera.com), feature ball pitches down to 0.5 mm, but typically have smaller I/O counts.

Single-chip package development in recent years is driven on one hand by higher and higher I/O counts, demonstrated by flip chip BGA packages with up to 2600 interconnects (see, e.g., Amkor Technologies, http://www.amkor.com), and on the other hand by smaller and smaller package form factors, witnessed by the growth in the area of chip scale packages (CSP). A characteristic of a CSP is a package footprint that is a maximum of 50% larger than the die area and a package perimeter no more than 20% larger than the chip perimeter. An example is the MicroLeadFrame (MLF) package developed by Amkor, a leadframe-based QFP with solderable lands instead of leads, thus also called quad flat no leads (QFNs). Single-chip packages are continuously developing and most up-to-date information on the newest CSP and other packages is found on the packaging manufacturer's and packaging service provider's web pages. The ultimate CSP will have the size of the actual die it protects. In this framework, considerable efforts in the area of WLP should be mentioned (see, e.g., Garrou and Tummala 2001). In WLP, some or all of the packaging steps, such as interconnect formation or encapsulation, are performed on a wafer level, before the singulation of the wafer into individual ICs. Section 1.15.3 introduces similar WLP concepts for microsystems and MEMS.

1.15.2.4 Microelectronics vs. Microsystem Packaging

The fabrication of microsystems and MEMS strongly relies on process steps borrowed from the IC industry. Can microsystem/MEMS packaging benefit in a similar way from developments in the microelectronics packaging area? The answer is Yes and No. Yes, because microsystem packaging indeed uses the same

chip interconnection techniques as the microelectronics industry to establish electrical interconnects and employs microelectronics packages wherever feasible. On the other hand, No, because a suitable microsystem/MEMS package usually requires more than protection, power distribution, signal distribution, and heat dissipation. In the following, the differences between microelectronic and microsystem packaging are briefly summarized.

One of the key features of microsystems is that they generally interact with their environment not only via the electrical energy domain. Microsensors need to sense the quantity of interest in the environment; microactuators generally need to transduce nonelectrical information through the package. As a result, a microsystem/MEMS package often requires not only electrical interconnects, but also feedthroughs for nonelectrical signals. At the same time, the package must still protect the microsystem from harmful environmental influences. The need for nonelectrical feedthroughs (or windows to the outside world) is fundamentally different from microelectronics packaging requirements and requires, depending on the applications, radically new packaging concepts. How can we sense a pressure inside a package? How can we transmit optical information in and out of the package? How can we detect chemical and/or biological analytes in air samples or, even more challenging, in a liquid sample and still protect our fragile MEMS structure? Packaging concepts developed in response to these and similar questions will be discussed in Section 1.15.4.

Microsystems/MEMS often comprise movable microstructures that cannot be encapsulated with a molding compound, the most common microelectronics packaging technique. In contrast, they need packages providing cavities while still protecting sensitive IC components and chip interconnect structures, such as wire bonds and bond pads. Frequently, MEMS structures also need extra protection during the wafer dicing process (see Section 1.15.4.1), prompting the development of wafer-level encapsulation techniques as discussed in Section 1.15.3. Moreover, microsystems/MEMS are usually more sensitive to mechanical stresses than are ICs and the influence of packaging-induced thermomechanical stresses must be carefully considered. Examples are piezoresistive pressure sensors, where packaging-induced stresses acting on the piezoresistive sensing elements can cause a sensor offset.

Yet another critical area influencing packaging cost are the manufacturing volumes of typical microsystem packages compared to microelectronics packages. Even though a number of very high-volume products exist (e.g., accelerometers, pressure sensors, inkjet print heads), most microsystem products have substantially smaller volumes or require packaging solutions that differ from customer to customer for a single product. An example is MEMS pressure sensors, where a given pressure sensor die might be packaged as an absolute or a differential pressure sensor, in a media-compatible package for operation in harsh environments or in a low-cost package with silicon gel for a consumer application. This calls for modular packaging approaches, which make use of basic packaging components for as many applications as possible.

Finally, the areas of assembly and testing/calibration cannot be emphasized enough. Single-chip packages are mounted onto PCBs in a highly automated fashion using pick-and-place systems. In order to benefit from these automated processes, microsystems packages must be handled by standard or customized pick-and-place tools and must be able to withstand standard assembly processes, such as a solder reflow. Otherwise, components must be assembled by hand, drastically increasing manufacturing cost. While the electrical testing of a microsystem might not be as involved as the electrical testing of an advanced IC, microsystem testing and calibration often involves other energy domains as well. Pressure sensors might be calibrated at different temperatures and pressures, requiring the development of dedicated testing equipment rather than the use of standardized off-the-shelf components.

1.15.3 Zero-Level Packaging for Microsystems

As mentioned earlier, various zero-level packaging technologies have been developed over the past decades to encapsulate microsystem/MEMS structures on a wafer level. Besides providing an obvious cost advantage by batch processing wafers rather than serial processing individual chips, the zero-level packaging steps offer two main advantages from a reliability point of view:

(1) The MEMS structures are (vacuum-) encapsulated in a clean room environment minimizing particle contamination that could lead to device failure.
(2) The fragile MEMS structures are protected by a capsule from water jets and sawing debris during the wafer dicing step.

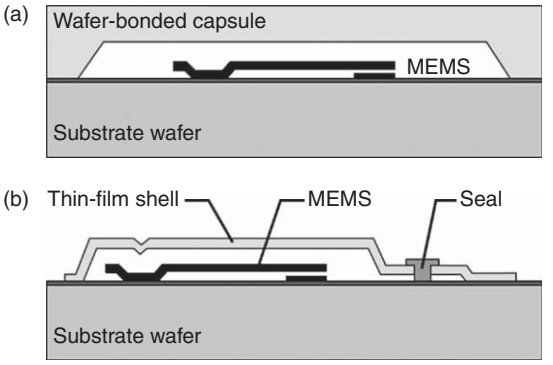

Figure 5 Zero-level packaging with (a) bonded capsule or (b) thin-film shell. (Source: Najafi K 2003 Micropackaging technologies for integrated microsystems: Applications to MEMS and MOEMS. *Proc. SPIE* **4979**, 1–19. Adapted with permission.)

In the following section, two basic zero-level packaging approaches (**Figure 5**), namely encapsulation by wafer bonding and encapsulation by thin-film shells, will be discussed in some detail. For additional information on zero-level packaging processes for MEMS/microsystems, the reader is referred to one of the review articles or books in this area (e.g., Hsu 2003, Iyer and Auberton-Herve 2002, Ko *et al.* 1985, Lin 2000, Najafi 2003, Schmidt 1998).

1.15.3.1 Encapsulation by Wafer Bonding

Wafer bonding refers to process technologies developed to bond two or more wafers to each other (Alex and Gösele 2004, Iyer and Auberton-Herve 2002, Schmidt 1998). Besides being used for zero-level packaging purposes, wafer bonding is used in the microsystems/MEMS field to build 3D microstructures, such as microturbine engines (Frechette *et al.* 2005), and to manufacture silicon-on-insulator (SOI) substrates. Wafer bonding techniques are not only used to bond two silicon wafers to each other, but can be employed for various substrates, including glass wafers or nonsilicon semiconductor (e.g., GaAs) wafers. The wafer bonding processes can be subdivided into direct bonding techniques, such as fusion and anodic bonding, and processes requiring an intermediate layer, a metal, dielectric, or adhesive film, for bond formation. Wafer bonding technologies based on intermediate metal films include metal TC bonding, solder bonding, and diffusion bonding; wafer bonding based on intermediate dielectric films include glass frit bonding. In the following, wafer bonding techniques pertinent to zero-level packaging are briefly introduced. For a more detailed treatment of bonding technologies, the reader is referred to Chapter 1.09. The characteristics of the most common wafer bonding technologies are summarized in **Table 5** of Chapter 1.09.

Direct bonding techniques typically require mirror-smooth wafer surfaces, while an intermediate bonding layer can level out surface topography resulting from, e.g., underlying electrical feedthroughs. The traditional silicon fusion bonding requires annealing temperatures around 1000°C, whereas most other bonding techniques have peak temperatures around or below 400°C and are, thus, compatible with standard complementary metal oxide semiconductor (CMOS) metallizations. Even silicon fusion bonding can be performed at CMOS-compatible temperatures by proper surface treatment before the bonding. The lowest bonding temperatures are typically achieved using adhesives as bonding film, but those bonds are not considered hermetic. State-of-the-art automated and manual wafer bonding tools are commercially available from Karl Suss (http://www.suss.com), EV Group (http://www.evgroup.com), and OAI (http://www.oainet.com). These bonding systems can handle different bonding processes and wafer diameters, and typically include a cleaning station, an alignments and a bonding tool.

Except adhesive bonding, all of the listed wafer bonding methods are considered hermetic and can potentially be used for vacuum packaging. A challenge for every vacuum package, however, is that gases are freed during the bonding process and desorption of gas molecules from the cavity walls takes place over time. Because of the relatively large surface-to-volume ratio of most microfabricated cavities, this outgassing can considerably increase the cavity pressure over time. This might not be tolerable for resonators requiring vacuum as low as 10^{-3} mbar for stable operation. A solution to this problem is getter films, which can be mounted or deposited inside the cavities and effectively getter residual gas molecules, thus, maintaining a constant cavity pressure over time (Moraja and Amiotti 2003, Sparks *et al.* 2003, 2004).

1.15.3.1.1 Fusion bonding

Fusion bonding or direct bonding (Alexe and Gösele 2004, Gösele and Tong 1998, Gösele *et al.* 1999, Schmidt 1998) is based on the fact that two mirror-flat, clean wafer surfaces will adhere to each other even at room temperature if brought into contact. While fusion bonding is mainly associated with the bonding of two silicon wafers, almost any material surfaces can be directly bonded if their surfaces are

sufficiently smooth. The room-temperature bond is, thereby, attributed to attractive van der Waals forces. Currently, the most important applications of silicon fusion bonding are in the manufacturing of SOI substrates and in the fabrication of silicon-based microsystems.

Silicon fusion bonding requires very smooth wafer surfaces with a typical surface roughness of better than 1 nm and a wafer bow of less than 5 μm on a 4″ wafer (Schmidt 1998). While prime-grade, polished wafer surfaces are generally sufficiently smooth for fusion-bonding applications, other surfaces can be prepared by chemical–mechanical polishing (CMP) steps. The fusion-bonding sequence comprises three process steps:

(1) wafer cleaning and surface conditioning,
(2) alignment and room-temperature bonding, and
(3) high-temperature anneal to improve bond strength.

Thorough wafer cleaning is essential to prevent nonbonded areas separated by small particles. The surface treatment generates either hydrophilic or hydrophobic wafer surfaces. Hydrophilic wafer surfaces are obtained either by growing a thermal oxide or by using the native oxide in combination with a proper surface treatment (e.g., a RCA cleaning procedure); the wafer surfaces are then terminated with –OH groups. If the surface oxide is removed by a dip in hydrofluoric acid, a hydrophobic surface with –H coverage is achieved (Gösele and Tong 1998). After surface preparation, the wafers are aligned in a clean room environment to reduce particle contamination and contacted by gently pressing them together at a central point. This way, the wafers will prebond without trapping air between the surfaces. Typical surface energies after the room-temperature prebond are 0.02 and 0.1 $J\,m^{-2}$ in the case of hydrophobic and hydrophilic silicon surfaces, respectively (Gösele and Tong 1998, Gösele *et al.* 1999). By annealing the wafer sandwich to temperatures between 800°C and 1200°C, the bond strength can be increased in both cases by one to two orders of magnitude with typical surface energies of 2–3 $J\,m^{-2}$. The surface chemistry involved in forming the bond at elevated temperature is described in detail in Gösele and Tong (1998). It is worth noting that hydrated wafer surfaces reach bonding energies >1 $J\,m^{-2}$ already with prolonged annealing steps at temperatures as low as 200°C (Gösele and Tong 1998, Gösele *et al.* 1999).

Considerable research activities are centered on reducing the required annealing temperature for silicon fusion bonding. Most approaches involve special pretreatment of the wafer surfaces, either using wet chemistries or by an appropriate surface plasma treatment (e.g., Berthold and Vellekoop 1997, Dragoi *et al.* 2005, Pelzer *et al.* 2004, Suni *et al.* 2006, Tong *et al.* 2003). While bonding temperatures around 200°C make silicon fusion bonding already compatible with IC processes and common surface metallizations, the ultimate goal is a reliable room-temperature bonding process. One of the main advantages of fusion bonding is its applicability not only to silicon surfaces, but to smooth material surfaces in general. This way, material combinations that cannot be epitaxially grown on top of each other (e.g., GaAs/Si or InP/Si) can be joined by wafer bonding. The main disadvantage of fusion bonding is the required surface smoothness and cleanliness.

One of the first applications of silicon fusion bonding in the microsystems area was the formation of reference pressure cavities for pressure sensors (Petersen *et al.* 1988). The proposed process involved etching of a reference cavity in one wafer and fusion bonding of a second wafer to seal the cavities. By thinning the second wafer, a membrane with desired thickness can be formed on top of the buried cavity. Piezoresistive sensing elements can then be implanted to make a pressure sensor. Compared to the conventional method of releasing the pressure-sensitive membrane with an anisotropic wet etching step from the back of the wafer, the fusion-bonding process can result in significantly smaller die sizes. Today, the SM5420 series pressure sensors of Silicon Microstructures (http://www.si-micro.com) utilize a similar technology to manufacture ultrasmall pressure sensor chips (Datasheet SM5420 Low-Cost, SO-8 Packaged Pressure Sensor, Silicon Microstructures Inc., Milpitas, CA, 2005). The underlying pressure sensor die SM5108 has a size of only 0.65 mm × 0.65 mm, allowing 24 000 die to fit on a 6″ wafer (Datasheet SM5108 Ultra-Small, Low-Cost, OEM Pressure Die, Silicon Microstructures Inc., Milpitas, CA, 2005). Other applications requiring sandwiches of several fusion-bonded silicon wafers include the above-mentioned microfabricated air turbine (Frechette *et al.* 2005) and microfabricated magnetic induction machines (Arnold *et al.* 2006).

1.15.3.1.2 Anodic bonding

Anodic bonding between a metal/semiconductor and a glass substrate was first demonstrated in 1969 (Wallis and Pomerantz 1969) and is today the most

widely used wafer bonding technique in the microsystems area. In anodic bonding, a silicon wafer is usually bonded to a sodium-rich glass wafer by applying voltages in the range 200–1500 V between the two wafers at temperatures in the range of 300–450°C (Najafi 2003, Obermeier 1995, Schmidt 1998). Thereby, the glass wafer is biased as the cathode, the silicon wafer as the anode. Under the applied electric field and elevated temperature, mobile sodium ions (Na^+) drift away from the bond interface toward the cathode, leaving behind fixed negative charges that form, together with mirror changes on the silicon side, a very strong electric field across the bond interface. The resulting electrostatic forces pull the wafers together and a strong chemical bond is formed at the elevated temperature (Schmidt 1998). A prerequisite for a good bond quality are clean and smooth wafer surfaces with a surface roughness of typically less than 1 µm. Because two different substrate materials are joined at an elevated temperature, the thermal expansion coefficient of the glass wafer must be carefully chosen in order to minimize mechanical stresses. For this reason, Pyrex 7740 of Corning Glass Works (http://www.slam.corning.com) and Borofloat 33 from Schott (http://www.schott.com) are widely used glass substrates with a room-temperature coefficient of thermal expansion of 3.3 ppm K^{-1} (compared to 2.6 ppm K^{-1} for silicon). Both substrates are available in different thicknesses and wafer sizes to match customer needs.

The most important commercial application of silicon-to-glass anodic wafer bonding is arguably in the area of piezoresistive pressure sensors. As an example, **Figure 6** shows a photograph of a Bosch pressure sensor, bonded to a glass constraint wafer and packaged in a transistor outline (TO) package (Marek 1999). The bonded glass wafer mainly serves two purposes:

(1) The formation of a vacuum reference cavity in case of absolute pressure sensors.
(2) The reduction of packaging-induced stresses acting on the piezoresistive sensing elements by increasing the physical distance from the sensor elements to the die bond area and package materials.

Triple-stack wafers with two Pyrex wafers bonded to a central silicon wafer (Grelland *et al.* 1999) and two silicon wafers bonded to a central Pyrex wafer (Despont *et al.* 1996) can be assembled as well.

Anodic bonding is not only possible between a silicon wafer and a glass wafer, but can be used to bond two silicon wafers with a sputtered or evaporated glass film in between (Berenschot *et al.* 1994, Obermeier 1995, Weichel *et al.* 1998). Moreover, Pyrex glass caps have been anodically bonded to passivated microsystem wafers with polysilicon bond rings (Ziaie *et al.* 1996). By reflowing the passivation layers underneath the bond ring, sufficiently smooth surfaces even over electric feedthroughs can be provided. To make the anodic bond less sensitive to the surface topography, a silicon wafer can be bonded to a glass wafer using a gold film in between (Harpster and Najafi 2003). At temperatures above the eutectic temperature of 363°C of the silicon–gold system, a liquid eutectic phase forms between the silicon and glass wafers. The electrostatic force pulls the wafers together and the liquid phase ensures that any surface topography is planarized. Because the Pyrex glass is transparent and biocompatible, the bonding technique is suitable for optical and biomedical applications. Finally, void-free glass-to-glass bonds have been achieved at temperatures as low as 375°C using anodic bonding (Wei *et al.* 2003).

1.15.3.1.3 Glass frit bonding

Glass frit bonding (Knechtel 2005, Knechtel *et al.* 2006) is mainly used to join two silicon wafers, but can be applied to a wide range of surface materials

commonly used in microsystems technology, including silicon dioxide, silicon nitride, or aluminum. Glass frit bonding is based on glasses with low glass transition temperatures. Widely used are lead-containing glasses with process temperatures below 450°C. Typically, the bonding layers are applied by screen/stencil printing techniques to the capping wafers. Alternatively, thin films can be deposited by sputtering. The screen-printable pastes have the low melting glass powder embedded in an organic binder. Fillers can be incorporated into the paste to adjust the thermal expansion coefficient of the glass frit closer to the substrate materials. After applying the paste to one of the two substrates, typically the cap wafer, the glass layer is conditioned, i.e., the organic binder is burned out and the glass film is premolten to form a compact layer without gas inclusions. Subsequently, the two wafers are aligned to each other and the bond is performed in a bonding tool by applying pressure, heating the wafer pair above the glass transition temperature, and finally cooling it down under applied pressure. Because the glass frits are applied by thick-film technologies, minimal line width and spacing are of the order of 200 and 100 µm, respectively, with typical film thicknesses (after preconditioning) of micrometers (Knechtel 2005). The flow properties of the viscous glass films enable to cover steps from underlying electrical feedthroughs, while still providing a hermetic seal. A disadvantage caused by the screen printing of the glass frit is that film thickness and uniformity over the wafer are difficult to control.

Glass frit wafer bonding is commercially used, e.g., by Freescale Semiconductor (http://www.freescale.com), to attach a silicon constraint wafer to their piezoresistive pressure sensors (schematic in **Figure 7(a)**) and a protective cap wafer onto their surface-micromachined accelerometers (**Figure 7(b)**) (Frank *et al.* 1994). The advantage of using a silicon constraint instead of an anodically bonded Pyrex wafer is the better matching of the thermal expansion coefficient of the two substrates. Depending on the application in absolute or differential pressure sensors, the silicon constraint wafer seals a hermetic cavity or features an etched pressure port, respectively. In the case of accelerometers, the bonded silicon cap protects the fragile MEMS structures during wafer dicing and allows for complete encapsulation of the MEMS chip with a molding compound (see Section 1.15.4.4) More recently, Analog Devices has demonstrated a wafer-level encapsulation approach for their inertial sensors based on glass frit bonding (Felton *et al.* 2003, Yun *et al.* 2005). Their latest packaging technology provides a true wafer-level package with through-wafer interconnects and solder balls for direct flip chip attachment to a printed wiring board (Yun *et al.* 2005).

1.15.3.1.4 Metal bonding

Wafer bonding based on metallic bonding layers includes a wide range of technologies, such as TC bonding, solid-state diffusion bonding, solder bonding, eutectic bonding, and solid–liquid diffusion bonding. While it is beyond the scope of the present chapter to review all investigated metal-based bonding processes and material systems, the fundamental differences of different bonding schemes are discussed in the following based on characteristic examples. Generally, one can distinguish between metal bonding techniques that only involve solid-state material phases and those involving liquid phases. Bonding processes involving a liquid phase,

such as solder bonding, eutectic bonding, or solid–liquid diffusion bonding, more easily enable hermetic bonds even in the presence of surface topography because of the leveling behavior of the liquid phase. However, these processes are usually more prone to outgassing than processes involving only solid-state phases, such as TC bonding and solid-state diffusion bonding. The processes involving a liquid phase can be further subdivided into two categories:

(1) Technologies in which the liquid is solidified by cooling the wafer below its melting temperature (e.g., solder or eutectic bonding).
(2) Solid–liquid diffusion technologies in which the liquid solidifies at constant temperature because of formation of intermetallic compounds with higher melting temperature (e.g., transient liquid-phase bonding, also called isothermal solidification).

In general, all bonding processes involving different metals in the bonding process are experiencing some amount of interdiffusion of the materials even at room temperature. The formation of intermetallic phases must be studied carefully in order to avoid the formation of, e.g., brittle phases or voids over time that could reduce the lifetime of the interconnect. These challenges are well known in the microelectronics packaging area, from which many metal-based wafer bonding techniques have been derived.

1.15.3.1.4.(i) TC bonding In TC bonding, two materials are welded together by the applications of temperature and pressure. The process is used in the microelectronics packaging industry for wire bonding and TAB (see Section 1.15.2.2). In order to form a bond, the separation between the two surfaces must reach atomic dimensions. At an elevated temperature, the involved metals soften and, thus, the required pressure needed for a reliable bond is generally lowered. The most common metal used for TC bonds is gold, because it is relatively soft and does not oxidize. For other materials, any surface oxides on potential bonding partners would first have to be removed either mechanically or chemically.

Wafer-level TC bonds (Taklo *et al.* 2004, Tsau *et al.* 2002, 2004) are carried out at temperatures around 300°C and pressures ranging from about four to several tens of MPA (with respect to the actual bonding area, not the wafer area). By using a compliant polymer film underneath the gold layers, an Au–Au bond has been achieved even at room temperature (Zhang *et al.* 2005). The micrometer-thick gold films can be evaporated, sputtered, or electroplated, with higher surface roughness typically translating into higher required bonding pressures. If silicon wafers are joined by TC bonding, a good diffusion barrier, e.g., a silicon dioxide film, must be placed between silicon substrate and gold layers in order to avoid Au–Si interdiffusion (Tsau *et al.* 2002). Thereby, considerable interdiffusion already takes place at temperature well below the Au–Si eutectic temperature at 363°C.

Recently, a wafer-scale package for RF-MEMS (Min *et al.* 2004) in the DC-50 GHz regime has been demonstrated based on a gold–gold TC bond between a glass substrate and a low conductivity silicon cap. On the substrate side, a 2.5-μm-thick sputtered gold sealing ring is used; on the bonding cap side, a 3.5-μm-thick electroplated gold film is used, resulting in a cavity height of about 6 μm. Bonding was performed at a comparably high temperature of 360°C.

1.15.3.1.4.(ii) Solder and eutectic bonding Solder interconnects are widely used in the microelectronics packaging industry for electrical connections, die bonding, and cavity sealing and it is, thus, no surprise that they have also found their way into wafer bonding applications (see, e.g., Goyal *et al.* 2003, 2004, Harpster and Najafi 2003, Mei *et al.* 2002, Najafi 2003, Wolffenbuttel 1997). Basically, a suitable solder material is deposited in the bond area between a substrate wafer with microsystem components and the capping wafer. The two wafers are aligned to each other and brought into contact and the temperature is increased until the solder reflows and creates a bond between the wafers. The solders can be applied by screen or stencil printing, electroplating, or using solder preforms. Advantages of solder bonding are the relatively low process temperatures, the ability to level surface roughness or topography, and the self-alignment capability originating from the large surface tension of molten solder. A major shortcoming of many solder pastes is that they contain solder fluxes to chemically break surface oxides and ensure proper wetting of the bonding surfaces. The aggressive fluxes can be detrimental to the encapsulated MEMS structures and flux residues should be removed together with other impurities embedded in the solder after the reflow cycle. Because this is generally not possible inside sealed cavities, fluxes should be avoided in the first place, relying on fluxless solder systems and other ways of surface activation. Another disadvantage is that common solder systems only have a

temperature stability up to their melting point; therefore, if SMTs are used to solder the first-level package onto a circuit board, the zero-level packaging must use a solder system with higher melting point. In order to accommodate lead-free solder systems (e.g., the Sn/Ag/Cu system with typical melting temperatures around 220°C), board assembly reflow processes must now maintain peak temperatures of 240–260°C. This generally limits suitable solder systems for zero-level packaging to those having melting points around 300°C, such as 80Au–20Sn or 88Au–12Ge with melting points of 280°C and 356°C, respectively (Tummala and Rymaszewski 1989). An alternative and widely used bonding system is eutectic Au–Si with a eutectic temperature of 363°C (Mei *et al.* 2002, Najafi 2003, Wolffenbuttel 1997). To form the eutectic composition, gold and silicon have to be provided to the interface where the wafers are joined. Typically, gold is deposited on one wafer, whereas either bulk silicon or a polysilicon layer is used on the second wafer as the other bonding surface. For all mentioned systems, adhesion, barrier, and wetting layers have to be carefully chosen in order to achieve a suitable process yield. Wafer-level packaged microsystem examples include an accelerometer with a MEMS wafer and a CMOS circuitry wafer joined by gold–silicon eutectic bonding (Brandl and Kempe 2001), a capacitive pressure sensor with a MEMS wafer and a CMOS circuitry wafer joined by Au–Sn solder bonding (Rogge *et al.* 1998), and RF components sealed by Sn–Pb (Jourdain *et al.* 2005) or Au–Sn (Cai *et al.* 2005) solder bonding. A thin surface-mountable capping wafer with solder balls and vertical electrical feedthrough has been developed by Hymite (http://www.hymite.com, Shiv *et al.* 2006). The cap wafer is bonded to the microsystem wafer using a Au–Sn solder, providing simultaneously a hermetic seal and electrical connections.

1.15.3.1.4.(iii) Solid–liquid diffusion bonding

As mentioned above, a challenge of using conventional solder bonding for zero-level packaging is that the bond will only withstand temperatures up to the melting point of the solder, i.e., up to roughly the initial bonding temperature. If solder joints are also used for the first- and second-level packaging, the solder systems have to be carefully chosen in terms of their melting temperatures in order not to compromise prior packaging steps. If standard SMT is used for the final PCB assembly, the final process temperature for lead-free solder systems is about 240–260°C and all prior soldering steps must have higher melting temperatures. Wafer bonding based on solid–liquid diffusion bonding (also called isothermal solidification or transient liquid phase bonding) (Baltes *et al.* 2000, Du *et al.* 2005, Karpenkopf *et al.* 2005, Waelti *et al.* 2000, Welch *et al.* 2005a, b) provides a temperature stability of the bond well beyond the actual bonding temperature while still offering the advantages of a liquid phase during joint formation. Bonding by isothermal solidification is based on solid–liquid interdiffusion of a high- and a low-melting-point component. By applying a bonding temperature between the melting points of the two components, a liquid phase is formed. The fast solid–liquid interdiffusion leads to the formation of higher melting phases, while the liquid phase is consumed. After all of the liquid phase has reacted, the bond has isothermally solidified. If the bond has not yet reached equilibrium at this point, solid-state interdiffusion continues at a slower rate, leading to the formation of new phases and the dissolution of others. Possible material systems for isothermal solidification are Ag–In, Au–In, Cu–In, Ag–Sn, Au–Sn, Cu–Sn, and Ni–Sn (Welch *et al.* 2005a).

Figure 8 shows an example of an infrared sensor array with a silicon filter attached by Au–In isothermal solidification (Waelti *et al.* 2000, 2001). The CMOS-based sensor chip comprises an array of thermoelectric infrared pixels embedded in a single dielectric membrane, multiplexing circuitry to address individual pixels, and a chopper-stabilized low-noise amplifier (Schaufelbuehl *et al.* 2001). To thermally isolate the individual pixels and mechanically stabilize the millimeter-sized dielectric membrane, a grid of 25-μm-thick gold lines is electroplated on top of the membrane (**Figure 8(a)**). The sensor arrays have been fabricated with a commercial 1 μm CMOS technology of EM Microelectronic-Marin SA, Marin, Switzerland, which also provides the gold electroplating, normally used to prepare the chips for TAB. Au–In isothermal solidification has been chosen to bond a silicon infrared filter directly onto the gold grid of the sensor array (**Figure 8(b)**). To prepare for the bonding step, the silicon filter is coated with a stack of metal layers: a Cr adhesion layer and a Au plating seed layer, jointly patterned by a lift-off technology, an electroplated Ni wetting layer and an electroplated In bonding layer (**Figure 8(c)**). Both, the Ni and In layers are electroplated using photoresist as plating mold. Subsequently, chip and filter are aligned and the fluxless bonding is performed in forming gas atmosphere. The optimized process parameters for

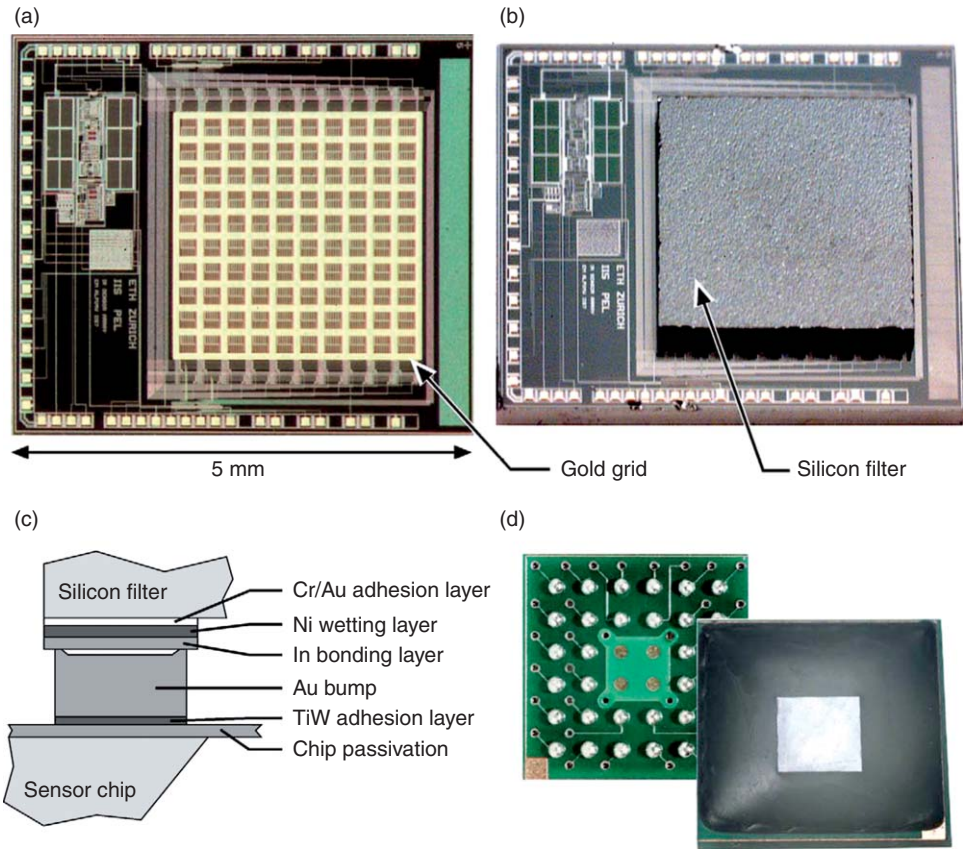

Figure 8 Infrared sensor array developed by ETH Zurich, Switzerland. (Schaufelbuehl *et al.* 2001; Waelti *et al.* 2001.)

the isothermal solidification are 195°C for 10 min under a load of 8 MPa (Waelti *et al.* 2001). The completed bond exhibits a temperature stability of 473°C, measured by applying a constant shear stress of 0.5 MPa and raising the temperature until the bond fails. As first-level packaging for the infrared microsystem, a plastic BGA has been chosen (Waelti *et al.* 2001). After die attach and wire bonding, a glob top epoxy is dispensed using a dam and fill process to protect the wire bonds and the microsystem, while providing access to the infrared filter (**Figure 8(d)**).

1.15.3.1.5 Polymer bonding

If a hermetic seal is not required, low-temperature wafer bonds can be achieved using polymer adhesives as bonding layers. Possible adhesives are benzocyclobutene (BCB), polyimide, polymethyl methacrylate (PMMA), SU-8, fluorocarbon polymers, parylene, or Mylar. A summary of the bonding properties of the different films is given in Kim and Najafi (2005). Typical bonding temperatures are well below 200°C for most polymers. An exception is the high-temperature stable polyimide with a bonding temperature above 250°C. While most polymers are applied by spin coating, parylene is deposited from the vapor phase (Kim and Najafi 2005). Most polymers are available in photosensitive versions, facilitating the patterning of the bonding layer. A common material choice is BCB; it features a low loss tangent, high resistivity, and low dielectric constant, making it suitable for high-frequency applications, such as RF-MEMS (see, e.g., Jourdain *et al.* 2003, Kim *et al.* 2005). Because its curing process does not involve catalysts, no outgassing occurs, which generally improves the bond quality (Oberhammer and Stemme 2004).

1.15.3.1.6 Bonding by localized heating

So far, the described wafer bonding processes were performed by heating the overall wafer sandwich to the required process temperature. Therefore, the bonding temperature must be compatible with all on-chip components, such as microstructures, metallization lines, or integrated circuitry. The resulting maximum bonding temperature can severely limit the number of possible bonding processes. However, for reliable bonding, not the overall wafer sandwich but only the actual bonding interface would have to be heated to the desired process temperature. Based on this concept, a number of bonding processes utilizing localized instead of global heating have been developed (see, e.g., Lin 2000, Najafi 2003). A conceptional schematic of a localized heating and bonding process based on resistive heating is given in **Figure 9**. A resistive heating element is integrated in the bonding area either on the substrate or on the capping wafer. After bringing the wafers into contact, the bond is performed by locally heating the bonding area with the integrated heater. Simulations show that the temperature elevation is highly confined to the heater, if it is placed on top of a thermally insulating layer (e.g., an SiO_2 film), which has been deposited on a thermally conductive substrate (e.g., silicon) attached to a good heat sink (Lin 2000). This way, temperature-sensitive components on the microsystem wafer are not affected by the potentially high bonding temperatures in the bonding area. The concept of localized heating and bonding using resistive heating elements has been demonstrated for gold–silicon eutectic bonding, silicon–glass fusion bonding, indium solder bonding, and a localized chemical vapor deposition (CVD) sealing process (Lin 2000).

It is worth mentioning that the localized heating cannot only be achieved with resistive heaters, but also by using microwave heating, laser heating, magnetic induction heating, or RF heating (Najafi 2003). This way, the need to electrically contact the chips or wafers during bonding can be avoided. However, it must be verified that only the bonding areas are heated by these indirect methods and not other microsystem components, such as metallization lines. As an example, localized magnetic induction heating of a solder joint has been demonstrated using ferromagnetic Ni–Co spacers in the vicinity of the bond interface (Yang *et al.* 2005). An induction coil in proximity to the wafer sandwich is powered by a high-frequency power supply, heating the ferromagnetic materials due to eddy current losses.

1.15.3.2 Encapsulation by Thin-Film Shells

The second way to achieve a WLP for fragile MEMS/microsystems is the monolithic thin-film encapsulation (Najafi 2003). In this case, surface-micromachining and thin-film deposition steps are

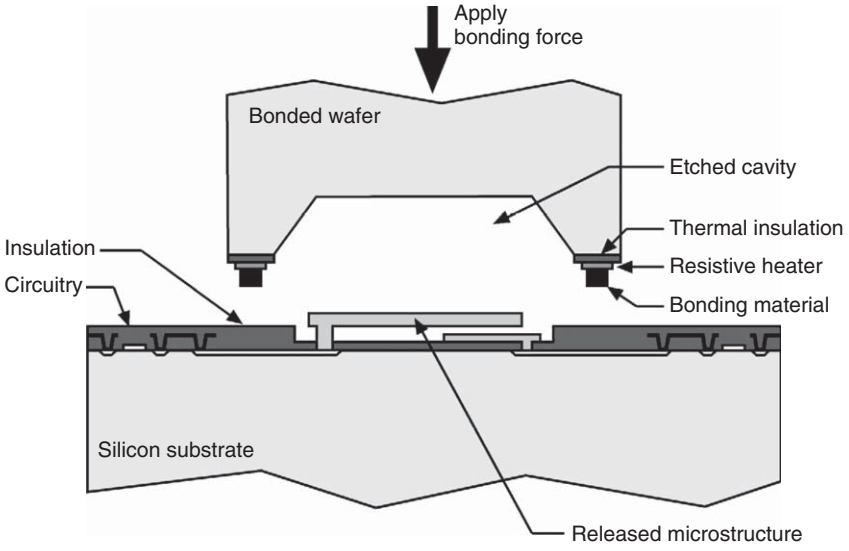

Figure 9 Conceptual schematic of wafer bonding by localized heating with a resistive heater; the heater is integrated in the bonding area of the capping wafer. (Source: Lin L 2000 MEMS post-packaging by localized heating and bonding. *IEEE Trans. Adv. Packag.* **23**, 608–16. Adapted with permission.)

combined to form a thin-film shell directly over the microstructures. These techniques avoid the processing and alignment of two wafers and eliminate the space consuming seal ring typical for wafer bonding. Early thin-film encapsulation processes were commonly developed to vacuum-encapsulate resonant microstructures (Brand and Baltes 1998) and employed polysilicon and silicon dioxide (Burns *et al.* 1995, Legtenberg and Tilmans 1994), highly and lightly p-doped silicon epitaxial layers (Ikeda *et al.* 1990), or silicon nitride and silicon dioxide (Lin *et al.* 1998) as shell and sacrificial layer material combinations. In all cases, the sacrificial layers are removed through etch channels in the shell structure, which must be sealed off in the last process step to provide a hermetic shell. Drawbacks of these processes are the involved high-temperature process steps, which limit the material choices for the microstructure itself. Moreover, the shells are typically rather thin and can be easily damaged themselves or can only be used to seal off rather small cavities.

More recent research is thus targeting fabrication processes, which use low-temperature steps only and can provide thicker shells. One possibility is the fabrication of electroplated metal shells, using photoresist as sacrificial material and electroplated nickel as structural material (Stark and Najafi 2004). With a metal shell thickness of 40 μm, 800 μm × 800 μm cavities have been hermetically sealed with a typical cavity pressure of 1.5 torr. The access channels for the sacrificial etching are sealed, e.g., with a solder plug, with the maximum process temperature being limited to about 250°C (Stark and Najafi 2004). Another recently developed process uses a porous Al_2O_3 thin film, obtained by postdeposition anodization of aluminum as shell material (He and Kim 2006). The sacrificial layer, a photoresist film, is removed though the nanopores of the shell, thus eliminating the need for larger access channels. Finally, the cavity is vacuum-sealed by depositing a low-temperature silicon nitride film over the Al_2O_3 shell. Thereby, the high aspect ratio of the nanopores prevents deposition of silicon nitride inside the cavity. The maximum process temperature is 300°C, but can be reduced by using a different sealing process. The pressure inside the cavity was found to be 8 torr (He and Kim 2006).

So far, all discussed on-chip shells were made from inorganic materials. Recently, an encapsulation method solely based on organic materials has been demonstrated for high-frequency filters and gyroscopes (Joseph *et al.* 2007, Monajemi *et al.* 2005, 2006). The process is based on the thermal decomposition of a sacrificial polymeric material, Unity 2000 (Promerus, LCC), through a solid, spin-coated polymer overcoat, Avatrel (Promerus, LCC). The sacrificial polymer is thermally decomposed at temperatures between 200°C and 300°C and the decomposition products diffuse through the solid overcoat film. Ultimately, an aluminum layer can be sputtered or electroplated over the overcoat to hermetically seal the encapsulated MEMS device (Monajemi *et al.* 2005).

The last process described in this section has been developed by the Bosch Group and Stanford University (Park *et al.* 2003) and was recently commercialized by SiTime (http://www.sitime.com) to encapsulate silicon resonators in epitaxially sealed epi-poly (epitaxially grown polysilicon) chambers buried under the wafer surface (Partridge *et al.* 2005). The MEMS-first process module completely defines, releases, and vacuum-encapsulates the resonant microstructures at the front end of the overall process sequence, providing a reliable zero-level packaging. The fabrication process is based on SOI wafers with a 10- to 20-μm-thick device layer (**Figure 10**). After defining the microstructure in the device layer by deep reactive ion etching (DRIE), an oxide layer is deposited and patterned to cover parts of the microstructure while providing openings for electrical contacts. A thin epitaxial silicon layer is grown and patterned to obtain openings to the oxide layer. After releasing the microstructure by sacrificial layer etching through the openings in the epi-silicon layer, the resonator chamber is sealed by growing a thick epitaxial silicon layer. Thereby, the epitaxial silicon growth yields polycrystalline silicon on top of the oxide layer covering the microstructures, but single-crystalline silicon where the oxide has been removed, i.e., in the potential circuit regions. After surface planarization and formation of contact isolation trenches, the wafers with encapsulated MEMS structures can be used as a starting material for a CMOS process (Partridge *et al.* 2005).

1.15.4 First-Level Packaging for Microsystems

Like conventional microelectronics packaging steps, the first-level packaging steps for microsystems include wafer dicing, die attach, and electrical interconnect formation. Depending on the previous fabrication steps, the wafers entering the first-level

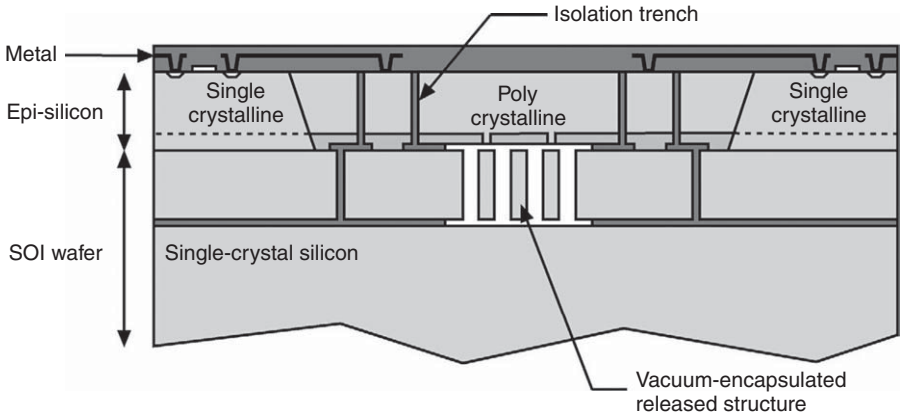

Figure 10 Cross section of EpiSeal technology by SiTime for fabrication of vacuum-encapsulated silicon resonators. (Source: Partridge A, Lutz M, Kim B, Hopcroft M, Candler R N, Kenny T W, Petersen K, Esashi M 2005 MEMS resonators: getting the packaging right. *Proc. 9th SEMI Microsystem/MEMS Seminar*, Semicon, Japan.)

packaging sequence might contain nonreleased microstructures, released and uncapped microstructures, released and capped microstructures, or no microstructures at all. While designing a particular process flow, one must consider that all process and testing steps after dicing are typically performed in a serial manner rather than the cost-effective wafer-scale batch processing. This way, if dicing is done before the final microstructure release in order to protect fragile mechanical structures, the final release step will have to be performed on a single-die level. To maintain the cost advantages of batch processing, the wafer dicing should be done as late as possible in the process flow; as an example, various manufacturers first perform device testing or even trimming steps on the wafer level before dicing.

The first-level package type is determined to a great extent by application and cost considerations: metal and ceramic packages provide a hermetic encapsulation, but are typically more expensive. Molded plastic packages and COB technologies, on the other hand, are more cost-effective packaging solutions if hermeticity is not required.

1.15.4.1 Dicing, Die Attach, and Interconnect

A dicing saw employs a high-speed spindle fitted with a thin diamond blade to dice the wafers. Water jets are used to cool the blade and remove dicing debris. The combination of these water jets and dicing debris can be a major challenge for wafers with released, fragile microstructures. Typically, thin, surface-micromachined microstructures are more prone to dicing damage than bulk-micromachined membrane structures. While the dicing yield can potentially be increased by reducing dicing speed and water pressure, the protection of fragile microstructures during dicing or a microstructures release after dicing might be required.

Several approaches to protect released microstructures during dicing have been discussed in the literature. Analog Devices has devised a backside sawing process for wafers containing released microstructures (Chau and Sulouff 1998). In this process, the wafer with released microsystems is mounted upside down onto a two-layer dicing tape. The top layer has punched openings at the location of the microstructures, thus providing protective air pockets during the dicing and cleaning process. A modified pick-and-place tool is then used to pick up the individual chips for die attach. Alternatively, fragile microstructures can be protected by coating the frontside and backside of the wafer with a protective film, e.g., a photoresist layer, before the sawing process (Agarwal *et al.* 2005). After dicing, the organic films are removed with a conventional resist stripper, washing away most of the sawing debris at the same time. Texas Instruments have implemented a different procedure to singulate their large Digital Micromirror Devices (DMD™) with hundreds of thousands of individual micromirrors (Mignardi 1998): before the mirror release, a protective layer is placed on top of the mirror level, the wafers are partially sawn and subsequently cleaned to remove sawing debris. Still on a wafer

level, the surface-micromachined mirror arrays are now released by removing the organic sacrificial layers in a dry etching step and subsequently tested in a wafer tester. Once the wafer-level tests are completed, the wafers are broken along the partially sawn scribe kerfs to separate the individual functional die.

Dicing of wafers with microstructures that have been capped in a zero-level packaging process is usually less critical. Here, the sawing process has to ensure access to the bonding pads, which might be covered by the capping wafer. In the case of wafer bonding with an intermediate layer, subsequent sawing steps with different sawing depths can individualize the wafer and provide access to the bond pads.

If wire bonding is used for the electrical interconnect formation, the individual dies are attached to the substrate/package after dicing. This can be done by a standard pick-and-place machine, equipped with a special pick-and-place tool to handle chips with released microstructures on their surface. In order to minimize packaging-induced stresses acting on the MEMS part, the soft die attach adhesives with a low modulus of elasticity are widely used. The die attach is followed by a conventional wire bonding process (Section 1.15.2.2). Alternatively, the microsystem can be attached and electrically connected to the substrate/package by flip chip bonding techniques. An example of this approach in the area of chemical sensors is presented in Section 1.15.4.5.

1.15.4.2 Windows to the Outside World

Unlike ICs, most MEMS interact with their environment. Therefore, not only electrical signals need to be routed through the package, but also information from other energy domains: a pressure sensor package must be able to transmit the pressure information to the actual sensor element and a chemical sensor package must provide access to the sensing elements for the analytes of interest. As discussed earlier, the need for windows to the outside world while still providing the typical packaging functions, in particular protection, is one of the major challenges for microsystem packages. Unfortunately, there is typically no *one size fits all* solution and the actual package for the same sensor might look completely different for two applications. A good example in this respect is the pressure sensor, where manufacturers typically offer a wide range of different packages for the same pressure range. Possible variations include through-hole and surface-mount packages, differential and absolute pressure sensors, shape and size of the pressure ports, and the way the actual silicon sensing element is protected. To illustrate this, **Figure 11** compares the schematic cross sections of two pressure sensors from opposite sides of the application spectrum: on the one hand, we have a low-cost pressure sensor in a premolded plastic package (**Figure 11(a)**), in which the sensor element and the wire bonds are protected by a silicone gel; on the other hand, we have a media-compatible pressure sensor (**Figure 11(b)**), in which a flexible steel membrane transmits the pressure into an oil-filled cavity containing the actual sensing element. In the following, a number of different windows or filters, transparent for the particular physical quantity of interest but opaque for others, are briefly discussed. The subsequent subsections then give examples of how such filters are integrated with various package types.

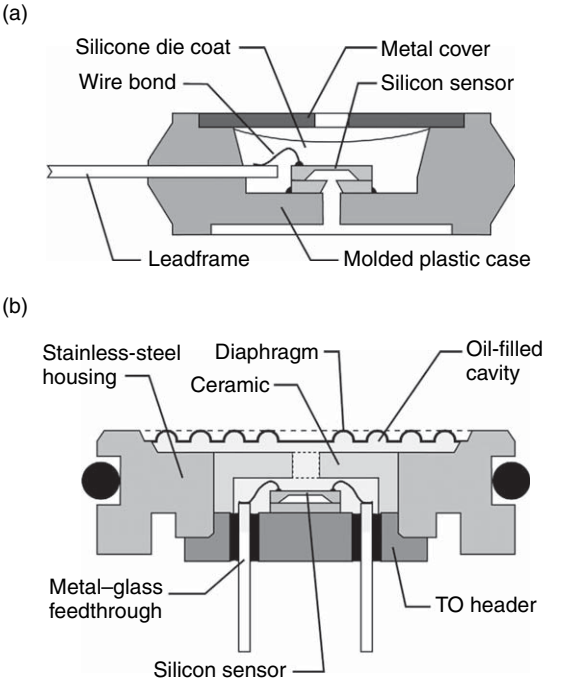

Figure 11 Schematic cross section of (a) low-cost pressure sensor in premolded plastic package. (Source: *Sensor Device Data*, Freescale Semiconductor, Rev. 6.1, 07/2005. Adapted with permission.) and (b) media-compatible pressure sensor embedded in oil-filled stainless-steel cavity bound by flexible membrane. (Source: Datasheet: Series 3L to 10L Pressure Transducers, Keller AG, Winterthur, Switzerland. Adapted with permission.)

Various optical windows are available for handling radiant signals. These windows/filters can be incorporated in metal or ceramic packages (see Section 1.15.4.3), thus providing hermetic microsensor packages. While standard optical glass is transparent in the visible wavelength regime, quartz glass is used to extend the transparent wavelength range into the UV range down to about 200 nm. On the other side of the visible spectrum, semiconductor filters, such as germanium and silicon, are transparent for wavelengths longer than about 1–2 μm, well suited for infrared sensing applications.

In the mechanical domain, the above-mentioned steel membrane or silicone gel are transparent for the pressure information, but protect the microsensor to a different extent from other influences. In particular, the media-compatible pressure sensors provide a hermetic package while still being able to transmit the pressure signal from the environment to the sensing element. Other common mechanical filters are meshes made from stainless steel or polymers, which can be used to protect the sensor element from direct physical contact, while providing access to the environment in, e.g., chemical sensing applications (see, e.g., Figaro gas sensors, http://www.figarosensor.com).

In the chemical domain, filters can reduce the influence of interference molecules on a chemical measurement. As an example, Figaro uses an active carbon filter in its TGS 2442 carbon monoxide sensor and a zeolite filter in its TGS 4161 carbon dioxide sensor to reduce the influence of interference gases (Product Information Sheets: TGS 2442 Carbon Monoxide Sensor and TGS 4161 Carbon Dioxide Sensor, Figaro USA Inc., 2000 and 2003). Zeolites are known to act as molecular sieves because of their microporous structure, while active carbon with its huge surface area efficiently adsorbs, e.g., volatile organic compounds, in the case of the Figaro sensor in particular ethanol.

It is worth noting that the package cannot only provide filtering functions, but also can concentrate the signal of interest. Examples are lenses for radiant signals, flow channels with varying cross-sectional areas to locally increase the flow velocity in mass flow sensors, or ferromagnetic concentrators to concentrate a magnetic field at the location of the sensor. In Popovic *et al.* (2006), such ferromagnetic elements change not only the magnitude but also the direction of the magnetic field, such that a magnetic induction in the plane of the chip can be sensed by conventional lateral Hall elements, sensitive only to field components perpendicular to the chip surface.

1.15.4.3 Metal and Ceramic Packages

Metal and ceramic packages are high-reliability packages, which are especially suited for harsh environments and are thus widely used for military applications. Both package types are considered hermetic and provide a cavity for the microsystem chip. As a result, they are mainly used for uncapped microsystems requiring a hermetic or even vacuum package. Metal and ceramic packages consist of a bottom part or header and a top part or lid. The cavity of a metal package is sealed by welding, soldering, or brazing the lid onto the header. Ceramic packages, on the other hand, frequently use glass frit seals, i.e., low melting temperature glasses with typical process temperatures around 350–400°C. While metal packages are generally through-hole components utilizing metal–glass seals to electrically insulate the individual feedthroughs, both through-hole and surface-mount ceramic packages are widely available.

TO packages are arguably the most common metal packages. Originally used to package single transistors or small circuits, they are widely used today for packaging small- and medium-volume microsystems. Companies such as Schott (http://www.schott.com) offer a wide range of TO headers with different sizes, pin layouts, and up to 16 I/O pins. Even more important for microsystem packaging, TO headers with additional nonelectrical ports are readily available; examples include headers with pressure ports or lids with embedded optical filters, lenses, or metal meshes. **Figure 12** shows a schematic of a TO package as well as images of a chemical sensor by Figaro (http://www.figarosensor.com), an accelerometer by Colibrys (http://www.colibrys.com), and an infrared sensor by Melexis (http://www.melexis.com). Figaro packages all of its chemical sensors in TO packages, generally using a lid with a metal mesh to protect the microsystem. As mentioned earlier, the carbon monoxide sensor TGS 2442 and the carbon dioxide sensor TGS 4161 feature chemical filters, which are integrated into the lid. In case of the MS7000 series accelerometers of Colibrys (Datasheet MS7000 series MEMS Capacitive Accelerometers, Colibrys, Switzerland, 2004), the TO package houses a small ceramic substrate carrying the sensor chip, an ASIC with the readout circuitry and an electrically erasable programmable read-only memory (EEPROM) chip.

Media-compatible pressure sensors, as discussed briefly in Section 1.15.4.2, are often based on TO

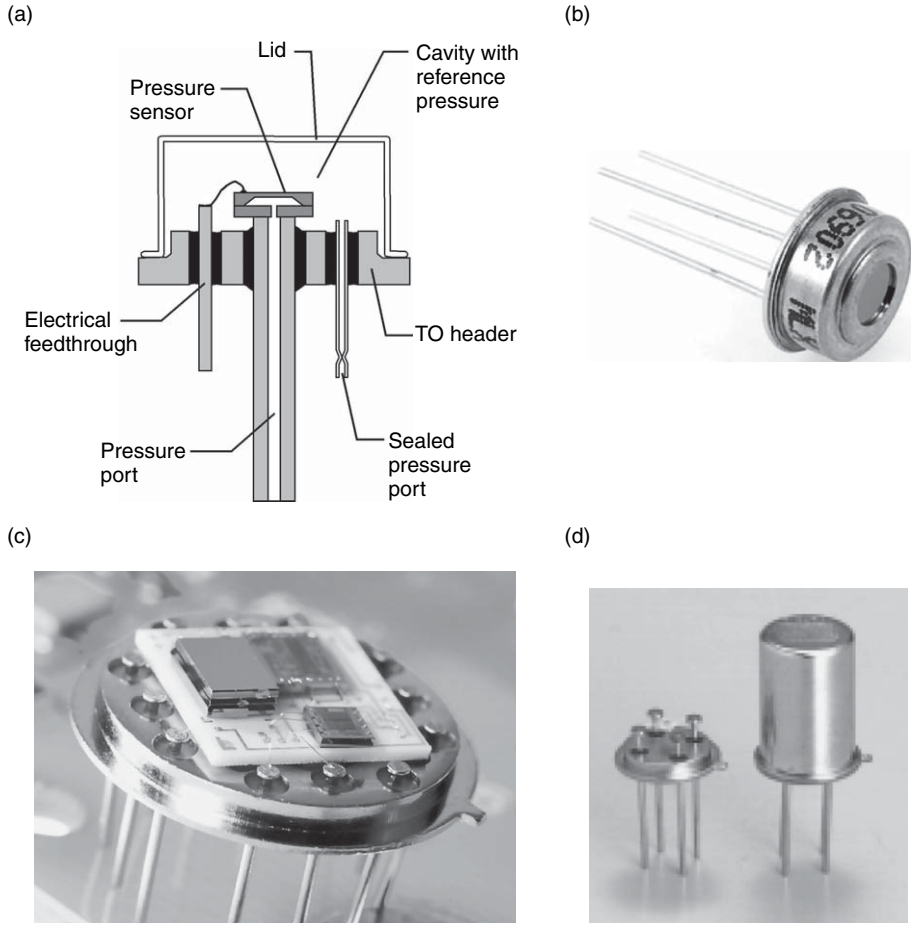

Figure 12 Examples of microsensors packaged in transistor outline (TO) packages. (a) Schematic cross section of TO package with pressure ports and mounted pressure sensor; (b) MLX90247 family of infrared thermopile sensors by Melexis. (Photo courtesy: Colibrys SA, Neuchatel, Switzerland); (d) TGS 4161 Carbon dioxide sensor by Figaro Engineering Inc. (Photo courtesy: Figaro USA, Glenview, IL, USA.)

packages (**Figure 11(b)**). Examples are the series 3L to 10L piezoresistive pressure transducers by Keller (http://www.keller-druck.com): each transducer features a piezoresistive pressure sensor, which is die and wire bonded to a TO header with glass–metal feedthroughs. The header is welded to a stainless-steel housing, which is filled with silicone oil and bound by a thin, laser-welded stainless-steel diaphragm. The diaphragm transmits the media pressure to the oil inside the cavity and, finally, to the silicon pressure sensor.

A large variety of metal and ceramic packages for special applications, in particular optoelectronic components such as fiber-optic transmitter/receiver modules, are available from, e.g., Kyocera (http://www.kyocera.com) and Schott (http://www.schott.com). These packages provide fiber-optic feedthroughs in addition to high-frequency electrical feedthroughs.

In contrast to metal packages, ceramic packages feature thermal expansion coefficients (CTE) that are better matched to those of silicon, helping to reduce packaging-induced stresses. Apart from this, they provide most of the advantages of metal packages, such as excellent mechanical strength, good thermal conductivity (especially in case of aluminum nitride (AlN)), heat durability, and hermeticity. The most common ceramics used in ceramic packaging technology are Al_2O_3, AlN, and low-temperature cofired ceramics (LTCC). LTCC are typically provided as sheets and consist of ceramic particles mixed with an organic binder. Multilayer ceramic circuit boards are manufactured using LTCC by laminating together individual sheets with filled through-holes and printed conductive lines

and cofiring the assembly at firing temperatures around 850°C (Tummala 2001). The cavity of a ceramic package is sealed by either a metal or a ceramic lid. Sealing with a solder system (typical process temperatures of 300–320°C) or a glass frit (typical process temperatures of 320–430°C) provides a hermetic package. If hermeticity is not required, the lid can be attached using an epoxy at a lower temperature between 120°C and 200°C. While through-hole ceramic packages, such as ceramic DIPs, are still widely used in research laboratories, leaded and leadless surface-mount packages dominate most commercial microsystems requiring ceramic packages, because of their compatibility with state-of-the-art circuit board assembly techniques.

Figure 13 shows a cross section of a typical leaded ceramic cavity package, as well as a photograph of a packaged gyroscope by Analog Devices (http://www.analog.com). Analog Devices packages its noncapped, high-volume micromachined accelerometers and gyroscopes in a variety of hermetic ceramic packages, including ceramic LCCs, ceramic LGAs, and ceramic BGAs (see http://www.analog.com/imems). The accelerometers and gyroscopes feature either polycrystalline or single-crystalline silicon sensing structures and are cointegrated with signal processing circuitry on a single chip (Judy 2004).

The DMD, developed and commercialized by Texas Instruments, is arguably one of the most complex MEMS devices. It features an array of 16 µm × 16 µm micromirrors fabricated on CMOS SRAM (static random access memory) cells (Mignardi 1998) and is used for image formation in a wide variety of projection displays. Depending on the image format, a DMD consists of up to 2 million individual mirrors, namely 1920 × 1080 pixels for high-definition television (HDTV) applications. The ceramic packages used to protect these delicate MEMS structures are described in Farris and Kocian (1998). The hermetic package for SVGA, XGA, and SXGA versions of the DMD chip is based on an Al_2O_3 header in a 114-pin LGA format (see schematic cross section in **Figure 14(a)**). A brazed Kovar (29%Ni/54%Fe/17%Co) seal ring forms the cavity for the DMD chip, which is die and wire bonded to the header with an adhesive and gold wire bonds, respectively. The lid consists of a stamped Kovar frame plated with gold/nickel and a projection-quality optical window with a hermetic glass-to-metal seal.

The hermetic window assembly is coated with antireflection coatings and finally seamwelded to the seal ring on the ceramic header, forming a hermetic package. Getter strips are mounted inside the hermetic cavity to getter residual gas molecules. Finally, a heat sink is attached with an adhesive to the ceramic header. All materials have been carefully chosen in order to minimize packaging-induced stresses acting on the mirror array. Besides describing the hermetic package, Farris and Kocian (1998) describe a nonhermetic package solution, in which the optical window is attached to the Kovar frame using an adhesive. A photograph of a packaged 1920 × 1080 pixel DMD chip is depicted in **Figure 14(b)**.

1.15.4.4 Molded Plastic Packages

We saw earlier that the number of different plastic packages for ICs is ever increasing and it can be challenging to keep up with all the designs and abbreviations. Luckily, most plastic packages used for MEMS have relatively low pin counts and are, thus, leadframe based. To package an IC using a leadframe-based package, the die is commonly die- and wire-bonded onto the leadframe, followed by molding a plastic compound, typically an epoxy, around the chip and wire bonds. Finally, the leads of the leadframe are formed to the desired shape. In case of packaging MEMS, we are typically facing two challenges:

(1) The released mechanical structures are possibly blocked during the molding process.
(2) Micromechanical devices are typically more sensitive to (packaging-induced) mechanical stresses than are ICs.

As a result, not only postmolded plastic packages, i.e., packages where the leadframe–chip assembly is encapsulated with the plastic mold after die attach, but also the so-called premolded plastic packages, which provide a cavity for the microsystem, are frequently used in microsystem packaging.

With a few exceptions (some of them are discussed below), postmolded plastic packages are used to package capped microsystems, i.e., microsystems where the fragile micromechanical structures have been protected by a zero-level packaging process, such as the wafer bonding processes described in Section 1.15.3. In this case, the capped microsystem can be handled just like any other IC and is die- and wire-bonded onto the leadframe and then inserted into a multicavity mold. In a transfer molding press, the hot, liquid molding compound is then transferred through so-called runners in the mold into the cavities surrounding the leadframe–chip assemblies. **Figure 15** shows a cross section

through a leadframe-based postmolded plastic package, as well as a photograph of a postmolded accelerometer from the Bosch Group (http://www.bosch.com). Freescale Semiconductor (formerly Motorola) uses a similar packaging approach for its surface-micromachined accelerometers (Frank *et al.* 1994). In both examples, the capped accelerometer sensor is mounted together with an interface circuit chip on a common leadframe. Electrical interconnects from sensor chip to circuit chip and from circuit chip to the package are made by wire bonding. **Figure 7(b)** shows the Freescale accelerometer after die and wire bonding to the leadframe but before the molding process. In contrast, **Figure 15(b)** shows the packaged Bosch accelerometer after transfer molding with part of the mold removed to illustrate the location of the sensor and circuit chip (Marek 1999). The encapsulation of the die with a transfer mold, paired with the different thermal expansion coefficients of the involved materials, generally results in considerable mechanical stress acting on the packaged silicon chips. To make things worse, the stress distribution is generally not uniform over the microsystem chip, potentially resulting in sensor offsets due to, e.g., piezoresistive effects. To obtain a more uniform stress distribution across the packaged chip, it can be encapsulated with an elastomer, e.g., a silicon gel or a polyimide resin, before the transfer molding process. Amkor Technology calls this process a Gel Dome (MEMS Technology Solution Sheet, Amkor Technology, 2005) and offers the possibility that the gel is in contact with the environment through an opening in the mold. The flexible elastomer inside the plastic package exerts a more or less uniform hydrostatic pressure on the microsystem chip. Microsystems relying on resistive sensing elements, such as Hall sensors or piezoresistive pressure sensors, are particularly sensitive to nonuniform packaging-induced stresses. The influence of a uniform hydrostatic stress on the output signal, i.e., the sensor offset, can be minimized using, e.g., Wheatstone bridge arrangements or dynamic offset compensation techniques.

While capped inertial sensors, i.e., accelerometers and gyroscopes, can be completely encapsulated within a molding compound and are still able to sense inertial forces, many other microsystems require nonelectrical feedthroughs to be able to sense the quantity of interest. This raises the question whether a postmolded plastic package can be outfitted with a pressure port or an optical window. The answer is actually Yes in both cases. As an example, SensoNor (now Infineon Technologies SensoNor AS, http://www.sensonor.com) has developed a packaging technology for its pressure sensors, which provides a pressure port in a postmolded plastic package (Grelland *et al.* 1999). In this approach, glass wafers are anodically bonded to both sides of the silicon sensor chip. One glass wafer features recesses to form the reference (vacuum) cavity on the topside of the micromachined silicon membrane. The glass wafer attached to the bottom features a through-hole that is aligned with an opening in the leadframe during the die attach. A pressure port is now formed during the transfer molding process by pressing a special molding tool directly onto the leadframe. **Figure 16** shows schematics

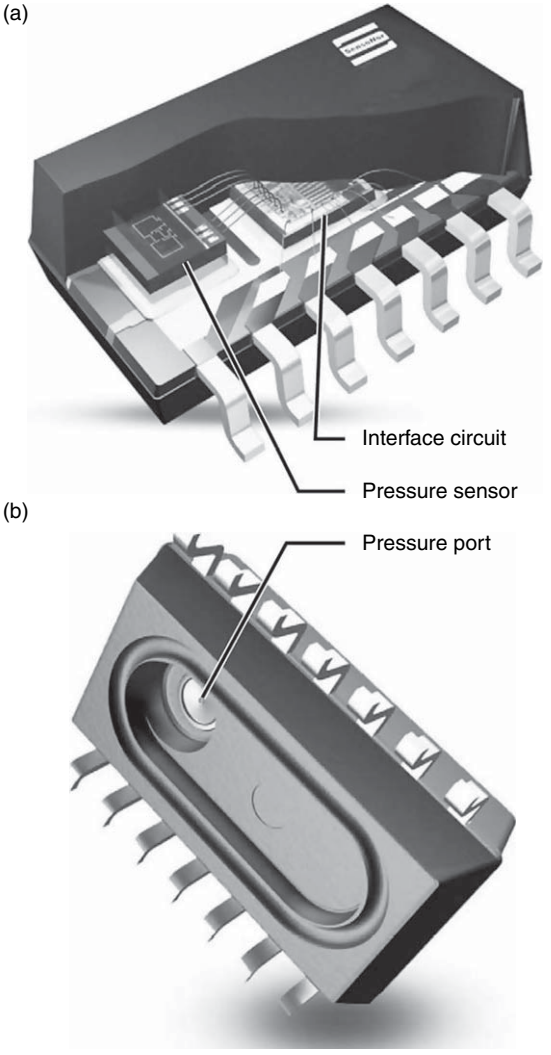

Figure 16 Pressure sensor by Infineon Technologies SensoNor AS packaged in postmolded small outline package. (a) Schematic of packaging concept with triplestack sensor chip and interface circuitry, die and wire bonded to leadframe; (b) Schematic of postmolded pressure sensor package with pressure access port. (Images courtesy: Infineon Technologies SensoNor AS, Horten, Norway.)

of the SP12 pressure sensor package by Infineon Technology SensoNor AS with the pressure port (depending on the actual sensor type located on either the bottom or the top of the surface-mountable SOIC package). Similar technologies have been described by Bossche *et al.* (1997) and are commercially offered by ELMOS Advanced Packaging (formerly Eurasem) (http://www.elmosap.nl) for packaging optical sensors (with an optional optical window), pressure sensors, and mass flow sensors.

The alternative to providing window options in postmolded plastic packages is the use of premolded plastic packages with a cavity for the sensor chip. In a premolded plastic package, the leadframe is partially surrounded by a molded plastic compound, providing a cavity for (uncapped) microsystem chips and access to the chip pad and bond pads for die attach and wire bonding. Premolded plastic packages are basically low-cost versions of the ceramic cavity packages discussed earlier for application that do not require a hermetic encapsulation. Compared to the postmolded plastic packages, microsystems assembled in premolded plastic packages benefit from a simpler, thus less expensive packaging process, are less sensitive to mechanical stress, but lack the possibility of protecting the wire bonds and parts of the chip with the molding compound. Typically, premolded plastic packages are used for pressure sensors, with the sensor chip and wire bonds protected by a silicone gel and/or a plastic lid closing the cavity. **Figure 17** shows a schematic cross section of a premolded plastic package and photographs of pressure sensors from Infineon Technologies (http://www.infineon.com), Silicon Microstructures (http://www.si-micro.com), and Freescale Semiconductor (http://www.freescale.com).

1.15.4.5 Chip on Board

Using COB technologies, bare silicon dies are directly attached to (multilayer) laminate polymer or ceramic circuit boards. Electrical interconnections are done either by wire bonding or by flip chip bonding. In case of ICs, a glob top material, typically an opaque epoxy, dispensed over the chip, finally protects the bare die and the wire bonds. Using COB, bare silicon chips can be mounted together with active and passive surface-mount components on a PCB, effectively skipping the conventional first-level package of the IC. Microelectronic components fabricated this way are nonhermetic, but very cost-effective. In recent years, COB techniques are also used more and more as the base of first-level packages. The main advantage is that not single

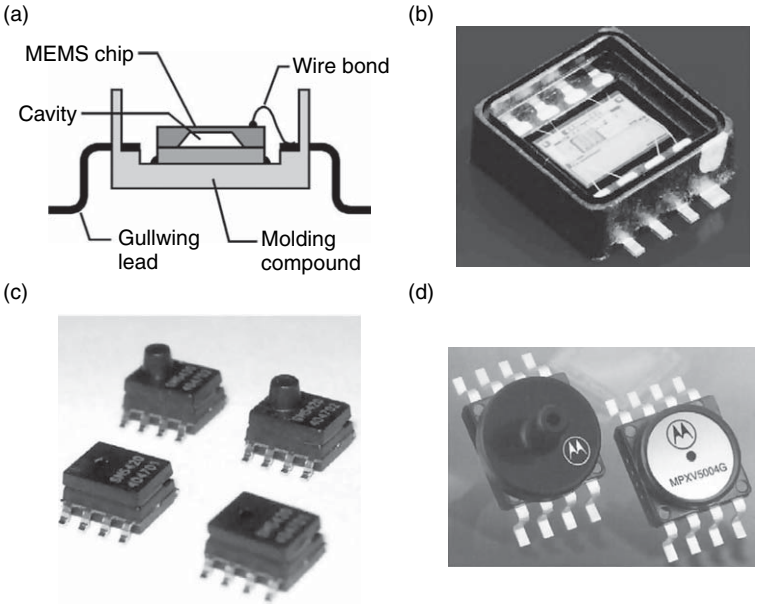

Figure 17 (a) Schematic cross section through premolded plastic package; photographs of pressure sensors packaged in premolded plastic packages: (b) KP100 side crash pressure sensor by Infineon Technologies. (Photo courtesy: Infineon Technologies, Neubiberg, Germany.); (c) SM5420 series pressure sensors by Silicon Microstructures. packages but a large-area polymer or ceramic sheet containing arrays of packages are processed. This way, quasi batch processing can be extended through part of the packaging process flow. It should be noted that the substrates are populated in pick-and-place machines that can handle both packaged and bare dies in a serial manner, and that processing a large substrate omits the time-consuming feeding and alignment of individual packages; this is not only true for package processing but also for device testing. Examples of microsensor packages employing COB technologies (**Figure 18**) include the MS5534 pressure sensor modules by Intersema (http://www.intersema.com), the SHT1x series humidity sensors by Sensirion (http://www.sensirion.com), and silicon-based microphones in SMT packages by Knowles (http://www.knowlesacoustics.com) and Infineon Technologies (http://www.infineon.com).

In the following, the package process flow for the MS5534 barometric pressure sensor module (**Figure 18(a)**) developed by Intersema (http://www.intersema.com) will be described in more detail (Datasheet MS5534B Barometer Module, Intersema Bevaix, Switzerland 2005). The module is a hybrid SMD comprising the silicon pressure sensor element and an interface IC on a common ceramic substrate. The interface chip also stores six calibration parameters for a software calibration performed in an external microcontroller. Communication between the sensor module and the microcontroller is achieved by a three-wire digital interface. The packaging process flow (World of Microsystems, multi-media CD-Rom, 1st edn., http://www.fsrm.ch 2000) starts with the preparation of the ceramic substrate by screen-printing conductive and dielectric thick-film patterns. Each ceramic substrate actually holds 81 sensor modules in a 9×9 array pattern. Next, the sensor die, a piezoresistive silicon pressure sensor, which is anodically bonded to a Pyrex wafer under vacuum, and the interface IC chip are die attached to opposite sides of the ceramic substrate. After wire bonding sensor and interface circuit chips, the application-specific integrated circuits (ASICs) are protected by dispensing and curing a glob top material. Next, metal rings surrounding the sensor chips are attached to the ceramic carrier and a soft gel is dispensed to protect the sensor chip from humidity. Then, the modules are calibrated in a pressure chamber at different temperatures and the calibration coefficients are stored in the interface ICs. Finally, the ceramic carriers are individualized.

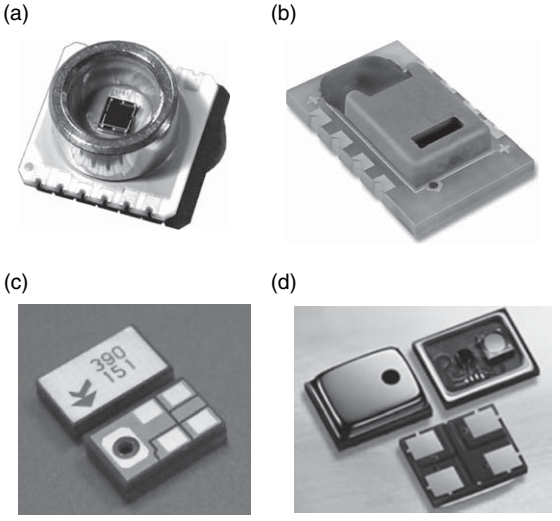

Figure 18 Examples of microsensor packages relying on chip-on-board technologies: (a) MS5534 pressure sensor by Intersema. (Photo courtesy: Intersema, Bevaix, Switzerland.); (b) SHT1x series humidity sensor by Sensirion (Photo courtesy: Sensirion AG, Staefa, Switzerland.); (c) SiSonic microphone by Knowles Acoustics. (Photo courtesy: Knowles Acoustic, Itasca, IL, USA.); (d) Silicon MEMS microphone SMM 310 by Infineon Technologies. (Photo courtesy: Infineon Technologies, Neubiberg, Germany.)

Sensirion's (http://www.sensirion.com) humidity/temperature sensor series SHT1x uses a similar packaging approach based on polymeric instead of ceramic substrates (Datasheet SHT1x/SHT7x, Sensirion, Staefa, Switzerland, 2005). The SHT1x is a single-chip sensor module comprising a polymer-coated capacitive humidity sensor, a bandgap temperature sensor, on-chip readout circuitry with a 14-bit analog-to-digital converter (ADC), and a serial interface. Calibration coefficients are programmed into one-time-programmable (OTP) on-chip memory. The CMOS chip is die and wire bonded to a standard FR4 polymer substrate and protected by a liquid crystal polymer (LCP) cap and a partial epoxy glob top. The SHT1x sensor module is, thus, supplied in a surface-mountable package, similar to a LCC (**Figure 18(b)**).

Figure 19 shows a packaging concept based on flip chip bonding developed at ETH Zurich, Switzerland, for CMOS-based chemical gas sensor arrays (Koll *et al.* 1998, Song *et al.* 2002). A similar concept has been implemented previously for the encapsulation of thermal flow sensors (Mayer *et al.* 1997). The chemical sensor array is based on a single-chip microsystem featuring three chemical sensor

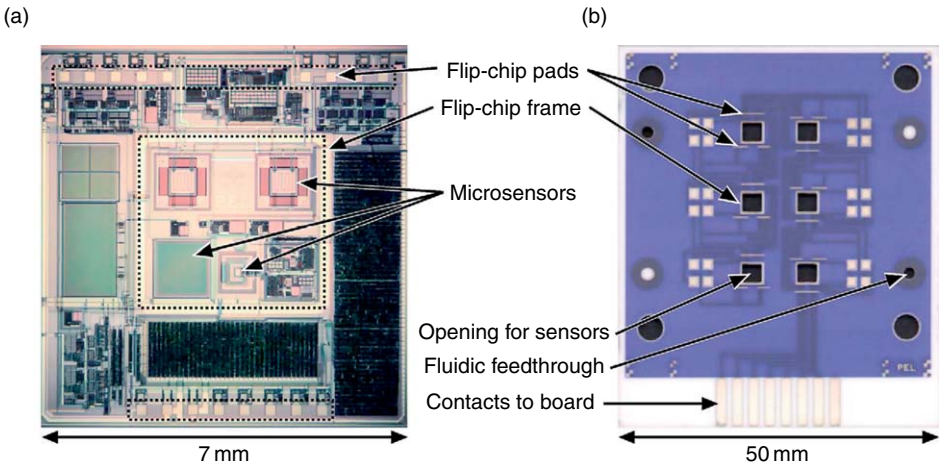

Figure 19 Flip chip packaging concept for chemical sensor microsystem developed at ETH Zurich, Switzerland. (a) Photograph of complementary metal oxide semiconductor (CMOS)-based chemical sensor array with flip chip seal ring and bond pads; (b) Ceramic substrate for flip chip attachment of six sensor chips. (Song *et al.* 2000)

types cointegrated with sensor driving circuitry, readout circuitry, analog-to-digital conversion, and a digital interface (Hagleitner *et al.* 2001). The three transducer elements, a capacitive sensor, a calorimetric sensor, and a mass-sensitive sensor, are each coated with a chemically sensitive polymer to detect volatile organic compounds (VOCs) in air samples. To improve the selectivity of the chemical sensing system, six CMOS chips with a total of 18 chemical sensors are combined on a ceramic substrate, with the sensors of each chip coated by a different polymer. The chip layout (**Figure 19(a)**) has been optimized for the flip chip packaging: the three sensing elements are located in the chip center and are surrounded by an aluminum frame. The on-chip electronics and most of the sensor references are located along the perimeter of the die. Due to the on-board digital interface, the number of I/Os could be substantially reduced and the flip chip pads are located along two edges of the chip. After processing the microsystems in a commercial CMOS process, the flip chip pads and the metal frame surrounding the sensing elements were coated with an electroless nickel/gold (5 µm Ni and 50 nm Au) UBM provided by the bumping service of PacTech, Nauen, Germany, to prepare for the flip chip bonding. After the UBM deposition, the sensor structures are mechanically released using bulk micromachining techniques (Hagleitner *et al.* 2002). Finally, the wafers are diced in a regular wafer saw operated with a reduced water pressure.

Figure 19(b) shows the 50 mm × 50 mm × 0.7 mm ceramic (Al_2O_3) substrate used for the packaging concept (Song *et al.* 2002). Palladium–silver conductor lines and a dielectric layer for electrical insulation were screen printed onto the substrate. The six openings cut into the substrate with a Nd:YAG laser mark the locations for the six microsensor chips. The openings have the size of the sensor area in the center of the chip and are used to expose the microsensors to the air sample. To this end, a fluidic network is attached to the back of the ceramic substrate, pumping the air sample across the polymer-coated sensor surfaces. At the same time, the ceramic substrate protects the circuitry components surrounding the sensor area. A hermetic seal can be achieved by soldering the metal frame surrounding the sensors to a mirror structure on the ceramic carrier during the flip chip bonding process. To prepare for the bonding process, $Sn_{62}Pb_{36}Ag_2$ solder paste is stencil printed onto the flip chip pads on the processed Al_2O_3 substrate. The microsensor chips are placed onto the substrate using a fine placer (or a pick-and-place machine in an industrial environment) and the solder is reflown in a computer-controlled furnace at a peak temperature of 215°C. Subsequently, an epoxy-based underfill is applied and cured to protect on-chip circuitry and solder interconnects and reduce thermal stresses acting on the interconnects. Because of missing capillary forces, the underfill does not flow onto the sensor structures within the openings in the ceramic substrate.

1.15.5 Conclusion: Automation and Cost Issues

After reading through this chapter, the reader might ask where the small outline package for the microsystems/MEMS field is, the first-level package that is good for one-third or even one-half of the microsystem chips. Obviously, such a package does not exist yet and it is highly questionable whether it will ever exist. The requirements for the package are just too different for the various microsystem applications. An RF-MEMS package requires materials and processes that are compatible with high-frequency applications, e.g., low-loss encapsulants with low dielectric constants and electrical interconnects based on flip chip bonding rather than wire bonding. A BioMEMS package might require, in the first place, biocompatible materials and processes that efficiently protect the microsystem from aggressive media. The focus for a microfluidic package might be on the side of standardized microfluidic interconnects and, finally, for an optical MEMS (MOEMS) package, the quality of the optical window or optical interconnect is decisive.

Having said that, the author still likes to acknowledge efforts toward modular packages for microsystems (Schuenemann *et al.* 2000, Ucok *et al.* 2005). System modularity can help reduce system cost, but modular packages will likely target certain application areas, such as microfluidics or optical MEMS. In such a given application area, customer-specific packages might only differ in a limited number of specifications, which can be accounted for in a modular approach. An example of a modular packaging concept is Match-X (http://www.match-x.org), which has been developed in Germany especially for microsystem applications with small- to medium-scale production volumes (Schuenemann *et al.* 2000). Match-X consists of a set of building blocks in the form of BGA packages, which are vertically integrated by standard SMT soldering processes. The building blocks are associated to different microsystem components, such as a pressure sensor, a microcontroller, a microfluidic component, or an MOEMS part. Besides electrical interfaces from level to level, optical and fluidic interconnects are also provided in the walls of the BGA packages. By stacking a set of building blocks on top of each other, a microsystem for a particular application can be built. Different customer needs now only might require the exchange of one particular building block. The individual building blocks can be built from LTCC carriers or from a combination of flexible polyimide-based layers and rigid FR4 layers (Schuenemann *et al.* 2000).

What are other ways to reduce packaging cost? First of all, think about the package at an early stage and design the package together with the MEMS/microsystem chip, making it an integral part of the microsystem. This might seem obvious, but it is more often not done than one might think. Just keep in mind that only about 15% of the microsystems/MEMS publications published over the past 20 years mention the word packaging or package in their searchable abstract. Considering the package needs at an early stage can result in small chip design changes that can reduce packaging cost substantially, because suddenly a standard rather than a custom package can be used. In some cases, parts of the microsystem functionality can be embedded into the package or the package might form the microsystem altogether. A good example along these lines are the recently developed medical pressure sensors that are implemented with standard packaging processes (Allen 2005, Fonseca *et al.* 2006).

Lastly, process automation and batch fabrication should be used wherever possible. WLP processes in the microsystems but also the microelectronics field illustrate this trend of extending batch processing into the packaging and testing process flow, dicing the wafer as late as possible in the packaging sequence. As mentioned earlier, not only wafers benefit from batch processing, but also large-area polymeric and ceramic panels holding arrays of microsystems. The need for automation does not end with first-level packaging, but also applies to the subsequent board assembly (second-level packaging). State-of-the-art board assembly is performed in pick-and-place machines that can handle single-chip packages, passive components, and bare dies for COB. If the microsystem is to be mounted on the board as well, it should be compatible with standard surface-mount assembly processes. A very good example in this respect are silicon-based capacitive microphones that have been commercialized by Knowles Acoustics (http://www.knowlesacoustics.com), Akustica (http://www.akustica.com), and Infineon Technologies (http://www.infineon.com) to replace conventional electret condenser microphones in high-volume applications, such as cell phones. A main selling point of this new generation of microphones is not necessarily a better performance compared to the electret

condenser microphones, but the fact that they are surface-mountable, thus withstanding the lead-free solder reflow cycles of standard board assembly processes (Loeppert and Lee 2006). This advantage leads to significant cost savings for the system integrator.

Biography

Dr. Brand is an Associate Professor in the School of Electrical and Computer Engineering at the Georgia Institute of Technology. He received his diploma degree in Physics from Technical University Karlsruhe, Germany in 1990 and his Ph.D. degree from ETH Zurich, Switzerland in 1994. From 1995 to 1997, he worked as a postdoctoral fellow at the Georgia Institute of Technology. From 1997 to 2002, he was a lecturer at ETH Zurich in Zurich, Switzerland and deputy director of the Physical Electronics Laboratory (PEL).

Dr. Brand has co-authored more than 120 publications in scientific journals and conference proceedings. He is a co-editor of the Wiley-VCH book series *Advanced Micro and Nanosystems*, a member of the editorial board of *Sensors and Materials*, a member of the technical program and steering committees of the *IEEE International Conference on Microelectromechanical Systems*, and has been elected General Co-Chair of the 2008 *IEEE International Conference on Micro Electro Mechanical Systems (MEMS 2008)*. Dr. Brand is a senior member of the *IEEE* and a co-recipient of the *2005 IEEE Donald G. Fink Prize Paper Award*. His research interests are in the areas of CMOS-based microsystems, microsensors, MEMS fabrication technologies, and microsystem packaging.

1.16.1 Introduction

While the electronic properties of silicon have been widely utilized in high-volume integrated circuit (IC) manufacturing for many decades, the use of its mechanical and other properties is catching up in many applications. IC-compatible micromachining techniques form the technological basis for the construction of miniature, high-precision mechanical structures in and on a silicon substrate and thus allow fabrication of various microsensing elements (Petersen 1982).

These developments in silicon technology also allow the implementation of nonelectrical functions alongside sophisticated microelectronic circuitry on the same silicon substrate (Manoli and Mokwa 1999, Wise and Najafi 1991). Thus, microsensors and microactuators can be merged together with microelectronics to form complex microsystems such as system-on-a-chip (SoC) or are realized as two-chip solution resulting in a system in package (SiP). Such systems may contain sensors fully compatible to a standard complementary metal oxide semiconductor (CMOS) process technology, as well as sensors requiring additional processing steps, or sensors on separate substrates. The accompanying microelectronics makes it possible to realize not only sensor readout but also signal conditioning, interfacing, and complex signal processing.

CMOS technologies are the preferred choice for electronic interface circuits, since CMOS is the mainstream technology and is distinguished by its ability to combine complex digital functions with analog electronics. Its low-power capabilities make it suitable also for energy autonomous sensor acquisition or portable and implantable systems. The silicon integration of both sensors and electronics or their combination in a package, besides lowering manufacturing costs for high-volume production, offers several significant advantages, such as small size and low weight (e.g., important for medical implants or portable systems), close physical proximity of sensors and readout electronics (important for low-noise pickup), and the possibility of integrating multisensor arrays in combination with highly complex signal processing.

This chapter discusses some of the challenges met in designing such silicon microsystems from the interface electronics point of view.

1.16.2 Electronic Interface Systems

The challenges faced when designing sensing or actuating microsystems span the whole spectrum of microelectronics. The wide range of applications as well as the demanding and often changing operating conditions for such microsystems makes the system design a challenging task. Illustratively, in **Figure 1** a typical architecture of a signal acquisition and processing system is given. Since the circuit designer must deal with all parts of it, the following discussions will focus on this overall system concept. In Sections 1.16.3 and 1.16.4, only the critical parts of sensor interfacing and analog signal processing as well as analog actuator interfacing are discussed in more detail.

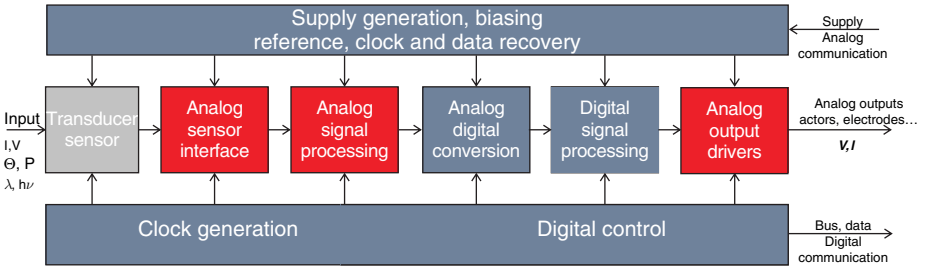

Figure 1 Illustration of an integrated sensor acquisition channel.

1.16.2.1 Integration Concepts

In the case of monolithically integrated systems, sensor and process engineers have to combine CMOS standard processes with additional steps for the implementation of the nonelectrical functions without influencing the electrical parameters of the standard devices. On the other hand, integrating multichip implementations makes life challenging for the package engineer as well. Whereas a usual package is designed to protect silicon from its aggressive environment, sensors need an approximate exposure that renders them sensitive to – and only to – the quantity to be detected. Circuit designers have to detect and amplify the usually minuscule signals delivered by the miniaturized sensors. This has to be accomplished when the circuit is being exposed to conditions (temperature, light, humidity, etc.) from which an IC is usually very well protected. In order to function as a sensor, silicon (as well as any other material) has, of course, to be exposed to its environment.

1.16.2.2 Sensing Devices

Although silicon is a promising sensor material, it should be noted that not all types of sensors are amenable to the silicon integration. Thus, while several physical effects in silicon, such as thermal conductivity, photoconductivity, or magnetoresistivity, can be used directly to build sensors, some effects (e.g., piezo- and magnetoresistivity) may require deposition of additional materials. In this case, the silicon chip can serve as a common carrier substrate for the deposition and for the integration of electronic circuits. In some cases, separate substrates for the sensors and the electronics are the solution of choice.

As already mentioned, for the implementation of silicon microsystems, those sensors and actuators that can be fabricated compatible to a standard CMOS process are usually preferred. One group of such elements is directly based on electronic devices. There is no need for additional masks or process steps and the sensor can be made part of the electronic circuit, i.e., a differential stage. Different devices, for example, can be designed so that they are sensitive to magnetic fields that are parallel or perpendicular to the silicon surface (Gottfried-Gottfried *et al.* 1991, Nathan and Baltes 1989). Photosensitive MOS transistors and complex CMOS camera systems have also been reported (Smith *et al.* 1998). Different electron devices can be used for temperature sensing (Kordas *et al.* 1990).

A further group of CMOS compatible sensors is also based on standard process techniques but additional photomasks and process steps (e.g., deposition and liftoff) are necessary for the fabrication of these devices. One example in this group are the chemically sensitive MOS devices (e.g., transistor, capacitors). In contrast to the standard polysilicon transistor gate or capacitor plate, a sensor-specific material is used. By applying the appropriate material, devices can be obtained that are sensitive to ion concentrations in aqueous solutions (ion-sensitive field-effect transistors, ISFETs). They can also serve as the basic structure for biosensors (Eversmann 2003, Kakerow *et al.* 1993).

In the 1990s, a major development focused on the field of surface micromachining. This technique also needs extra deposited materials such as polysilicon or metal but processes them so that moveable parts are produced. One example is the digital mirror device utilized in the digital light processing technology (van Kessel 2001). **Figure 2** shows an example of a pressure sensor fabricated with planar etching techniques, which also fits into this group of devices. This sensor is formed by a capacitor consisting of a polysilicon membrane and a silicon substrate. The membrane is obtained by laterally etching a sacrificial oxide layer, and the spacer, via etch channels. These channels are sealed by depositing silicon dioxide on the membrane. The pressure sensors are very small, having diameters of up to 150 µm. To get larger signals, sensor arrays can be easily designed (Dudaicevs *et al.* 1994). The capacitive readout techniques compatible with this sensor are discussed in Section 1.16.3.2.

Using similar techniques, accelerometers can be produced, which, nowadays are widely used in air bags and stabilization systems in automobiles. In this

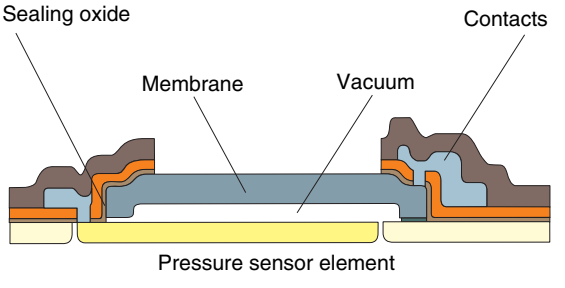

Figure 2 Cross section of a surface-micromachined capacitive pressure sensor.

case, etching the polysilicon layer and the sacrificial oxide forms moveable finger structures that are intertwined with matching counterparts that are fixed. Acceleration forces the moveable parts toward the fixed parts resulting in a higher capacitance, which is detected and evaluated by the on-board electronics (Payne *et al.* 1995). A more complex and much more sensitive device is the angular rate sensor or gyro (Link *et al.* 2005), as shown exemplarily in **Figure 3**. Together with the accelerometers they constitute complete inertial systems. The small capacitive signals achieved with these sensors present a challenge to the circuit designer and require low-noise techniques as discussed in Sections 1.16.3.1–1.16.3.3.

The widely sold silicon sensor is still the old-fashioned bulk-micromachined pressure sensor. Here the whole silicon wafer of about 500 µm is used to produce the moveable parts. Through backside etching a cavity is formed defining a thin membrane on the order of 5 to 10 µm at the surface of the silicon wafer. Piezoresistors implanted in the membrane are sensitive to deformations caused by exposing the membrane to a higher pressure (Bryzek 1993). The same process steps can be used to define a membrane for a flow sensor (Kersjes *et al.* 1996) or a large moving mass for high-precision accelerometers. The sensing elements in these cases are usually piezosensitive resistors arranged in a Wheatstone bridge configuration. This reduces parasitic effects and directly provides a voltage output.

1.16.2.3 Analog Electronic Interfacing

A sensor or a transducer converts a physical or a chemical effect into an electrical quantity. This can be a voltage, a current, a change in a resistance or capacitance or similar. For the purpose of further processing, these quantities have to be converted into an electric signal, usually a voltage. Due to very small sensor signals, an amplification and filtering must take place as well. Compensation, linearization, and calibration are then necessary to correct nonidealities that the signal might present. Ideally, this signal processing should be performed before transmission, thus avoiding signal distortion.

MOS analog integrated circuit design techniques make use of device-matching properties rather than relying on absolute values of devices. Whereas absolute values of resistors, capacitors, etc., are subject to process variations on the order of 10–30%, the matching errors of these elements are on the order of 0.1–0.5%. In addition, the voltage and temperature coefficients also match very well. This property of MOS processes has led to the wide application of the switched capacitor (SC) circuit technique that makes use of capacitor ratios as precise circuit elements. The charge collected on a capacitor can be nondestructively sensed due to the almost infinite input resistance of the MOS transistor gate and converted into a voltage. The corresponding circuit techniques are discussed in Section 1.16.3.2.

1.16.2.4 Digital Postprocessing for Electronic Interfaces

After analog signal processing, an analog-to-digital (A/D) conversion provides a digital output that is more appropriate for transmitting the data over longer distances. Further, a bus interface can be implemented, simplifying the interconnection of the sensor or a number of sensors to a microcontroller or a network. Although analog calibration is possible, it might be easier from the system point of view to do the calibration in the digital domain. Calibration is, apart from packaging, one of the less obvious cost-determining factors for a sensor. It has to be considered thus as a part of the system design and has to be dealt with early in the design cycle. Calibration is necessary to correct any offset, gain, linearity, or other errors such as temperature dependence of the sensor. The process requires subjecting the sensor to a number of well-known conditions and extracting the necessary parameters.

These parameters can be used to adjust the sensor signal or the readout electronics to eliminate or reduce the nonidealities.

Doing the correction in the digital domain makes it possible to use polynomial linearization functions or a table-look-up. Applications with extensive signal processing on the digital side or complicated control sequences would require a large chip area, if done in a standard cell application-specific integrated circuit (ASIC) manner. To avoid this and the long design time that such implementations would require, a configurable microcontroller that can be easily adapted to the application represents the most economic solution. Not only the size of the nonchip RAM and ROM is variable but the configuration and the kind of peripheral units are flexible as well (Lerch *et al.* 1995).

1.16.2.5 Peripheral System Components

The overall system design of sensing or actuating microdevices covers such a wide range of applications and demands operation over changing environmental conditions that the system design becomes a challenging task; microsystem as well as circuit designers can contribute to alleviate this task.

For portable or very small devices, for example, battery operation may be required. Considering the volume and the lifetime of batteries, low-voltage (LV) operation and low power dissipation are very desirable. In order to minimize overall power consumption, sensor and circuit concepts, system operating speed as well as analog and digital signal processing and partitioning should be selected properly. A telemetric data transmission might be desirable or necessary if a direct connection to the microsystem is not possible. If battery operation is not applicable, not only the information data but also the power for the device operation has to be transmitted via nongalvanic links. For power transmission, an inductive coupling is recommended for high power efficiency. Energy harvesting techniques might be applicable, which can then convert, for example, vibration energy into usable electrical power (Spreemann *et al.* 2006). For data transmission, besides radio frequency (RF) and carrier modulation, other media can also be used, e.g., infrared. For a reliable transmission, digital coding of the information is desirable since it is less susceptible to noise pickup and allows easy error detection.

1.16.3 Electronic Interfaces for Micromechanical Devices

1.16.3.1 Basic Limitations for Sensor Readout Electronics

Various noise mechanisms limit the performance of sensor readout electronics. In this section, two main noise sources, i.e., the mechanical and electrical noise, are considered and their influence on the performance of the readout electronics is investigated. Whereas the mechanical noise cannot be influenced by a circuit designer, the electronic noise can be improved by a good design choice of the interface circuit. An understanding of the sensor noise source is required in order to appropriately design the interface electronics, which should be smaller than the mechanical noise to have the full performance of the sensor system. Thus, some fundamentals of mechanical noise are discussed before covering the electrical noise sources.

1.16.3.1.1 Mechanical noise

Noise generated by temperature fluctuation occurs in any mechanical system. Commonly in large-scale sensors, this kind of noise is usually neglected. But for microelectromechanical (MEM) sensors having very small masses, these effects dominate the sensor performance. The mechanical noise sources can be distinguished into external and internal noise source, e.g., Brownian noise and phonon–phonon noise, respectively (Djuric *et al.* 1998). The most frequent noise is the Brownian motion that originates from the interaction of molecules with flexible parts of the sensing elements immersed in a gaseous or a liquid medium. This behavior can be described by the equation of a harmonic oscillator which is as follows:

$$m\frac{\mathrm{d}x^2}{\mathrm{d}t^2}+\xi\frac{\mathrm{d}x}{\mathrm{d}t}+kx=\mathbf{F}(t)+F(t) \qquad [1]$$

where $\mathbf{F}(t)$ is the deterministic excitation force, $\mathrm{F}(t)$ is the stochastic force excited from the surrounding molecules on the flexible part of the sensor, m is the mass, ξ is the damping coefficient, and k is the mechanical spring constant. Assuming that the mean of the stochastic force is zero, $\mathrm{F}(t) = 0$, and no external force $\mathbf{F}(t)$ is applied, the mean velocity $\bar{v} = \mathrm{d}\bar{x}/\mathrm{d}t$ vanishes. On the other side, the instantaneous velocity $v(t) = \mathrm{d}x/\mathrm{d}t$ is not zero as the sensor is excited constantly by the surrounding molecules. The Brownian force (Gabrielson 1993,

Gabrielson *et al.* 1998a) is given by the following equation:

$$F_B = \sqrt{4k_B T\xi} \quad [2]$$

which causes Brownian motion of the harmonic oscillator x_B and can be solved by combining eqns [1] and [2]. Solving the Laplace domain results in

$$x_B = \frac{\sqrt{4k_B T\xi}/(\omega_n^2 m)}{\left(\frac{s}{\omega_n}\right)^2 + \frac{1}{Q}\frac{s}{\omega_n} + 1} \quad [3]$$

where Q is the quality factor, k_B is the Boltzmann constant, and w_n is the natural resonance frequency. Recalculating the equivalent acceleration originating from the Brownian force gives the following equation:

$$a_B = \frac{\sqrt{4k_B T\xi}}{m} = \sqrt{\frac{4k_B T\omega_n}{mQ}} \quad [4]$$

Eqn [4] shows that a high Q factor and a huge mass are desirable, if the sensor is used as an accelerometer. A huge mass can be achieved by bulk micromachining being carved out of a full wafer. To further reduce the influence from the Brownian noise, the Q factor has to be increased. This can be achieved by suspending the proof mass in vacuum. But for high-performance accelerometers this is sometimes not enough. Therefore, other noise sources can become dominant and the different contributions have to be investigated and design rules for the sensor design need to be derived. These additional contributions are the following (Hosaka *et al.* 1995):

- Internal friction, which is often negligible with single-crystal materials.
- Change of entropy caused by heat flow.
- Phonon interaction with phonons from the supporting structures.

1.16.3.1.2 Electronic noise

As mentioned in Section 1.16.1, analog signals processed by integrated circuits are also corrupted by noise. These can be distinguished into two types of noise: device electronic noise and environmental noise sources. The first includes the offset as a direct current (DC) noise, the thermal noise, and the flicker or the so-called $1/f$ noise. The environmental noise comprises random disturbances that enter the circuit through the supply, ground lines, or through the substrate (Razavi 2001). In the following, the consideration of noise is restricted to thermal, $1/f$, and kT/C noise, with kT/C noise being the most dominant.

1.16.3.1.2.(i) Thermal noise

Similar to the mechanical system and its Brownian motion, thermal noise occurs in resistors by the random motion of electrons in a conductor. The average of these electron fluctuations can be measured as a voltage across the conductor being proportional to the absolute temperature. Commonly, the power spectrum density of the thermal noise can be assumed to be white. White noise follows from the definition of white light meaning a constant amplitude or power density for all frequencies. In both cases, this cannot be true as the power of such a signal would be infinite. In the case of thermal noise, the cutoff frequency is in the range of 70 THz for room temperature and thus the assumption of white noise holds for most practical applications.

Very often it is necessary to estimate the noise power at the output or the input of a circuit. Therefore, the thermal noise has to be modeled within the circuit. This can be done easily by using a voltage source in series with the resistor having a spectral density of

$$\overline{V_{nth}^2} = 4k_B TR \quad [5]$$

From eqn [5] it can be seen that a high temperature T and a resistance R excites a large voltage noise. Consequently, the resistance has to be small and the temperature reduced if a low thermal noise is desired. Alternatively, the noise can be modeled by a current source in parallel having the spectral density as

$$\overline{I_{nth}^2} = \frac{4k_B T}{R} \quad [6]$$

Depending on the circuit topology, one model may result in a simpler expression than the other. The calculation itself is done by using Kirchoff's law, as it is also valid for noise signals. But as a rule of thumb, the voltages and currents of uncorrelated noise sources are estimated by superposition and afterward added quadratically.

Not only resistors exhibit thermal noise, but also MOS transistors constitute thermal noise due to the resistive channel of the transistor in the active region. For a long-channel MOS device operating in saturation the thermal noise can be modeled by a current source connected between the drain and the source. The value of this output current noise is

$$\overline{I_n^2} = 4k_B T\gamma g_m \quad [7]$$

where γ is approximately $2/3$ depending on the technology used. Eqn [7] suggests that to reduce the

current noise of a transistor its transconductance g_m should be as small as possible. This is true if a transistor operates as a constant current source, whereas for an input transistor in a differential stage g_m should be high. This is because the input referred voltage noise reduces with large g_m.

To generate the drain current, a corresponding voltage with the value I_D/g_m has to be applied to the gate of the transistor. Dividing eqn [7] by g_m leads to

$$\overline{V_n^2} = \frac{4k_B T\gamma}{g_m} \quad [8]$$

1.16.3.1.2.(ii) Flicker noise For semiconductors, flicker noise is mostly generated between the gate oxide and the silicon substrate (van der Ziel 1978). Since the silicon crystal lattice ends at this interface, dangling bonds occur, giving rise to extra energy states. Charge carriers that move across this interface can be trapped in these energy states and later randomly released, generating flicker noise. In circuits, the flicker noise is modeled as a voltage source in series with the gate and is given by the following equation:

$$\overline{V_n^2}(f) = \frac{K}{C_{ox} WL}\frac{1}{f} \quad [9]$$

where K is a process-dependent parameter and can vary widely for different devices in the same process (Johns and Martin 1997). The variables W and L are the width and the length of the transistors, and C_{ox} represents the gate capacitance per unit area. To achieve the equivalent noise current, eqn [9] has to be multiplied by g_m^2, leading to

$$\overline{I_n^2}(f) = \frac{K}{C_{ox} WL}\frac{1}{f} g_m^2 \quad [10]$$

The trap-and-release phenomenon, as eqn [9] reveals, occurs more often at low frequencies, and therefore flicker noise is also called $1/f$ noise. An important attribute of flicker noise is its inverse dependence on the area of the transistor, which suggests that to decrease the $1/f$ noise, the $W \times L$ of the transistor must be maximized. In addition, P-channel-metal-oxide-semiconductor (PMOS) exhibit less flicker noise than their N-channel-metal-oxide-semiconductor (NMOS) counterparts as there are less electrons in the conduction band and are thus less likely to be trapped. In **Figure 4**, both spectral densities of $1/f$ and thermal noise are plotted in one graph. The intersection point is referred to as the $1/f$ noise corner frequency and

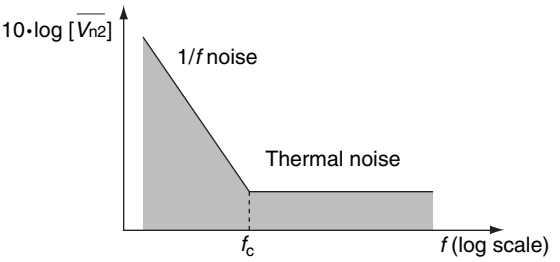

Figure 4 Spectral densities of both flicker noise and thermal noise are drawn on the same axis. The intersection point is referred to as the $1/f$ noise corner frequency, f_c, and indicates what part of the band is corrupted dominantly by flicker noise or thermal noise.

serves as a measure of which part of the band is dominantly affected by flicker noise. Eqn [9] with eqn [10] and solving for the $1/f$ noise corner frequency, f_c, leads to

$$f_c = \frac{K}{C_{ox}}\frac{g_m}{WL}\frac{1}{4k_B T\gamma} \quad [11]$$

This result indicates that the corner frequency is a function of the device dimensions and the bias current.

1.16.3.1.2.(iii) kT/C noise The kT/C noise occurs only in SC circuits and is not a fundamental noise source like those mentioned previously. Commonly, a switch in an electrical circuit is realized through a transistor. This transistor has a high resistance if it is switched off and a low resistance, $R_{on,}$ if it is switched on. While switching the capacitor, the thermal noise of the on resistor R_{on} is stored on the capacitor along with the instantaneous value of the input voltage. The on resistor and the capacitor together form a low-pass filter if they are shorted to the ground. As it is possible to estimate the noise power stored on the capacitor, the spectral density over the noise bandwidth has to be integrated. Using eqn [5] for the spectral noise of the on resistor, the total output noise is

$$P_{kT/C} = \int_0^\infty \left|\frac{1}{R_{on}C + 1}\right|^2 \overline{V_{nth}^2}\, df \quad [12]$$

Eqn [12] reveals that a sufficiently large capacitor C reduces the kT/C noise. Further it is independent on the used sampling frequency f_s and thus it describes a fundamental limitation for SC circuits. This restriction can be reduced by increasing the capacitance of C. But this also requires more current to charge the capacitance, if the same bandwidth is

desired. Thus, the kT/C noise can be reduced only by accepting a higher power consumption.

1.16.3.2 Capacitive Readout Electronics

As the dimensions of micromachined inertial sensors are small, the signals from these devices are also very small. As an example, the displacement of a proof mass for an accelerometer with 10 kHz natural resonant frequency and a 5 mg input acceleration, where 1g means the gravity acceleration, is only one-tenth of an angstrom. For gyroscopes, the displacement, which has to be detected, is even smaller (Clark and Howe 1996). In the literature, many different techniques are shown for sensing such small displacements, e.g., tunneling tips (Zavracky *et al.* 1993), magnetic, capacitive, or optical transducers (Garcia-Valenzuela and Tabib-Azar 1995).

While each approach has specific advantages, none of them outperforms the other. So, the choice for a specific technique is guided primarily by other factors such as available experience or the number of fabrication steps required. From the last point of view, capacitive interfaces have several appealing features as in most micromachining technologies where no or minimal additional processing is needed (Boser 1997). Additionally, capacitors can be used as sensors and actuators having high sensitivity. Further, the capacitors are designed through lithography having well-defined properties and are insensitive to temperature. On the other hand, the dual operation of capacitors both as sensors and as actuators increases the requirements on the interface design. As the readout of the capacitor itself excites a force on the capacitor plates, active shielding has to be considered. Especially for two-chip hybrid realizations consisting of one chip for the sensor and one chip for the electronics, wiring and stray capacitances can reduce the signal strength and thus the performance of the entire sensor device. Hence, alternative transducers (e.g., piezoresistive) are frequently attractive in situations where parasitics due to wiring are dominating. But, this comes with a higher temperature sensitivity and power consumption of such transducers (Boser 1997).

1.16.3.2.1 Capacitive-to-voltage converters

When using capacitive sensors, it is necessary to convert a change in capacitance ΔC to a corresponding voltage. Charge integration is the method of choice due to its lower susceptibility to parasitics (Boser 1997). **Figure 5** shows two different architectures of capacitive sensing.

In **Figure 5(a)** a differential capacitive-to-voltage converter based on charge integration is presented. The functional concept can be described as follows. An alternating current (AC) or DC signal V_m is applied to the sense capacitances. The resulting charge will be transferred from the sensor to the feedback capacitors C_i of the amplifier by integration. At the output a differential voltage V_0 will appear depending on the variation of ΔC (Baltes *et al.* 2004):

$$V_0 = \frac{2\Delta C}{C_i} V_m \qquad [13]$$

The advantage of this design is that the signal V_m is easy to realize. It is important to note that the differential amplifier must be able to handle large input common-mode signals. In case the common-mode range of the amplifier cannot accomplish the voltage step caused by V_m, an input common-mode feedback (ICMFB) is absolutely essential. Reducing the voltage step V_m to a lower value is not desirable, because to improve the signal-to-noise ratio a large voltage step is required.

In **Figure 5(b)** a single-ended capacitive-to-voltage converter is shown. The charge integrator is connected to the middle node being the sensor proof-mass. The

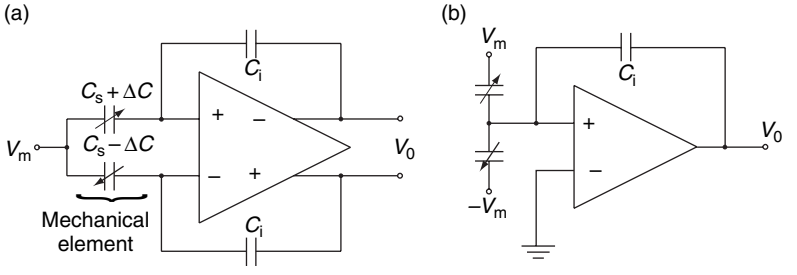

Figure 5 Draft of a differential capacitance-to-voltage converter based on (a) charge integration and (b) single-ended capacitive-to-voltage converter.

AC or the DC signal is applied to the ends of the capacitive bridge with two out-of-phase waveforms. In this case the input of the amplifier is at the virtual ground and ICMFB is not needed (Baltes *et al.* 2004). Unfortunately, this architecture requires a precise generation of two AC drive signals to ensure high output stability (Lemkin and Boser 1999).

Besides the easier implementation of the carrier signal V_m, the differential capacitive-to-voltage converter has some other important advantages such as suppression of even-order harmonic distributions in the output signals (Razavi 2001) or improved power supply rejection ratio (Lemkin and Boser 1999).

1.16.3.2.2 Noise in capacitive-to-voltage converters

Capacitive interfaces have the attributes to measure very small capacitance changes and hence very small displacements. The following amplifier can boost these signals to manageable amplitudes. Unfortunately, not only the signals but also the undesired noise are amplified. Since all physical systems suffer from low-frequency flicker noise as mentioned in Section 1.16.3.1.2.(i), two different techniques have been developed over the years. The first one is called correlated double sampling (CDS) and is a discrete-time technique. The advantage is that its output can be easily digitized by using an analog-to-digital converter (ADC). An additional pre-filtering in the adjacent stage is therefore not needed. Further, no additional ICMFB is necessary reducing the circuit complexity. The second one is referred to as chopper stabilization (CHS), which is a continuous-time technique. To digitize its output, a prefilter in the adjacent stage is required. Both techniques can reduce low-frequency noise and the offset of the amplifier. The functional concept of both techniques are discussed in the following section.

1.16.3.2.2.(i) Correlated double sampling As already mentioned above, CDS is a discrete-time technique and has the advantage that its output signal can be digitized with an ADC without the need for an additional antialiasing prefilter (Baltes *et al.* 2004). The basic idea of this technique is to subtract two sampled signals. The first containing only the error, such as noise and offset, and the second containing both the error and the desired signal (Enz and Temes 1996). If the error has strongly correlated values in both samples, the error can be eliminated by subtracting these two samples. The condition that the two error samples have to be strongly correlated indicates that an effective cancellation is possible only if the frequencies of the error components are much lower than the sampling frequency f_s.

In **Figure 6** the functional concept of CDS is described. The process requires three phases. In phase 1 the reset takes places. All the nodes are connected to the ground except for the node M of the mechanical element. At node M a voltage V_1 is applied and the sense capacitors C_{s+} and C_{s-} are charged to the difference between V_1 and the ground. During this first phase the two integration capacitors C_{i+} and C_{i-} are discharged. In the second phase the nodes are taken from the ground and the amplifier is active. Error components such as offset, flicker noise, switch kT/C noise, and charge injection are now stored on the capacitors C_{H+} and C_{H-}. At the beginning of phase 3, a signal with magnitude of V_1-V_2 is applied to the node M. The errors stored in C_{H+} and C_{H-} of phase 2 are now in series with the output signal of phase 3 and are subtracted. This results in an output signal containing the signal and the kT/C error generated by the last sampling step between phases 2 and 3.

When compared to the CHS technique being outlined in Section 1.16.4.2.2.(ii), no antialiasing filter is necessary if an A/D conversion is required. Unfortunately, this technique suffers from several drawbacks. Like any sampled system, CDS suffers from noise folding, which limits the resolution. The noise density can be reduced by increasing the load capacitance, which results in a higher power

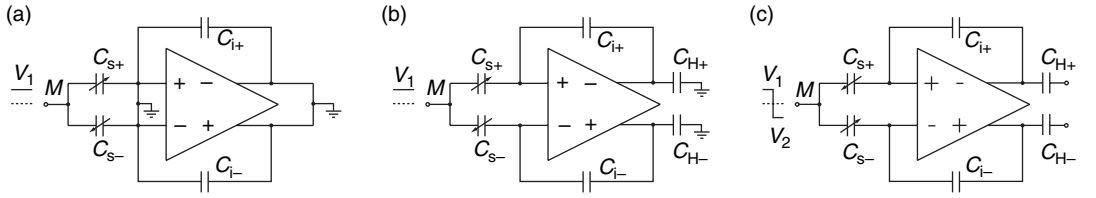

Figure 6 Correlated double sampling (CDS) has three phases. In phase 1 (a) the reset takes place. In phase 2 (b) the offset and low-frequency noise are sampled. In phase 3 (c) the input is applied and previously sampled errors are subtracted (Baltes *et al*. 2004).

consumption in order to preserve the bandwidth (Baltes *et al.* 2004).

1.16.3.2.2.(ii) Chopper stabilization Like CDS, the CHS technique can be employed to reduce low-frequency noise and amplifier offset. Unlike the CDS process, the CHS does not use sampling and is therefore a continuous-time technique. **Figure 7** shows the operation in case of a capacitive sensor readout (Baltes *et al.* 2004). A sinusoidal voltage V_m with frequency f_m is applied to the center node and modulates the signal to a higher frequency where there is no $1/f$ noise. A displacement of the mass will change ΔC and produces a current difference Δi that flows into the integrating capacitor C_i. As a result, a corresponding voltage proportional to ΔC appears at the output with a frequency of f_m. Assuming that the signal of the sensor is band limited at least to half of the modulation frequency f_m, no signal aliasing occurs. If the signal is modulated with a frequency f_m, much higher than the $1/f$ corner frequency, flicker noise and offset will not disrupt the signal. After the signal is amplified it can be demodulated back to the original frequencies, thereby modulating the low-frequency noise to higher frequencies in a band out of interest. To recover the original signal in an amplified form, a low-pass filter must follow with a cutoff frequency slightly above the signal bandwidth of the sensor and with a high slope to eliminate the noise that is shifted to higher frequencies and higher harmonics.

To ease the generation of the modulation signal, a square wave instead of a sine wave can be used for modulation. In this case the signal power also appears at multiples of the modulation frequency f_m. Further, this increases the requirements of the charge amplifier, as it has to provide bandwidth and slew rate.

1.16.3.2.3 Slope converter

Another very simple conversion method is the single-slope converter. This converter works in two phases. In the first phase, a reference capacitor C_L is charged by the unknown reference current source. As long as the voltage over the reference capacitor C_L is above a reference voltage U_{ref} the output of the comparator is 1. The output of this converter is a pulse-width-modulated signal of the unknown current signal. This method, which is well-known for ADCs, can also be used with slight modifications as a capacitive interface. The reference current source charges the sensing capacitance cycle. Thereafter, the sensor capacitance is shortened which starts the next conversion cycle. This is also shown in **Figure 8**. One major advantage of this approach is its simplicity and that the output signal can be easily digitized by a counter. But the resolution is limited by the accuracy of the reference current source and it is feasible only for slowly varying sensor signals.

1.16.3.2.4 Example: Integrated interface circuit for a capacitive pressure sensor

The capacitive pressure sensor consists of an array of single circular pressure-sensitive elements connected in parallel and of similarly built reference elements. An exemplary circuit design and a chip photo are

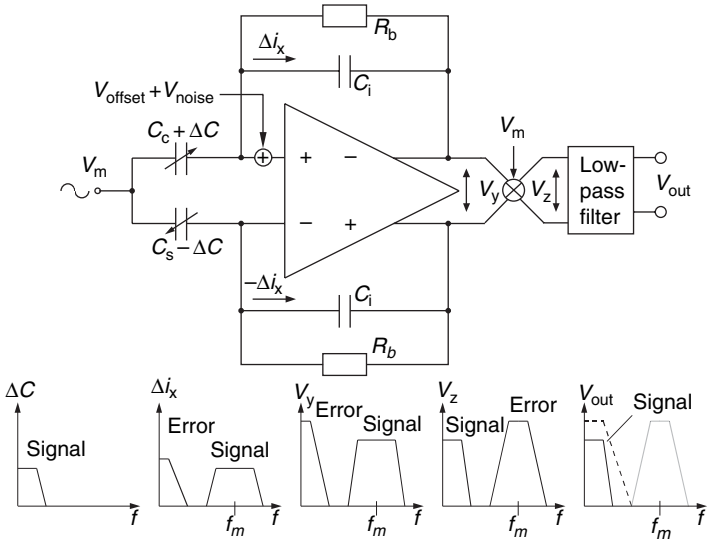

Figure 7 The functional operation of chopper stabilization (CHS) for capacitive sensor readout (Baltes *et al.* 2004).

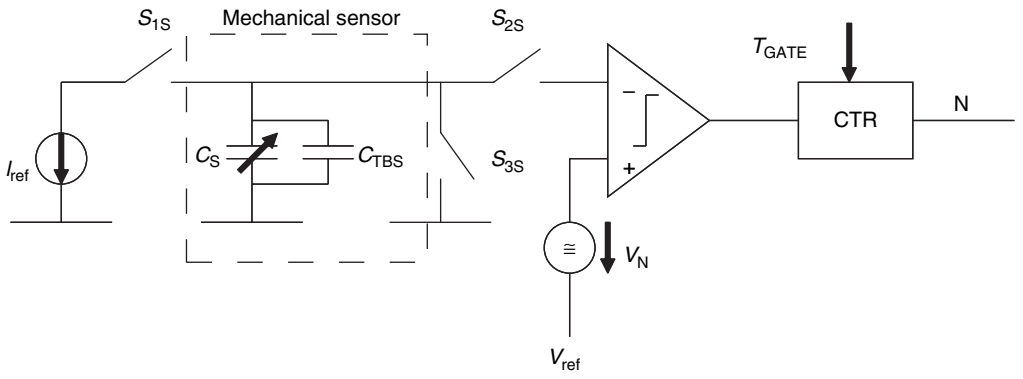

Figure 8 Single-slope converter with current source, comparator, and counter used for digital output.

shown in **Figure 9**. The capacitor is formed by a fixed electrode in the substrate generated by implantation and a moveable membrane of polycrystalline silicon above. The cavity under the membrane is obtained by etching a sacrificial layer of silicon dioxide via etch channels and later by vacuum sealing. The height of the cavity is less than 1 µm while the membrane diameter is in the range of 100 µm, depending on the pressure range. These reference elements are constructed in an identical manner with the only difference being the thickness of the membrane. The output voltage signal is proportional to the quotient of the capacitance of the sensor and the reference element. Thus, parasitic effects are suppressed.

The signal conditioning is based on the SC technique (Hosticka *et al.* 1977). The capacitor of the pressure sensor C_S and its reference sensor C_R is implemented in the first stage of the readout electronics. In this stage a signal conversion from the capacitance to voltage occurs as discussed in Section 1.16.3.2.2.(i). Because of the negative influence in the case of clock feedthrough and current leakage, the differential path technique is used, so the pressure sensor is divided into two parts.

In the second stage a subtraction of he zero pressure signal, a differential to single-ended conversion, and an amplification are performed. An integrated sample and hold function supplies a continuous output signal. The excitation voltage is generated by a

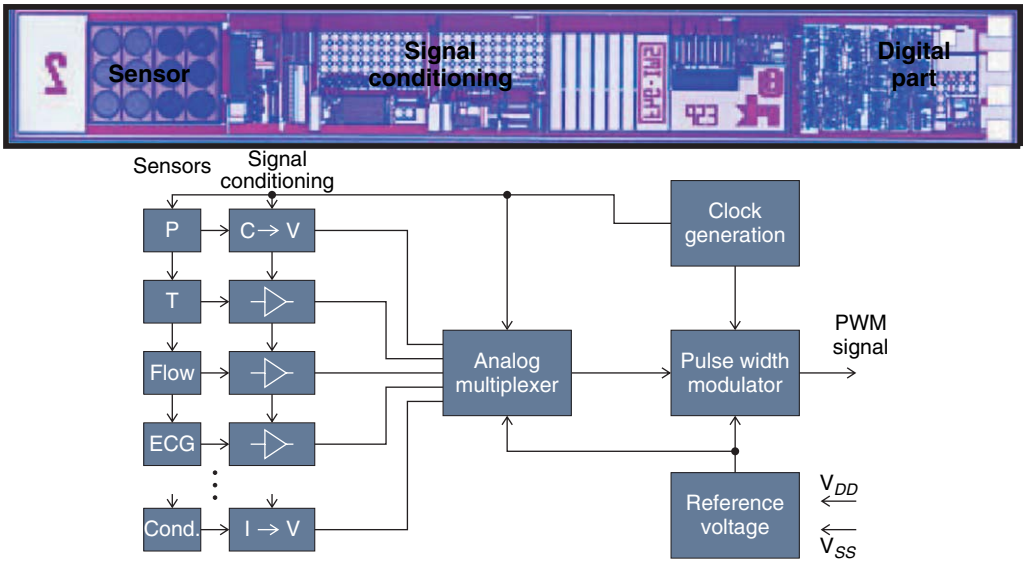

Figure 9 Pressure sensor chip and its block diagram consisting of the pressure sensors, the signal conditioning, and the digital electronics.

matched resistor network that leads to a full ratiometric signal conditioning. A central bias circuit and an oscillator that generates a four-phase clock for the SC amplifiers complete the system to a three-terminal device (Schmidt *et al.* 1995).

1.16.3.3 Sigma–Delta Interface

As the quality of the mechanical systems improves, the performance of the interface electronics becomes the limiting factors on the performance of the whole system. Being able to improving the performance of microelectromechanical systems (MEMS) even further, it is not possible to separately examine the mechanical and the electrical part of the system. In circuit design, the application of feedback is well-known for improving, e.g., the linearity or the temperature stability of an amplifier. Due to the increasing demand for sensors with digital output, the development of novel interface circuits focuses on this new aspect. The sigma–delta conversion is well-known in the field of electrical A/D conversion. It offers many advantages compared to Nyquist rate converters being relaxed circuit complexity, such as precision requirements and often lower power consumptions by using oversampling and its noise shaping behaviour. This approach is carried over to the sensor readout in the following section.

1.16.3.3.1 Fundamentals of sigma–delta modulator

An A/D conversion of the sensor signals is desirable so as to transit them over long distances and to perform complex signal processing. Depending on the signal bandwidth, different ADC concepts can be implemented. Although successive approximation ADCs are usually a best fit for sensor applications, a sigma–delta modulator (**Figure 10**) has significant advantages making it also a very good concept (Geerts *et al.* 2002).

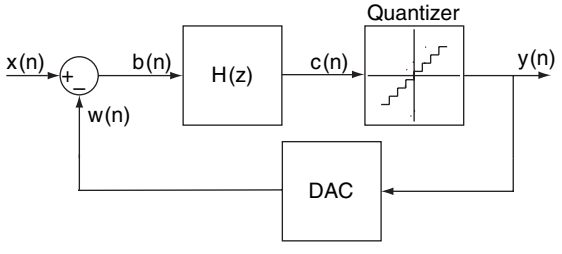

Figure 10 Block diagram of a sigma–delta modulator.

1.16.3.3.1.(i) Oversampling Oversampling a signal, which means sampling the signal with a rate higher compared to the Nyquist rate, reduces the quantization noise. If a signal is sampled at the Nyquist frequency, all of its quantization noise power is folded in the frequency range between $-f_s/2$ and $f_s/2$, which is equal to $-f_b$ and f_b, respectively. Since the quantization noise power σ_e^2 depends only on the number of quantizer bites, an increase of the sampling rate beyond the Nyquist rate spreads the noise power over a wider band and hence decreases the power in the band of interests, as eqn [14] reveals. The quantization error in sigma–delta modulators can be modeled as an additive noise source. From the quantization noise power σ_e^2, which is $\Delta^2/12$ (Jarman 1995), where Δ is the size of the least significant bit of the internal quantizer, the power spectral density (PSD) b_e can be calculated as follows:

$$b_e = \frac{\Delta}{\sqrt{12 f_s}}. \qquad [14]$$

1.16.3.3.1.(ii) Noise shaping As already mentioned, the main property of a sigma–delta modulator is its noise shaping and can be explained as follows. By feeding the output signal back to the input via a feedback loop, it is possible to suppress the quantization error. In **Figure 11** a block diagram of a sigma–delta modulator is shown. Compared to **Figure 10** the quantizer is replaced by an additional noise source e. Under the assumption that the quantization error is not correlated with the input signal, the error can be modeled as white noise.

From **Figure 11**, the following expression can be found for $y(n)$:

$$y(n) = x(n)\frac{1}{1+\frac{1}{H(z)}} + e(n)\frac{1}{1+H(z)} \qquad [15]$$

$$y(n) = \mathrm{STF}(z)x(n) + \mathrm{NTF}(z)e(n) \qquad [16]$$

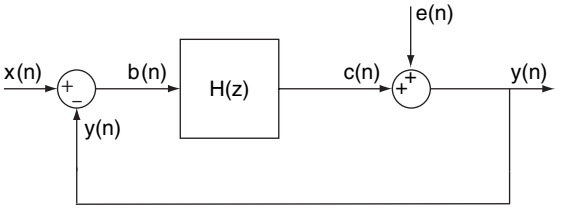

Figure 11 Block diagram of a sigma–delta modulator, where the quantizer is replaced by the white noise model.

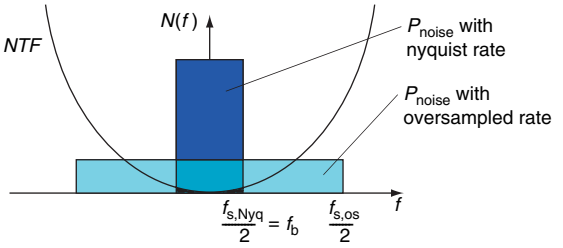

Figure 12 The noise transfer function (NTF) shifts the undesirable noise out of the band of interest to higher frequencies.

As eqn [16] reveals, there are two transfer functions. One for the signal called signal transfer function (STF) and one for the undesirable noise called noise transfer function (NTF). To obtain the best performance, $H(z)$ must have a large amplification at low frequencies and a low amplification at high frequencies and hence shifting the noise to higher frequencies in a band out of interest. Usually $H(z)$ is realized as a chain of integrators (Aboushady and Louerat 2002).

The noise-shaping attribute of a sigma–delta modulator can be illustrated graphically as in Figure 12. Oversampling a signal spreads the quantization noise over a wider band. Since the total noise power is still the same, as if sampled with the Nyquist rate, the noise spectral density in the band of interest is greatly reduced. The additional noise-shaping feature of a sigma–delta modulator shifts the undesirable noise to higher frequencies.

1.16.3.3.2 Electromechanical sigma–delta modulator

Due to the continuous-time nature of the mechanical element, the obtained signal has to be quantized in time and amplitude. Whereas the quantization is performed by the internal quantizer in the sigma–delta loop, the time quantization (sampling) can be done in the sensor front end instead. Figure 13 shows a block diagram of a single-bit sigma–delta modulator. In the forward path, a mechanical element, a capacitance-to-voltage converter, a gain, a lead compensator, and the binary quantizer are seen. The feedback circuit consists of a voltage-to-force converter that generates a corresponding force to keep the proof mass in its nominal position. Thus, the mechanical stress of the springs are reduced, which improves their linearity, as the influence of the cubic spring term is reduced. Lower stress can also increase the lifetime of the sensor. Alternatively, a mechanical resonator with a softer spring or larger mass can be applied, yielding a higher static resolution.

The feedback architecture also provides a linearization of the sensor's STF and increases the usable bandwidth. These advantages and the attributes of sigma–delta modulators, in general, supplement each other and a high-performance capacitive interface with direct digital output, noise-shaping feature, low chip area and with it low cost and low power consumption can be derived. In contrast, a more complex system design has to be considered due to potential instability of the system. This is because typical mechanical sensor can be modeled as resonators, which feature two dominant conjugate complex poles. Thus, the system in Figure 13 shows internal state variables that are difficult to control. One solution is the lead compensator, which gives a positive phase shift and thus stabilizes the system concerning the two poles of the sensor (Petkov and Boser 2005).

1.16.3.3.3 Sigma–delta interface conclusion

As mentioned previously, electromechanical sigma–delta modulators have several advantages compared to the common open-loop sensor evaluation. These are the increased linearity, bandwidth, and reduced circuits requirements, among others. But on the other hand, the circuit designer has to perform a complex circuit design due to the possible

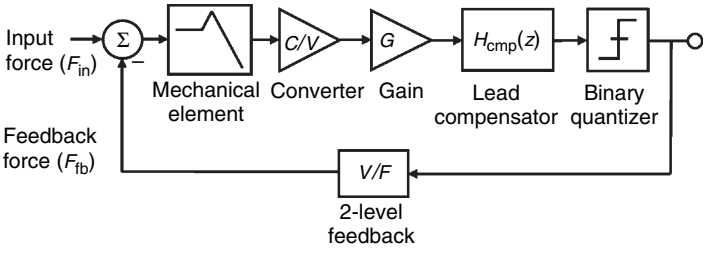

Figure 13 Schematic of an electromechanical sigma–delta modulator.

instability of the electromechanical sigma–delta modulators, which reduces the attractiveness of this novel approach.

1.16.4 Electronic Interface for Biomedical Applications

Over the past few decades, the development of implantable, functional electrical stimulation (FES) or functional neural stimulation (FNS) have emerged as promising approaches in the treatment of neural or muscular disabilities. Among others, the cochlear implant (McDermott 1991), cardiac pacemaker, visual prosthesis (Zrenner 2002), deep brain stimulators (Kuchta 2004), implants for bladder or sphincter control, or stimulators for hand or extremity control are some of the prominent examples. Today's neural prosthesis are systems that try to restore the functionality of disabled parts of the biological nervous system through electrical stimulation. Therefore, they selectively generate action potentials in nerve cells by electrical stimulation, which yield, e.g., to the contraction of a muscle or the excitation of the optic nerve. The stimulation is executed in a coordinated manner, so as to generate functional movement, visual, or acoustic reception.

Beyond the purely stimulating systems, the interest for general analysis of biosystems has increased over the last few years. Exemplary applications come from neurosciences, e.g., the understanding of neural communication on cellular-level chemical processes amongst neurons, rapid, diagnosis, or cell-based pharma screening (Aziz and Genov 2006, Eversmann 2003, Harrison *et al.* 2006). These sensor arrays for noninvasive neural monitoring from living cells are becoming a key tool in neurosciences for studying and understanding biological systems and neural networks. This is because they allow the study of an enormous amount of difficult to investigate neurophysiological phenomena, e.g., in sensory–motor systems, hippocampus, auditory nerve, and visual cortex. Thereby, the availability of the vast amount of data recorded simultaneously from many distributed sites is necessary in studying and analyzing heterogeneity across neural populations.

1.16.4.1 Electronic Nerve Signal Recording

Over the last few years, scientists from neurology and also clinicians have started to use implantable, MEMS by means of arrays with a large number of electrodes to simultaneously observe the activity of many neurons in the brain; knowledge gained from these studies increasingly yields to clinical and neuroprosthetic applications.

By observing, for example, the potential, or spikes, of many neurons in a certain region of the brain, it is now possible to obtain sufficient information to electronically predict hand trajectories in real time for reaching tasks. Experiment have shown that the development of neuroprosthetic devices becomes possible, which are controlled directly by thoughts, i.e., the brain–computer interface is becoming reality.

Thereby, the microintegration of both the electrodes and the readout electronics is a key objective for the successful evolution of such systems; currently, data are often recorded from implanted multielectrode arrays using bundles of thin wires and connectors that are mounted onto the patient's head; all electronics for amplification and recording are externally realized, i.e., outside of the body. This presents three major barriers to the development of neuroprosthetic devices with practical use:

(1) The transcutaneous connectors give rise to infection.
(2) External noise and interfering signals can couple more easily to the wires that convey the weak neural signals ($<500\,\mu V$) from high-impedance electrodes ($>100\,k\Omega$).
(3) The cable, connector, and external electronics are typically large and inconvenient to handle, when compared to the small ($<5\,mm^2$) electrode arrays.

In order to eliminate these problems, data from the numerous implanted electrodes must be preprocessed and wirelessly transmitted out of the body. This requires integrated microelectronics at (each of) the recording sites, which amplifies, preprocesses, and digitizes the neural signals from all electrodes. Such circuitry must also be powered wirelessly, since rechargeable batteries are large and have limited lifetimes, and an exchange of batteries is not possible as it would require surgery. Consequently, low-power operation ($<<100\,mW$) is essential, as for any implantable electronics, because only a limited power budget can be provided wirelessly, and even more critical, a temperature rise of 1°C may harm the tissue (Harrison and Charles 2003).

1.16.4.1.1 General challenges for nerve signal recording

A neuron that is not sending a signal, is at rest; then the inside of the neuron is negatively charged relative to

the outside, which is achieved by different ion concentrations. The balancing of the concentrations to an equilibrium is prevented by ion channels in the cell membrane, which can be closed or opened. The resting membrane potential of a neuron is approximately −70 mV. The action potential occurs when a neuron sends information via an axon, away from the nerve cell body. This spike firing is caused by an exchange of ions across the neuron membrane; therefore, an external stimulus causes sodium channels to open. Since the inside of the neuron is negative relative to the outside, sodium ions (Na^+) flow into the neuron. Consequently, the neuron becomes depolarized. When the opening of the potassium (K^+) channels are delayed, they reverse the depolarization. Almost at this time, the sodium channels start to close. This causes the action potential to return toward −70 mV (repolarization). Since the potassium channels stay open slightly longer, the action potential reaches −70 mV (hyperpolarization). Then, the ion concentrations gradually go back to resting levels and the cell returns to −70 mV. The external stimulus for firing the spike is critical, since a neuron will fire an action potential only if the depolarization reaches about −55 mV. This is called the threshold. If the neuron does not reach this threshold level, consequently no action potential will fire. This scheme for action potentials is indicated by **Figure 14**. These elementary neural signals are thus temporal peaks of the intracellular voltage relative to its environment. When recorded extracellularly, neural action potentials typically show amplitudes up to 500 μV, with a spectral content between 100 Hz and 7 kHz (Najafi and Wise 1986); in contrast, the so-called low-frequency local field potentials (LFPs) can be as large 5 mV, while containing signal energy even below 1 Hz (Harrison and Charles 2003). Even more challenging, signals typically recorded from electroencephalogram (EEG), electrocardiogram (ECG), and electromyogram (EMG) waves outside the body may be in the lower microvolt range. A major hindrance for direct measurement of these biopotentials are huge DC signals on top of the small signals: due to electrochemical effects at the electrode–tissue interface, offsets in the range of several hundred microvolts to several volts can arise across differentially recorded electrodes (Ferris 1978, Najafi and Wise 1986, Wise *et al.* 2004).

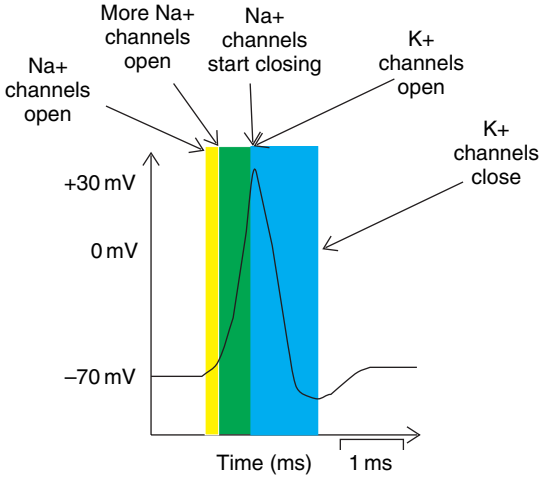

Figure 14 Illustration of neural action potential.

In conclusion, the common challenge of all biopotential readout circuits is the detection of very small, low-frequency signals, combined with high common-mode rejection ratio (CMRR) and sufficient blocking (high-pass filter characteristic) for the DC offset potentials, which are orders of magnitudes larger.

1.16.4.1.2 Circuit concepts for nerve signal recording

As mentioned above, the design of a readout circuit for nerve signal recording requires most of all high sensitivity, i.e., low noise and DC signal blocking combined with high CMRR in order to avoid the influence of the large DC offsets at the electrode–electrolyte interface. A high-pass filter with very low cutoff frequency is the obvious solution, but low cutoff in the range of tens of hertz requires very large capacitor–resistor values. Most early and even some recent integrated bioamplifier designs made use of large off-chip capacitors in the nanofaraday range to achieve this low corner frequency (Martins *et al.* 1998, Steyaert *et al.* 1987). But obviously, this approach is not feasible for large numbers of sites nor for implanted systems.

Generally, there are two dominant methods for neural recording: current mode readout and voltage mode readout (Aziz and Genov 2006). The former performs chemical neural activity recording, while the latter monitors electrical neural activity. Current-acquisition systems use potentiostats, which record (the change of) chemical concentrations by measuring reduction–oxidation currents between the electrolyte and the electrodes. Thus, the current-acquisition potentiostat is able to simultaneously transduce neurotransmitter activity at multiple locations; the neural interface acquires oxidation–reduction currents generated at the surface of each sensing electrode. The voltage-acquisition neural

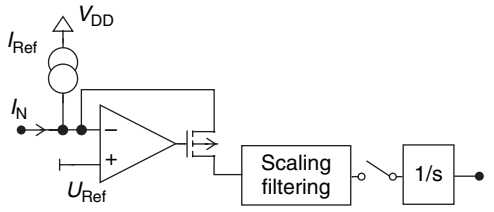

Figure 15 Current-acquisition neural interface. (Source: Aziz J N Y, Genov R 2006 Electro-chemical multi-channel integrated neural interface technologies. *Proc. IEEE Int. Symp. Circuits and Systems*, pp. 2201–4.)

interface monitors a 2D action potential field, e.g., within a brain tissue area under observation.

Recently, an increasing number of integrated potentiostats have been presented (Kakerow *et al.* 1995, Murari *et al.* 2005), which achieved impressive low-power operation and high dynamic range in the lower picoampere range. An exemplary current-acquisition neural interface is schematically shown in **Figure 15** (Aziz and Genov 2006). Usually, for amperometric sensing over electrodes, potentiostatic instrumentation is required (which allows current measurement at regulated potential). Each potentiostat recording channel features a working electrode at the virtual ground, and a reference electrode, which applies the redox potential. The potentiostat provides the voltage for driving the redox reactions at the sensor with respect to the reference in the bath and a counter electrode on the electrode array. Since the expected currents are in the range of nanoamperes to picoamperes, they do not severely affect the reference electrode. Thus, the principally required three-electrode system is most often reduced to a two-electrode system (Aziz and Genov 2006) and the large counter electrode is used instead of a currentless reference. To provide some flexibility for the potentiostat readout, the reference voltage should be programmable, while the detectable currents need a large dynamic range. Also, the filtering behavior must be adjustable in order to acquire the signals under different working conditions (Aziz and Genov 2006, Eversmann 2003).

The circuit in **Figure 15** illustratively works as follows: in order to convert the bipolar input signal into a unipolar form, it is shifted by summing with a constant reference current I_{ref}. As voltage measurement needs high impedance measurement, so does current measurement require low input impedance of the measurement system. This is achieved by the transconductance amplifier that drives the PMOS transistor in **Figure 15**. The acquired signal current is then conducted into normalization circuit, which scales the different signals into a unified range of 0.1 μA. This normalized unipolar signal is fed into an antialiasing low-pass filter. The capacitive feedback amplifier at the end of the channel is used as current-to-voltage converter. Several of these signals can subsequently be multiplexed into an output word (Aziz and Genov 2006) or further processed in parallel.

In opposition to the current measurement, the more commonly used voltage-acquisition microsystems record neural action potentials by measuring the extracellular potential field generated by action potentials as explained in Section 1.16.4.1.1 (Aziz Genov 2006, Harrison *et al.* 2006, Wise *et al.* 2004). Thereby, most existing designs trade between acquisition channel circuit area and thus the number of parallel channels against intrinsic circuit noise. One of the most often used interface circuits for neural spike detection is shown as a simplified circuit in **Figure 16**. It features a preamplifier, which is capacitively AC-coupled in order to filter the DC offset through polarization at the electrode–electrolyte interface (Harrison and Charles 2003, Olsson *et al.* 2002, Wise *et al.* 2004). This amplifier ideally shows a high-pass transfer function:

$$A_{cc}(i\omega) = -\frac{R_{fb}C_{in}}{\frac{1}{i\omega} + R_{fb}C_{fb}} \qquad [17]$$

Thus, a zero gain at DC is obtained and the midband gain is set by the capacitors to:

$$A_{mb} = -\frac{C_{in}}{C_{fb}} \qquad [18]$$

and a low cutoff frequency at:

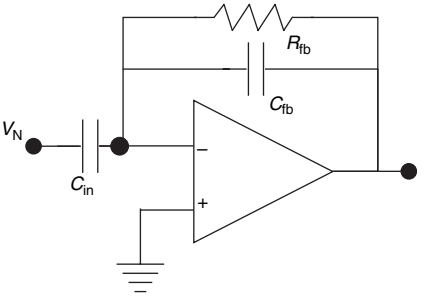

Figure 16 Capacitively coupled neural readout amplifier. (Source: Olsson R H, Gulari M N, Wise K D 2003 A fully-integrated bandpass amplifier for extracellular neural recording. *Proceedings of the IEEE Engineering in Medicine and Biology Symposium*, pp. 165–8.)

$$f_{\text{lowcut}} = \frac{1}{2\pi R_{\text{fb}} C_{\text{fb}}} \quad [19]$$

For realistic integrated capacitances in the picofaraday range, in order to obtain very low cutoff frequency below $\leq$100 Hz, the feedback resistor must be in the gigaohms range. Therefore, the feedback resistors are usually realized by specially biased transistors, e.g., MOS in the subthreshold range (Olsson *et al.* 2002). This capacitive feedback scheme in its various implementations (Harrison and Charles 2003, Olsson *et al.* 2002, Wise *et al.* 2004) allows a precise amplifier, since it is set by the capacitor ratio in eqn [18]; these can be very precisely achieved in an integrated CMOS process. The large feedback resistors also form a DC path, which supports a lower output offset voltage. Thus, the output offset approximately equals the input offset of the amplifier. This is important, first in order not to saturate the preamplifier by too large offsets, and second this is important in time-multiplexed systems, where the multiplexer otherwise could see large switching transients and thus might saturate.

Finally, a recently reported approach to overcome the limitations of this usually employed voltage readout in **Figure 16** is discussed. Among others, Harrison and Charles (2003) has shown that the feedback capacitor may degrade the input referred noise, and furthermore lowers the input impedance of the amplifier. High input impedance is, on the other hand, mandatory for voltage readout. Consequently, Gosselin *et al.* (2006) proposed a preamplifier with active rather than passive DC rejection, thus avoiding the need for passive high-pass-filter (HPF) with very low cutoff frequency, large resistors, etc. It consists of a low-noise operational transconductance amplifier with an active feedback loop that rejects any DC offset. An illustrative schematic is shown in **Figure 17** (Gosselin *et al.* 2006). The integrator time constant is set by a small capacitor C_i and a very large MOS resistor, implemented as in Harrison and Charles (2003). Beyond its advantages, the proposed amplifier is obviously more prone to noise, since more active devices are seen at the electrode input.

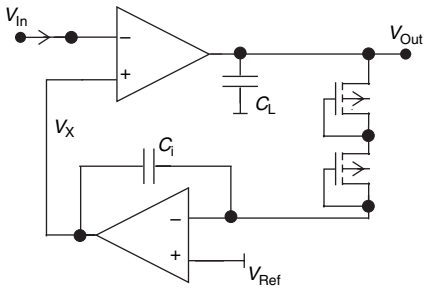

Figure 17 Illustrative schematic of a bioamplifier with active direct current (DC) suppression. (Source: Gosselin *et al*. 2006.)

In conclusion, a third way for neural recording is, based on the ISFET principle, by connecting the electrode to the gate of a metal oxide semiconductor field-effect transistor (MOSFET). Within an electrically grounded electrolyte, a neuron can be brought in direct contact with an extracellular electrode, covered by a dielectric layer; as a result, a cleft of the order of 50 nm between the cell membrane and the dielectric is obtained. Membrane currents that flow through the cleft lead to a potential drop due to the resistance of the cleft. This voltage signal is capacitively coupled to the electrode below. An illustrative model is presented, for example, in Eversmann (2003). Thus, the neuron's action potential induces changes in the sensing electrode potential, which again results in a modulation of the transistor's drain current. This method was used, for example, as early as 1986 (Najafi and Wise 1986) or as recently as 2003 (Eversmann 2003), to achieve a 128×128 electrode sensor with a readout rate of 2000 frames per second; note that this results in a data rate of approximately 32 million samples per second, which must be processed and subsequently transmitted.

1.16.4.1.3 Advanced circuit techniques

Beyond the basic ideas of nerve signal recording, various circuit techniques are quite commonly adopted in order to improve the signal-to-noise ratio and therewith increase the resolution. Moreover, the high-pass filter behavior should not be degraded, but even improved. Some of these techniques are the following:

- Differential recording of each electrode with respect to a dedicated, reference electrode, which improves the common-mode rejection. This technique, usually adapted in analog signal processing, also improves the signal-to-noise ratio, the dynamic range, suppression of even order harmonics, and more.
- CDS, which is usually adopted in subsequent analog signal processing in order to remove offsets that are caused by device mismatch (Aziz and Genov 2006).
- The use of voltage-dependent resistive devices in the feedback of the readout amplifier in **Figure 16**.

It can, for example, be realized by a pseudoresistor, i.e., two antiserial diodes (Olsson *et al.* 2003) or two serial MOS diodes (Harrison and Charles 2003), as used in **Figure 17** (Gosselin *et al.* 2006). This combination has a very large resistance (>1 GΩ) for low AC signals (<200 mV), but decreases its value for larger signals, thus lowering large signal distortion. Additionally, the devices used do not need a biasing circuit, as, for example, subthreshold transistors would need (Wise *et al.* 2004).

- The use of analog signal chopping, which is a commonly used technique for suppressing unwanted low-frequency signals, thus implementing high-CMRR and low-noise front ends (Enz and Temes 1996). This is achieved by mixing the signal to an intermediate frequency (IF), and after low-frequency noise and offset appearance, this deteriorated signal is mixed again, bringing the disturbance to the IF and the signal back to DC. Since chopping amplifiers are by principle DC-coupled devices, a modified concept was proposed for an AC-coupled instrumentation amplifier in Yazicioglu *et al.* (2006).

1.16.4.1.4 Parallel recording

Nowadays, development of neural signal recording is driven mainly by one demand: the possibility to massively record in parallel at a vast amount of different electrode sites (Wise *et al.* 2004). Many previously published integrated neural interfaces with large number of electrodes were realized with time-multiplexed signal acquisition, i.e., multiple sites are connected to a smaller number of signal-recording channels. Nonetheless, time multiplexing prevents the accurate capture of heterogeneity or communication across biological ensembles because the recording on different channels is performed consecutively rather than parallelly and simultaneously (Aziz and Genov 2006).

Thus, the development of very small, low-power readout amplifiers with subsequent parallel analog signal processing is a must, and many recent publications focus on this topic (Aziz and Genov 2006, Eversmann 2003, Wise *et al.* 2004, Yazicioglu *et al.* 2006). Furthermore, the integration and packaging of the system also becomes a major focus, since huge amounts of circuitry, wiring, and electrode tips must be assembled in a small, reliable housing. Outstanding advances have been achieved at the University of Michigan in this field over the past decades, who integrated active circuits with electrodes in a 3D system, nowadays also combining recording and stimulation electronics (Wise *et al.* 2004).

Finally, a common, very important topic is the data transmission: if, for example, a number of 100 electrodes is assumed, each of which is sampled at a data rate of only 5 kb s^{-1}, and if each of the sampled data points provide only 5 bits of resolution then a huge amount of data of 2.5 Mbits s^{-1} is available from this recording system. If such a system is wired and used for *in vitro* experiments, then the major task is to handle the data on chip (Eversmann 2003). A completely different challenge appears, if the recording system is implanted into the body: a wireless link with a capability of data rate of several megabits per second is a nontrivial task. This becomes especially true, because power consumption for an implantable device is a very critical issue. Therefore, either multiplexing is employed again or signal preprocessing is performed before the data is sent over the wireless link. This can be as easy as a simple spike detector (Harrison *et al.* 2006, Watkins *et al.* 2004) or a more complex digital signal processing (O'Driscoll *et al.* 2006).

1.16.4.2 Electronic Stimulators for Functional Electrical Simulation

As outlined in Section 1.16.4.1.1, the nerve cell potential can be depolarized from its resting potential at −70 mV toward ≈ −55 mV by an external stimulus; when this threshold is crossed the nerve cell fires a spike that runs along an axon toward the nervous system, e.g., the cell could be one out of millions in the human retina, stimulated by the incoming light whose action potential is transmitted via the optic nerve toward the brain. Nonetheless, the external stimulus can also be electrically generated by means of a neural stimulator implant.

1.16.4.2.1 Basics of FES

During the past decade, the development of implantable FES and FNS has made great progress in the treatment of neural and muscular disabilities. Among others, the cochlear implant, cardiac pacemaker, deep brain stimulators, implants for bladder control, or stimulators for hand or extremity control are some of the prominent examples. One of the most recent advances is the retinal implant for visual restoration (Chow and Chow 1997, Eckmiller *et al.* 2005, Liu 2004, Ortmanns *et al.* 2006b, Stieglitz 2006, Wyatt and Rizzio 1996, Zrenner 2002). Electrical stimulation of a neural response is achieved by transferring

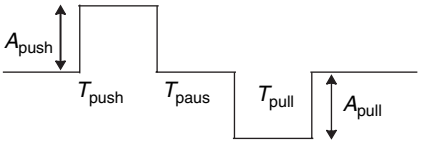

Figure 18 Biphasic, push–pull stimulation current.

the charge over a conducting electrode into the neural tissue. The amount of charge needed and the time for this transfer heavily depend on many factors: the stimulation circuitry, the stimulation waveform, the frequency, the excitation threshold of the cells (see Section 1.16.4.1.1) as well as on the stimulating electrode's location, geometry, surface coating, and configuration (Merrill *et al.* 2005). Commonly, the charge transfer is done using biphasic current pulses as indicated in **Figure 18**, with amplitudes ranging from as low as 10 μA for stimulation in the cortex to as high as several hundred microamperes for the cochlear or retinal implant (Humayun *et al.* 1999, Liu *et al.* 2000, Prutchi and Norris 2004, Weiland *et al.* 2003, Wise *et al.* 2004). Constant voltage stimulation has been used especially in commercially available, external stimulators, but the control on the delivered charge is low and therefore the safety is doubtful, unless external measures can be taken. Other approaches, for example, SC charge delivery, are still under research (Ghovanloo 2006), since it is unknown how the neural cells respond on spiking excitation.

If electrical current is forced through an electrolyte via electrodes, electrochemical effects must be taken into account. By bringing a conducting material in contact with a saline solution, a molecular layer of water is adsorbed at the interface, as indicated in **Figure 19**. As a consequence, when charging the electrode, the opposite charge in the solution is separated from the electrode by the so-called Helmholtz double layer acting as a capacitor (Dymond 1976). A feasible electrical model of the electrode–tissue interface will therefore incorporate the double layer capacitance and in parallel an impedance that models the electrode–electrolyte charge movement (Franks *et al.* 2005). This current results from both reversible and irreversible electrochemical faradaic reactions. In addition, the solution itself represents a resistance for the current, and thus a series resistor is taken into account.

Figure 20 shows this simplified electrode model for two stimulation electrodes and one counter electrode; C_E represents the double layer interface

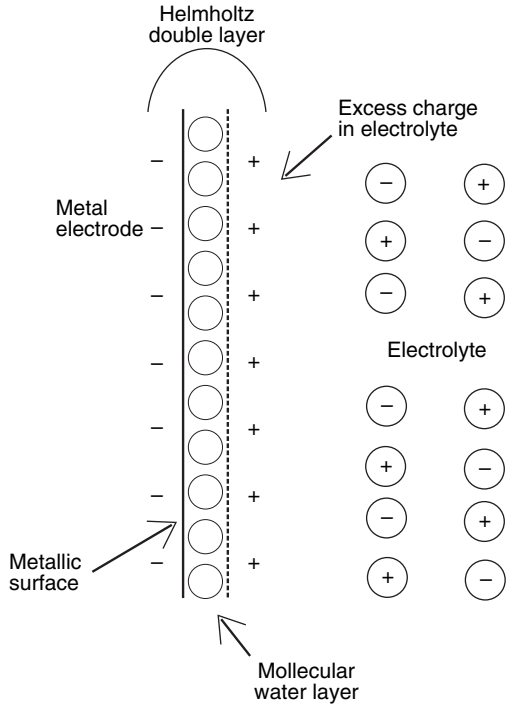

Figure 19 Simplified model for an electrode–tissue interface.

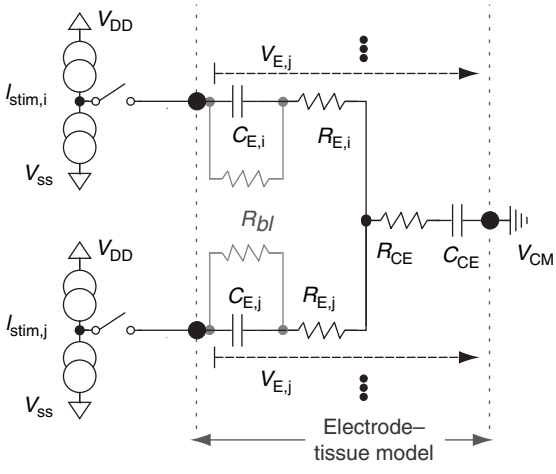

Figure 20 Simplified model for an electrode–tissue interface.

capacitor, R_E the solution–tissue impedance, while R_{Bl} represents the charge transfer resistance, which models reduction and oxidation currents flowing in equilibrium. In other models (Ortmanns *et al.* 2006b), diodes with series resistors R_D in parallel to R_E model strong faradaic currents that flow if the potential over the electrode–tissue interface permanently increases over a large oxidation–reduction potential, also

known as the water window. Even more complex models can be found in Franks *et al.* (2005), Najafi and Wise (1986), and Olsson *et al.* (2003); but commonly, for safe operation only R_E and C_E are of interest. In the exemplary case of a retinal implant, experimental results with the geometrically small electrodes yields $R_E \approx 10\,k\Omega$ and $C_E \approx 100\,nF$; the common ground electrode has $C_{CE} \approx 10\,\mu F$, whose influence can thus be neglected.

Generally, in multichannel microstimulators, the stimulator circuitry selects an active electrode and controls a stimulus current I through it. Especially, if many electrodes are spaced very closely to each other, a possible cross talk between neighboring sites can be significant (Lovell *et al.* 2005), which is not considered in the simple model in **Figure 20**. Constant current stimulation with biphasic current pluses is also schematically indicated in **Figure 20**; in bipolar stimulation, current is stimulated from one electrode to another, while in monopolar stimulation a physically large ground electrode serves as a common counter electrode.

1.16.4.2.2 Basic requirements and challenges

Besides the commonly accepted requirements of an implantable integrated circuit, i.e., low power consumption, small physical size, only few external components (Wise *et al.* 2004), modern stimulation systems, e.g., a visual prosthesis, mainly exceed these by one more critical feature: stimulation currents have to be independently delivered into a very large number of small electrodes, all of which need to fulfill the same safety issues as before (McDermott 1991, Scheiner and Mortimer 1990). This results in three major tasks that have to be fulfilled: high voltage compliance, high parallelism, and safety and test. These are discussed in more detail in the following sections.

1.16.4.2.2.(i) High voltage compliance Constant current stimulators can work only as long as the maximum possible output voltage swing ($\leq V_{DD}$ in **Figure 20**) is larger than the stimulation current times the effective electrode impedance. For example, for a biphasic stimulation current of ± 1 mA and a tissue impedance in the range of 10 kΩ (Humayun *et al.* 1999, Ortmanns *et al.* 2006b, Sivaprakasam *et al.* 2005), the stimulator voltage compliance must be larger than ± 10 V. With some voltage overhead for the current sources and the stored charge on the interface capacitor C_E, this yields in a supply voltage of 20–25 V. Several approaches have been presented to achieved this voltage compliance:

- Using old CMOS technologies with larger breakdown voltage (Sivaprakasam *et al.* 2005, Suaning and Lovell 2001).
- Limiting the maximum output current to a value feasible for the chosen technology.
- Using electrode reversal, i.e., a monopolar current source is adapted, but the polarity of the electrodes is turned around (Liu *et al.* 2000, McDermott 1991).
- Employing a high-voltage (HV) CMOS technology (Doguet *et al.* 2000, Ortmanns *et al.* 2006b).

Note that an old CMOS requires much higher die area, especially if a large digital overhead is needed for communication, signal processing, or control, since digital area is quadratically reduced with CMOS scaling. Second, a flexible stimulator should cover a large range of output currents, thus its limitation limits the functionality and the flexibility of the stimulator. Finally, electrode reversal requires voltage switches that are realized in CMOS by transmission gates; these need the highest switching voltage at their gates and even in HV technologies, such transistors are not available (Ortmanns *et al.* 2006a). Furthermore, electrode reversal allows only one electrode being stimulated at a time, if monopolar systems with one large counter electrode are used.

1.16.4.2.2.(ii) Parallelism For many modern FES systems, the primary requirements is a large number of stimulation electrodes (Liu 2004, Zrenner 2002), e.g., for a visual prosthesis in order to provide basic pattern recognition. In addition to the pure number of stimulation sites, the frequency of their independent stimulation is also important. In order to achieve flicker-free vision in a retinal prosthesis, stimulation frames should be applied at a rate of 50–60 Hz. Imagine as the little as 16 bits of addressing and programming data for each electrode, 60 Hz frame repetition means approximately $100\,kb\,s^{-1}$ data per 100 electrodes. This amount of data must be received with low power consumption and thereafter effectively distributed and stimulated on the ASIC. Recent approaches with large numbers of electrodes provided only a limited number of independent current sources, which were then multiplexed to a large number of output electrodes (Kim and Wise 1997, Liu *et al.* 2000, Sivaprakasam *et al.*

2005, Suaning and Lovell 2001). Nonetheless, this limits the flexibility and, most importantly, multiplexing again requires serial switches, which are not available in a HV stimulator (see Section 1.16.4.2.2.1).

1.16.4.2.2.(iii) Safety and test In order to be feasible for long-term implantation, besides the basic functionality of delivering stimulation currents into a large amount of electrodes, test and safety features must also be provided. Typically, the electrode impedance may vary significantly depending on the patient, long-term effects as well as attachment to the tissue (Weiland *et al.* 2003). Therefore, a possibility for an electrode impedance measurement is commonly provided (Ortmanns *et al.* 2006b, Wise *et al.* 2004).

The most critical safety risk is the prevention of DC stimulation currents into the electrodes in order to protect the tissue from destruction electrolysis with electrode dissolution and pH change (Rattay 1990, Scheiner and Mortimer 1990). Ideally, biphasic stimulation pulses as in **Figure 18** do not show net charge transfer; but through device mismatch, a finite DC current appears (Liu *et al.* 2000). Previous measurements for a retinal stimulator showed that DC currents I_{dc} must be <10 nA for the used electrodes (Ortmanns *et al.* 2006b). (This corresponds to a large charge transfer resistor R_{BI} in **Figure 20**.) Then, charge accumulation on the electrodes is prevented and strong faradaic currents do not flow. On the other hand, stimulation currents of more than 1 mA are commonly seen (Liu 2004, Ortmanns *et al.* 2006b); thus, biphasic current pulse matching should be in the range of:

$$\frac{\Delta I}{I} \leq \frac{10\,\text{nA}}{1\,\text{mA}} = 0.001\,\% \qquad [20]$$

which is not a realistically achievable value. The corresponding countermeasures are explained subsequently.

1.16.4.2.3 DC current prevention through charge balance concepts

Besides the biphasic current in **Figure 18**, which achieve first-order charge-balanced stimulation (Scheiner and Mortimer 1990), several methods exist to guarantee safe, DC-free current stimulation.

1.16.4.2.3.(i) Blocking Capacitors In most designs since 1970s, serial blocking capacitors between the stimulation sources and the tissue interface capacitors (C_E in **Figure 20**) have been the predominant technique (Huang *et al.* 1999, Sauning and Lovell 2001). By their physical property, they cannot conduct DC currents, which is the wanted characteristic, and furthermore this is the only safety feature in the case of semiconductor failure. But blocking capacitor have two major disadvantages: first, a serial capacitor integrates the total stimulation current, while it must not saturate the output current source by too high-voltage requirements; thus usually much larger values than the interface capacitor C_E are required, which cannot be realized on chip. Additionally, one capacitor is needed per electrode if parallel stimulation is required. For a large number of sites (e.g., the retinal prosthesis), the technique is thus not feasible (Liu 2004, Ortmanns *et al.* 2006b).

1.16.4.2.3.(ii) Passive and switched charge balancing Recent integrated FNS implementations used charge-balancing techniques, which made use of shorting all electrodes (Liu *et al.* 2000) after stimulation or of discharge resistors between the stimulation electrodes and/or the counter electrode (Sivaprakasam *et al.* 2005): therewith, accumulated charge and thus excess electrode voltage should be neutralized. But there arise two contradictory requirements: small discharge resistors are efficient for fast and reliable charge balancing at all electrodes, but they carry a substantial amount of stimulation current if they are in the range of the electrolyte resistance R_E as in **Figure 20**. On the other hand, large discharge resistors are efficient during stimulation, but the time constant may become too large for sufficient charge balancing, e.g., for the retinal implant in Ortmanns *et al.* (2006b), with $C_E \approx 100\,\text{nF}$ and $R_E \approx 10\,\text{k}\Omega$, a discharge resistor of $100\,\text{k}\Omega$ already carries 10% of the stimulation current, but the discharge time constant is 10 ms; if the charge imbalance is 1–10 μA over time, the voltage over the electrode increases to several hundred millivolts, which may finally yield strong faradaic currents.

Consequently, recent implementations used switched electrode shortening with low discharge resistors, which are connected only after a stimulation; this is efficient during stimulation and sufficient for reliable charge balancing. But, for HV applications, there arises again the question of a HV switch, and additionally, common to all of these techniques the charge balancing is not a closed-loop controlled process, but rather uncontrolled.

1.16.4.2.3.(iii) Active charge balancing In order to solve these challenges, active charge balancers were studied; until recently, mostly all active approaches relied on controlling a copied version of the stimulation current and performing electrode charge balancing until the copy was also balanced (Gnudason 1999). The disadvantage of such techniques is the need for an exact copy, and as indicated in eqn [20] the required mismatch is unrealistically high. Consequently, in Ortmanns *et al.* (2006b) a direct closed-loop control of charge-balanced stimulation has been presented. This system actively steers the excess electrode potential after a mismatched biphasic stimulation into a safe window. The idea is illustrated in **Figure 21** as an extension of the two stimulation electrodes in **Figure 20**: after stimulation at either electrode with a biphasic current I_{Stim}, due to mismatch an excess electrode voltage will be left on C_{E}. This voltage is not directly accessible, since without the additional sensing electrode, only the counter electrode or the stimulation electrodes can be electrically connected. As long as the current flows, mainly the large resistive voltage drop over the tissue and the electrolyte impedance R_{E} is seen, but not the voltage over the interface capacitance. Without current, $V_{\mathrm{CE}} \approx \Delta V_{\mathrm{E}}$ can be measured. (The voltage over the counter electrode interface capacitance is negligible because $C_{\mathrm{CE}} \gg C_{\mathrm{E}}$.) Note that the exact value is important only if the excess voltage exceeds a safe voltage window around the common-mode potential. This check is done subsequent to each stimulation by using a window comparator, for which a feasible implementation has been presented in Ortmanns *et al.* (2006b). In case $V_{\mathrm{E}} > V_{\mathrm{CM}} \pm \Delta V_{\mathrm{E,safe}}$, after the measurement the stimulation current sources are used to counteract

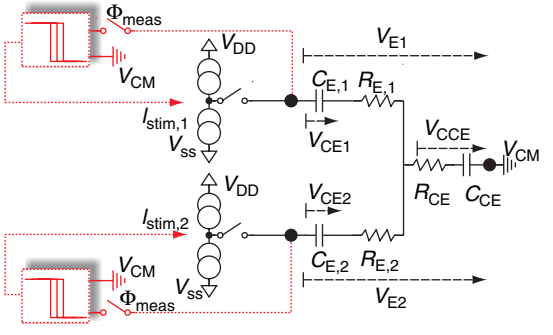

Figure 21 System of closed-loop, active charge balancer. (Source: Ortmanns M 2007 Charge balancing in functional electrical stimulators: a comparative study *Proc. IEEE Int. Symp. Circuits and Systems,* New Orleans, LA, USA, pp. 573–6).

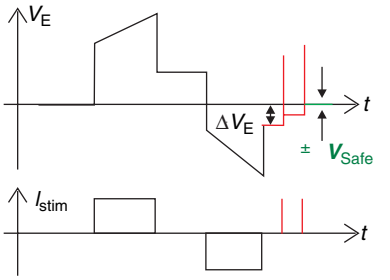

Figure 22 Excess electrode potential elimination.

the excess electrode voltage by applying a small charge packet of feasible polarity. This can be done with current spikes, as indicated in **Figure 22** (Ortmanns *et al.* 2006b), but other implementations are also feasible. This check-and-charge operation is repeated until the electrode potential lies within a safe window. Therewith, an exact control of the safe operating condition is given to the system and the operator.

1.16.4.2.4 A retina stimulator ASIC

As an example for electronic interfaces to neural tissue, a recently presented visual prosthesis will be shortly reviewed (Ortmanns *et al.* 2007). About 1.5 million people worldwide suffer from a chronic degeneration of the retina (retinitis pigmentosa or age-related macular degeneration), which disables their ability of vision. Therefore, basic restoration of vision through functional electrical nerve stimulation has become a focus for biomedical implants over the past few years (Ohta *et al.* 2005, Ortmanns *et al.* 2006a, Liu 2004, Zrenner 2002). Several techniques are used, while the retinal approach relies on electrically stimulated neurons in the retina that bypass the damaged photoreceptors and directly create visual excitation.

Most systems of such stimulators consist of external image reception by means of a camera and an external image preprocessing. A system, which has been implemented by IIP Technologies GmbH and sci-worx GmbH, has been published in Ortmanns *et al.* (2006a, b, 2007) and is illustrated in **Figure 23**. The data are sent to the implanted stimulator via an optical link at $1\,\mathrm{Mb\,s^{-1}}$ Manchester code. The energy is transferred with a telemetric RF link at 13.56 MHz. Internal rectification and buffering provide supply voltage for the stimulator. Uniquely, the system of Ortmanns *et al.* (2006a) uses two internal coils that provide three voltage levels: a high voltage is used for the stimulator output ($V_{\mathrm{Stim}} > 20\,\mathrm{V}$); a middle tap gives the counter electrode potential

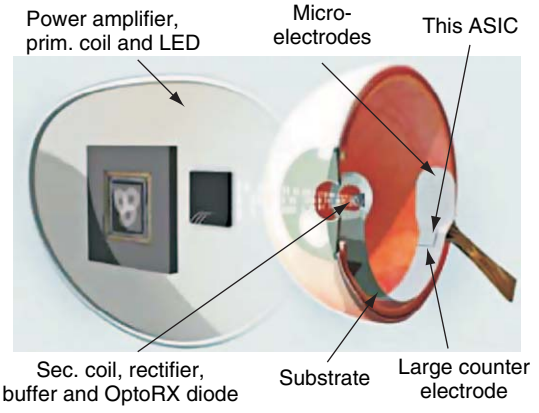

Figure 23 System overview of en epiretinal implant. (Courtesy: IEEE and IIP Technologies GmbH. Source: Ortmanns M, Unger N, Rocke A, Rackow S, Gehrke M, Tiedtke H J 2007 A 232 channel visual prosthesis ASIC with production compliant safety and testability. *Proceedings of the IEEE International Solid-State Circuits Conference*.)

$V_{cm} = V_{Stim}/2$, which is a large area connected to the intraocular tissue; and a second coil provides the unregulated low supply voltage (4–5 V) for the LV analog and digital part of the implant. In order to achieve high flexibility and efficient execution of the stimulation commands, the implant itself has to be separated into shared, global functions and an array of digitally programmable stimulation pad cells with dedicated functionality.

This concept of row/column stimulation array has been used as early as in 1973 (Donaldson 1973) for addressing that different electrodes has been used; but here, it is extended to a digitally programmable array of dedicated stimulation cells in Ortmanns *et al.* (2006b).

1.16.4.2.4.(i) Shared functions The architecture of the global functions is illustrated in **Figure 24(a)**. From the unregulated low supply voltage a constant $V_{DD} = 3.3$ V supply is provided by a series regulator. The high supply voltage is safely limited to approximately $V_{Stim} = 25$ V with a shunt regulator. A bandgap circuit provides a reference voltage and a current. An optical receiver (OptoRX) recovers the incoming optical data stream at 1 Mb s^{-1} Manchester coded data and clock recovery is directly performed on the sinusoidal RF input signal. A global stimulation control unit (GSU) serves as a communication interface. It decodes the 1 Mb s^{-1} incoming serial data stream and restores the information of the next stimulation sequence. Using load modulation on the secondary coil, data are back communicated sent outside with 20 kb s^{-1}. An attached 32-bit PROM block stores the implant ID and also contains tuning bits. The data transfer from the GSU to the local pad cells is done over a digital bus and a row column decoder. Finally, a dual-slope ADC is used for the measurement of electrode voltage.

1.16.4.2.4.(ii) Local stimulation functions The architecture of the local functions is shown in **Figure 24(b)** (Ortmanns *et al.* 2006b). Since not all pads are stimulated in parallel due to power issues,

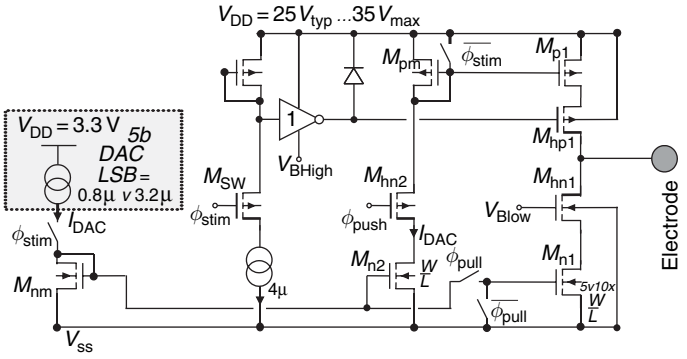

Figure 25 Output stimulation current source. (Courtesy: IIP Technologies GmbH. Source: Ortmanns M, Unger N, Rocke A, Gehrke M, Tiedtke H J 2006 A tetina stimulator ASIC with 232 electrodes, custom ESD protection and active charge balancing. *Proc. IEEE Int. Symp. Circuits and Systems*, pp. 652–5; Ortmanns M, Unger N, Rocke A, Gehrke M, Tiedtke H J 2006 A 0.1 mm^2 digitally programmable nerve stimulation pad cell with high-voltage capability for a retinal implant. *Proceedings of the IEEE International Solid-State Circuits Conference*.)

each local stimulation pad cell serves as a pair of stimulation electrodes. This way, the local functions are used twice, die area is saved, and full flexibility is still achieved. The distributed pad cells are programmed via the digital bus. A digital pad control unit (PCU) accepts and stores data from the bus if addressed. Then, the local amplitude data are provided to a 5-bit current steering digital-to-analog converter (DAC), which features two bias ranges (1LSB = 0.8/3.2 µA; LSB = least significant bit). The DAC output is mirrored into a HV output current source, which connects the stimulation electrode (**Figure 25**). The output mirror gain is either 5 or 10. Thus, the output current can be adjusted between 4 and 992 µA with 5-bit resolution and dynamic range (DR) ≈ 50 dB. Finally, the active charge balancer circuit explained in **Figure 21** is implemented at each stimulation electrode (Ortmanns *et al.* 2006b).

Figure 26 shows the used circuit for the charge balancer explained in Section 1.16.4.2.3.3. Differential voltage measurement is performed without stimulation current, thus the residual charge on the electrode capacitance C_E is obtained. The voltage measurement at a high common-mode electrode potential ($V_{cm} = V_{Stim}/2 \approx 10$ V) is achieved with a HV differential pair with source degeneration: it translates the HV difference $V_E - V_{CM}$ into an equivalent current difference, mirrors it into the LV domain, where it is compared to a reference window. If the corresponding voltage exceeds a safe operation window of ±50 mV, a charge packet of correct polarity is applied. In **Figure 25** the HV push-pull current source is also shown. For good matching of the biphasic pulse and thus good first-order charge

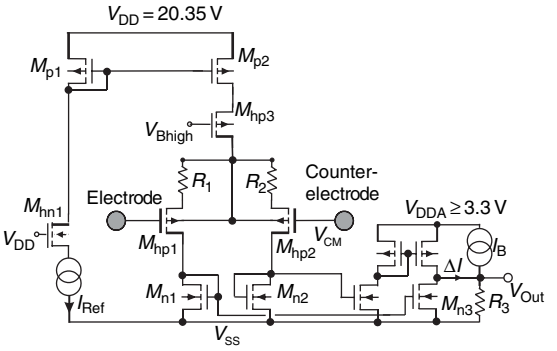

Figure 26 Exemplary implementation of the active change balancer. (Courtesy: IIP Technologies GmbH. Source: Ortmanns M, Unger N, Rocke A, Gehrke M, Tiedtke H J 2006 A tetina stimulator ASIC with 232 electrodes, custom ESD protection and active charge balancing. *Proc. IEEE Int. Symp. Circuits and Systems*, pp. 652–5; Ortmanns M, Unger N, Rocke A, Gehrke M, Tiedtke H J 2006 A 0.1 mm^2 digitally programmable nerve stimulation pad cell with high-voltage capability for a retinal implant. *Proceedings of the IEEE International Solid-State Circuits Conference*.)

balancing, the current mirror matching is critical; therefore, LV transistors are used for the mirrors in the HV domain, while HV transistors shield the LV domain from overvoltage. Electrostatic discharge (ESD) protection is a must, even with the large number of 232 electrodes; standard ESD-protected HV pads are about the target size of the stimulation pad cell. Thus, in this design the parasitic drain-bulk diodes of the HV output transistors were used as ESD diodes to the supply rails (Ortmanns *et al.* 2006a, b).

1.16.4.2.4.(iii) Chip design This presented circuit concept for a visual prosthesis stimulator has

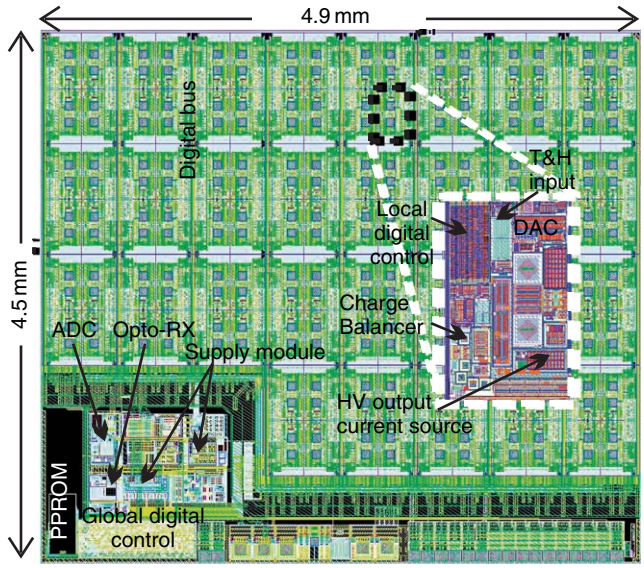

Figure 27 Layout of the 232 electrodes retina stimulator application-specific integrated circuit (ASIC). (Courtesy: IEEE and IIP Technologies GmbH. been realized in a 0.35-μV HV CMOS technology, which provides up to 50 V voltage capability, while being feasible for a small digital circuit area. In total 116 stimulation pad cells were placed, each serving two electrodes; thus, this retinal stimulator shows the largest number of stimulation sites presented up to now (Ortmanns *et al.* 2007). Each pad cell consumes as little as 100,000 μm^{22} of die area, making the overall chip $\approx 20\,mm^2$ large. The layout of the retina stimulator ASIC is shown in **Figure 27**.

1.16.5 Conclusion

A number of different microelectronic techniques employed in the integration of microsystems have been presented in the previous sections. The use of microelectronics has brought major breakthroughs to a wide range of fields of application and the possibility of combining various individual microtechniques is seen as a major economic factor. This technology delivers microsensors with integrated electronics for local signal conditioning. The output signals are less susceptible to noise, thus enabling a safe data acquisition, transmission, and further processing. Not only is the size, weight, and power consumption of such systems reduced, but their functionality is also drastically enhanced. This miniaturization opens new application fields – some of which we are just beginning to envision. The most challenging and at the same time exciting part of this development is the fact that a number of engineers from different disciplines join together to make this possible.

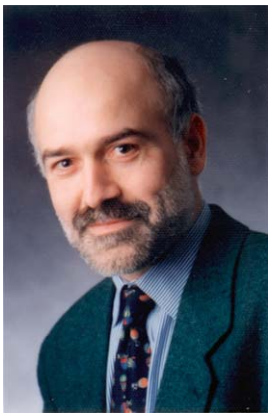
Biographies



Yiannos Manoli was born in Famagusta, Cyprus, in 1954. As a Fulbright scholar, he received the B.A. degree (*summa cum laude*) in Physics and Mathematics from Lawrence University in Appleton, Wisconsin, in 1978 and the M.S. degree in Electrical Engineering and Computer Science from the University of California, Berkeley, in 1980. He obtained the Dr.-Ing. Degree in Electrical Engineering from the Gerhard Mercator University in Duisburg, Germany, in 1987.

From 1980 to 1984 he worked at the University of Dortmund, Germany, in the field of digital and analog MOS integrated circuit design with an emphasis on A/D and D/A converters. For his patented work on a self-calibration method he received the best paper award of the European Solid-State Circuits Conference (ESSCIRC 1988).

In 1985 he joined the newly founded Fraunhofer Institute of Microelectronic Circuits and Systems in Duisburg where he established a design group for microsystem and microcontroller integrated circuits. His work there concentrated on mixed-signal CMOS circuits especially for monolithic integrated sensors such as surface micromachined pressure sensors, flow sensors, biosensors etc. Another highlight of his work was the design of application specific microcontrollers as well as novel architectures and development tools for such microcontrollers. This work has resulted in several patents and over 60 technical publications.

In September 1996 he joined the Department of Electrical Engineering at the University of Saarland in Saarbruecken, Germany where he held the Chair of Microelectronics. His research interests were focused on the design of low-voltage/low-power mixed-signal CMOS circuits and VLSI embedded system design and design methodology. As department head (1998–2000) he initiated a number of reforms that boosted the research activities and enhanced the teaching curriculum of the department. In 2000 he had the opportunity to spend half a year on a research project with Motorola in Phoenix, Arizona.

In July 2001 he was appointed Chair of Microelectronics at the Department of Microsystems Engineering (IMTEK) of the Albert-Ludwig-University in Freiburg, Germany. His current research interests are the design of low-voltage/low-power mixed-signal CMOS circuits, wireless sensor network electronics, sensor read-out circuits as well as A/D- and D/A-converters. In 2006 he spent his sabbatical semester on a research project with Intel in Santa Clara, California.

Since May 2005 he and two other IMTEK colleagues additionally serve as directors at the Institut für Mikro- und Informationstechnologie of the Hahn-Schickard Gesellschaft (HSG-IMIT) in Villingen-Schwenningen.

Professor Manoli has served on the committees of a number of conferences such as ISSCC, ESSCIRC, ICCD and DATE and was Program Chair (2001) and General Chair (2002) of the IEEE International Conference on Computer Design (ICCD). He is a member of Mortar Board, Phi Beta Kappa, IEEE, VDE and VDI.

Maurits Ortmanns received the Dipl.-Ing. in electrical engineering from the Saarland University, Saarbruecken, Germany, in 1999 and the Dr.-Ing. degree from the Albert-Ludwigs-University, Freiburg, Germany, in 2004, both with highest honors.

In 1997 and 1998, he was with the Research Center Karlsruhe, Germany, and with EXAR, Inc., Fremont, CA, as an engineering intern working in the field of Microsensors. In 1999, he joined the Institute of Microelectronics of the Saarland University, where he was working as a research assistant. In 2001, he moved to the Institute of Microsystem Technology, Albert-Ludwigs-University, where he was working toward the Ph.D. degree in the field of continuous-time sigma-delta modulator design until March 2004.

From 2004–2005, he has been with sci-worx GmbH, Hannover, Germany, where he was working in the field of mixed-signal and analog circuits for biomedical implants, low voltage, low-power applications, and high-speed circuits. In the beginning 2006,

Mr. Ortmanns was with the HSG-IMIT, Villingen-Schwenningen and additionally a guest lecturer at the Institute for Microsystems Engineering at the University of Freiburg, Germany.

Since May 2006, Mr. Ortmanns is an assistant professor for Integrated Interface Circuits at the same university. His main research interests include mixed-signal circuit design, smart microsensors, and biomedical applications.

Mr. Ortmanns received the VDI award for the Best Masters Degree and the VDE award for the Best Masters Thesis in electrical engineering from the University of Saarland in 1999. He is a member of the German National Academic Foundation, the IEEE and VDE.

Alexander Buhmann received the Dipl.-Ing. degree from the University of Freiburg, Germany, in 2003, with a thesis on the optimization of MEMS based micro resonators. He is currently pursuing the Ph.D. degree at the Chair of Microelectronics, Institute for Microsystems Engineering (IMTEK), University of Freiburg. His current research interests include sensors and systems, control theory, and algorithm development.

1.17.1 Introduction

In microelectromechanical systems (MEMS) technology, testing is a verification technique for the performance, quality, or reliability of the devices. Furthermore, extensive testing is used for the control of manufacturing steps as well as for field monitoring and self-test of MEMS. A distinction must be made between the phases of design and development, and production. This chapter describes and discusses the various tests that are applied for MEMS and their specific features. Furthermore, it demonstrates how these methods can be utilized as part of a comprehensive quality strategy.

1.17.2 Qualification Procedures and Test Strategies

This section discusses systematically how tests are utilized in the life cycle of development and production of microsystems. Hence, it is helpful to consider the various domains of the process of product generation. The principal ones are the chain of supply and the timescale.

Typically, microsystems are developed and produced by a supplier of components for an original equipment manufacturer (OEM) like a car manufacturer who defines requirements and specifications. The three basic elements of a specification are functionality, reliability, and costs. A typical development model is the V-model (**Figure 1**).

As a first step, the concept of architecture for the microsystem and the specification must be validated. The validated specification must be fault-free, i.e., correct, complete, free of contradictions, and applicable. As a result of the formal validation, the specification will be a binding requirement for all further activities.

Based on the specification of the system, subspecifications are derived for the individual blocks of the system. In this case, such blocks might be MEMS hardware, software, and assembly and packaging technology. A specification for the system comprises an environment temperature of 150°C. As the MEMS device exhibits a heater, the hardware is specified for operation at 175°C. Also such a requirement must be validated formally. In a similar manner, requirements for the utilized materials are generated and formally accepted. All these activities make up the top-down branch of the V-model.

On the bottom-up path, the materials are first checked for their suitability, which requires materials testing. In the next step, they are used to build up hardware, which is subsequently tested to verify whether it meets the specification. Finally, the microsystem is integrated from its building blocks, and its functions and its reliability are verified. A large portion of this verification is done experimentally, i.e., by testing. Only when the system meets all the specifications, can it be qualified formally (**Figure 1**).

The V-model is an idealized structure. Also it does not make clear whether the number of subsystem elements increases like for a pyramid. All activities on one layer must be coordinated and synchronized. For that purpose, it is helpful to partition microsystems into three columns, as it has been implemented successfully for the design of mechatronic systems. In this case, separately designing software, MEMS hardware, and assembly and packaging technology appears to be an efficient partitioning. Also, it reflects the individual worlds of engineers working in different organizations and using different methods and tools (**Figure 2**).

By partitioning, parallelization is also achieved. In each branch, a standard sequence of analysis, design, prototype generation, and test is applied. After the individual tests and verifications, the system is integrated and tested as a whole. Design-for-testability is an important issue as testing costs make up a large portion of the development costs.

The considered approach is quite efficient when the microsystem development is performed in a steady-state process where subsequently similar systems are generated. Under the present conditions

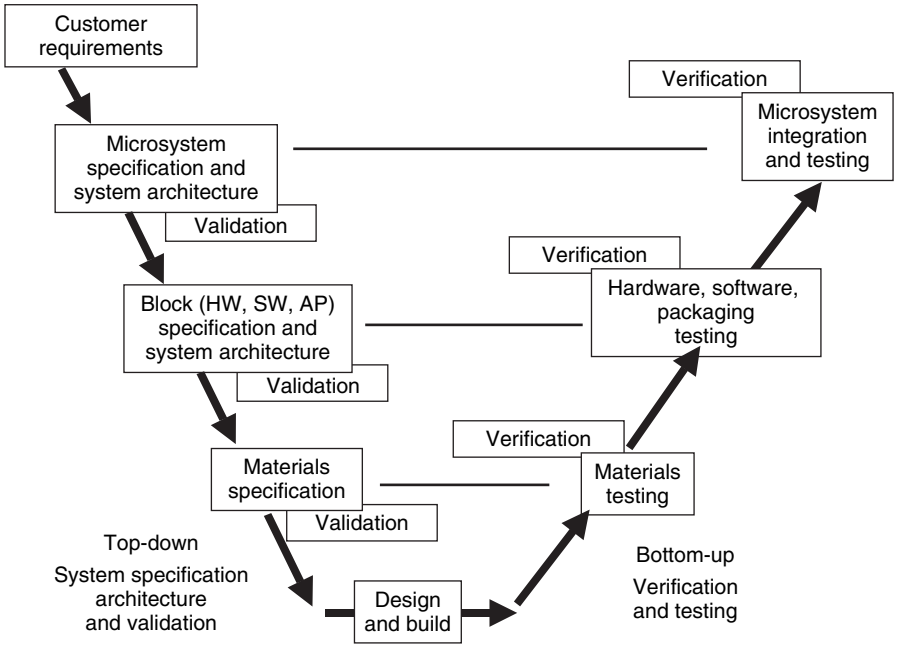

Figure 1 The V-model of top-down specification and bottom-up verification of microsystems.

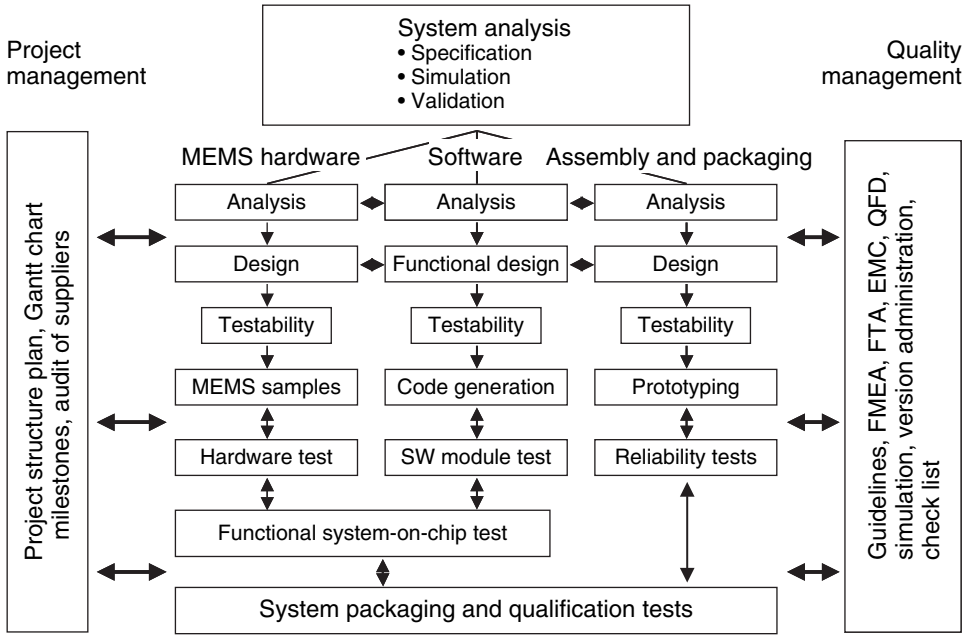

Figure 2 Partitioned system development of micromechatronic systems. EMC, electromagnetic compatibility; FMEA, failure mode and effects analysis; FTA, fault tree analysis; QFD, quality function deployment.

of accelerating development processes, the introduction of new technologies must also become more efficient. Also it will significantly affect the testing strategy.

Sometimes a microsystem producer plans to introduce a new technology. Examples include a transition from bulk micromachining (BMM) to surface micromachining (SMM) or a change from hermetic packages to wafer-bonded chips in plastic housings. In order to generate series products and to keep these qualified, several stages of qualification are necessary (**Figure 3**).

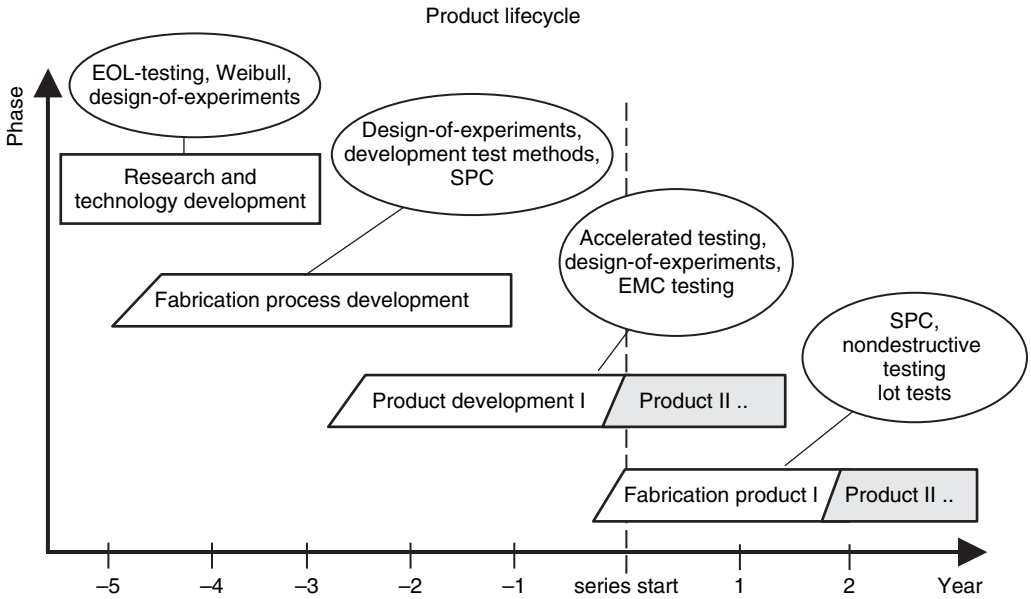

Figure 3 Reliability testing during different phases of the product generation cycle of microsystems. EOL, end-of-life; SPC, statistical process control.

Table 1 Characteristics of reliability tests in the technology-, process-, and product-development phases of MEMS hardware

Phase of life cycle	*Motivation of testing*	*Tests and test samples*	*Test scheme*
Technology development	Analyze and optimize design parameters, which affect reliability	Technology samples, dummies Accelerated tests Systematic failure analysis Simulation	Systematic design variations
Process development	Analyze process parameters and disturbance variables, which affect reliability	Robust fabrication processes Accelerated tests Optional failure analysis	Systematic process variations
Product development	Verify that new product meets all specifications	Test for conformity with requirements	Stable processes Some variations
Product series production	Monitor minimum quality and reliability levels	Statistical process control Accelerated tests Functional tests	No variations Constant fabrication
	Avoid faulty products	Nondestructive testing Failure analysis of defects	

(1) In the first phase, it is necessary to perform research projects in order to characterize a new technology.
(2) In the second phase, fabrication processes must be qualified for the new technology.
(3) In the third phase, products will be developed and qualified using the new technology.
(4) In the last phase, the products are fabricated and a requalification of the series products is verified on a lot-by-lot basis.

In **Table 1** the different requirements and purposes of testing in the subsequent phases of the product life cycle are summarized. The methodology as well specific reliability tests will be described in Section 1.17.7.

1.17.3 Process Monitoring

1.17.3.1 Statistical Process Control

The MEMS facility must produce devices that fulfill their specifications with respect to performance, quality, and reliability. Typically, at the end of a MEMS fabrication process the devices will be subjected to comprehensive final tests to verify their accordance with the specifications. Unfortunately, this concept usually does not allow for fast process monitoring and control. Therefore, the method of statistical process control (SPC) has been established in order to check whether a process is controlled and capable. Also it is an efficient technique to analyze the transient quality in comparison with the long-term behavior.

The total process chain must be partitioned into individual steps, which can be analyzed efficiently. In the SPC, charts are used to visualize the quality level of each step. For control charts, it is necessary to measure certain properties that are relevant for the quality and for subsequent fabrication steps.

(1) In the first step, all properties to be monitored must be determined, such as layer thickness, adhesive strength, and etch rate.
(2) These values are recorded over a certain period of time in lots of size n. From these mean values $\widehat{\mu}$ and variances $\widehat{\sigma}^2$ are computed for the total process. A test on the normal distribution should be performed.
(3) For the control charts upper and lower limits (ULs and LLs) are computed. These are the warning limits and the control limits.
(4) Within short periods of time lots of a limited size are taken repetitively. For each lot, mean values and variances are computed.

There are two principal types of control charts. The first one is the chart for mean values, which is applicable when always the same target value, e.g., a certain film thickness, is expected. The second is the control chart for the variability (scatter), which is sensible when the target property is variable.

1.17.3.1.1 Shewhart control charts for mean values

In order to determine the control limits, the mean value $\widehat{\mu}$ and the standard deviation $\widehat{\sigma}$ of the total process are computed as follows.

	In each lot	*Total process*
Mean value	$\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i$	$\hat{\mu} = \bar{\bar{x}} = \frac{1}{k}\sum_{i=1}^{k} \bar{x}_i$
Standard deviation	$s = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(\bar{x}-x_i)^2}$	$\hat{\sigma} = \sqrt{\frac{1}{k(n-1)}\sum_{i=1}^{k}\sum_{j=1}^{n}(x_{ij}-\hat{\mu})^2}$
Upper limit UL	$\mathrm{LL} = \hat{\mu} - \left(\frac{u_{1-\alpha/2}}{\sqrt{n}}\hat{\sigma}\right)$	$\mathrm{UL} = \hat{\mu} + \left(\frac{u_{1-\alpha/2}}{\sqrt{n}}\hat{\sigma}\right)$
Lower limit LL		

x_i is the property of the product which is regarded.

$u_{1-\alpha/2}$ is taken for a certain confidence level $1-\alpha$ based on the normal distribution. α is the significance level. For $1-\alpha = 0.99$, $u_{1-\alpha/2} = 2.576$.

$1-\alpha$	0.90	0.95	0.99	0.999
$1-\alpha/2$	0.95	0.975	0.995	0.9995
$u_{1-\alpha/2}$	1.645	1.960	2.576	3.291

Upper and lower control limits (UCL and LCL) are taken for the confidence level of $1-\alpha = 0.99$ and warning limits UWL and LWL for the confidence level of $1-\alpha = 0.95$. This leads to four characteristic limits shown in the chart as follows:

Control limit	*Warning limit*
$1-\alpha = 0.99$	$1-\alpha = 0.95$
$\mathrm{LCL} = \hat{\mu} - 2.576\,\frac{\hat{\sigma}}{\sqrt{n}}$	$\mathrm{LWL} = \hat{\mu} - 1.960\,\frac{\hat{\sigma}}{\sqrt{n}}$
$\mathrm{UCL} = \hat{\mu} + 2.576\,\frac{\hat{\sigma}}{\sqrt{n}}$	$\mathrm{UWL} = \hat{\mu} + 1.960\,\frac{\hat{\sigma}}{\sqrt{n}}$

In **Figure 4**, a typical control chart is shown for the oxidation process of silicon wafers at a temperature of 950°C. The limits have been computed according to the equations above.
