A typical test distribution is the χ^2-distribution, which is the basis for control charts for the variability of the product properties:

Control limit	*Warning limit*
$1-\alpha = 0.99$	$1-\alpha = 0.95$
$\mathrm{LCL} = \sqrt{\frac{\chi^2_{n-1;\ \alpha/2}}{n-1}}\,\hat{\sigma}^2$	$\mathrm{LWL} = \sqrt{\frac{\chi^2_{n-1;\ \alpha/2}}{n-1}}\,\hat{\sigma}^2$
$\mathrm{UCL} = \sqrt{\frac{\chi^2_{n-1;\ 1-\alpha/2}}{n-1}}\,\hat{\sigma}^2$	$\mathrm{UWL} = \sqrt{\frac{\chi^2_{n-1;\ 1-\alpha/2}}{n-1}}\,\hat{\sigma}^2$
$M = \hat{\sigma}\cdot a_n$ for s or $M = \bar{R}\cdot d_n$ for $\bar{R}$	

Typically, the scatter of each lot is recorded in the control chart. It is computed as the standard deviation of each sample. In some cases it is easier to monitor just the span R, i.e., the difference between the maximum and minimum values of each lot. Correction factors for the middle of the chart are taken from the following table:

Sample size n	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*
Factor a_n	0.798	0.886	0.921	0.940	0.952	0.959	0.965	0.969	0.973
Factor d_n	1.128	1.693	2.059	2.326	2.534	2.704	2.847	2.970	3.078

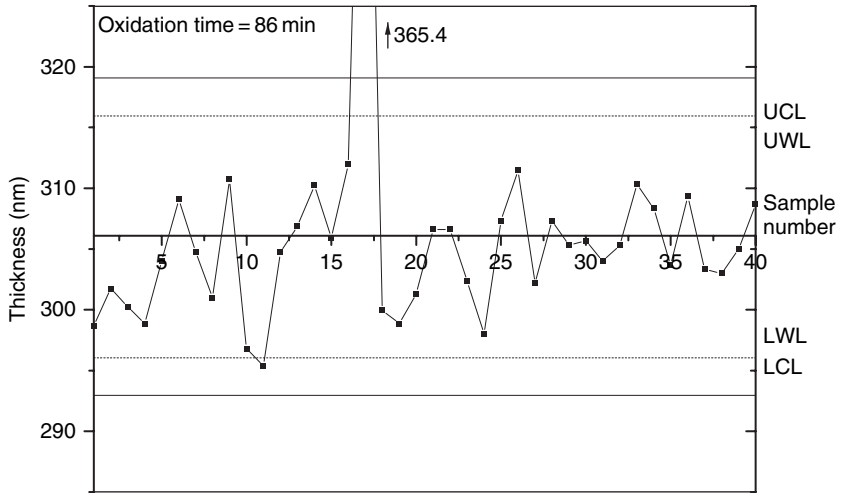

Figure 4 Statistical process control (SPC): Shewhart mean values control chart of wet oxidation of silicon at 950°C. Upper and lower control limits (UCLs and LCLs) and upper and lower warning limits (UWLs and LWLs).

1.17.3.2 Test Structures for Process Monitoring

In MEMS technology many individual process steps must be monitored by specific tests, which are listed in Table 2.

There are mainly four basic groups of test, which can be used on these structures:

Visual inspection	Optical microscope, scanning electron microscope (SEM), focused ion beam (FIB)
Electrical measurement	Resistance, dielectric properties
Optical measurements	Elipsometry, refractive index, infrared (IR) transmission
Mechanical tests	Adhesion, microhardness, internal stress

Many of these tests can be performed on wafers without specific test structure, but in many cases well-defined test features must be generated.

Only a part of the test methods is described by standards. A number of national and international standards define the test structures. Many of these have been established in very large-scale integration (VLSI) silicon processing. A well-known source is the US National Institute of Standards and Technology (NIST), which has defined test structures for contact resistance, feature sizes, or electromigration.

When a manufacturing process of a device is monitored, metrology of the device-specific structures on product wafers will yield the most realistic results. The main purpose of special test structures is standardization. This will make it possible to measure the properties of materials or process data under comparable conditions. In semiconductor technology, the use of test structures is established for decades and many test structures have been standardized by the NIST. A typical example is the NIST electromigration structure that requires a well-defined line width and contact geometry in order to generate comparable reliability data for an individual metallization. Another important property is the contact resistance. It depends on contact geometry, size, doping concentration, intermediate layers, and heat treatment. All parameters of the test structures must be variable in order to allow an adaptation to all products. There are several general requirements to test structures for MEMS. These are as follows:

- Versatile application over a wide range of technologies, materials, and sizes.
- Generation of data, which can be compared to existing and future structures.
- Ease of implementation on test wafers as well as on production wafers.
- Representative of target product and technology.

In the following the required test structures for diffused or implanted resistors in silicon will be discussed as illustrated in Figure 5. Such elements are frequently used as stress-sensitive transducers in pressure sensors or load cells.

The schematic structure exhibits a conductor realized by p-diffusion in an n-substrate. A layout as well as a cross section and a parallel section are shown. The resistance is affected by the following factors:

- Sheet resistance of the doped regions, which depends on the diffusion profile as well as on the specific resistance (doping concentration).

Table 2 Tests and test structures for the monitoring of the basic MEMS process steps

Process step	*Property*	*Test structure needed*
Oxidation, nitridation	Thickness and deposition rate, stress, dielectric breakdown strength, pinhole density per area, refractive index	No
Photoresist	Thickness, pattern definition and size, aspect ratio	Yes
Metallization and conductors	Thickness, pattern definition and size, adhesion, stress, resistance, contact resistance, electromigration resistance, aspect ratio, edge coating, bondability	Yes
Implantation or diffusion (resistors)	Doping profile, concentration, implantation depth, implantation width, resistance, contact resistance	Yes
Dielectric layers and insulators	Thickness, pattern definition and size, aspect ratio, adhesion, stress, resistance, planarization, insulation resistance, dielectric breakdown strength, edge coating, refractive index	Yes
Surface micromachined structures	Pattern definition and size, aspect ratio, stress, mechanical quality factor, resonance frequency	Yes
Deep etching	Deepness and etch rate, aspect ratio, wall angle, anisotropy, roughness	Yes
Wafer bonding	Adhesive strength, hermeticity, defects per bonded area	No

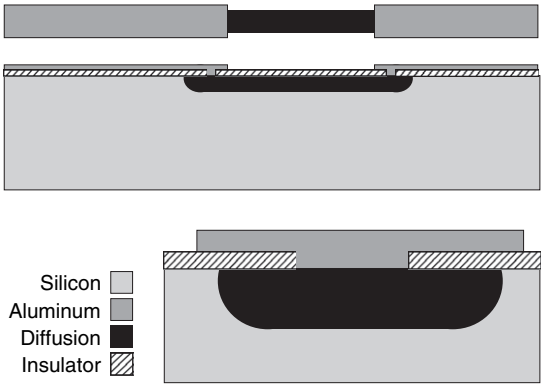

Figure 5 Cross section of an implanted resistor in silicon.

- Cutoff voltage and the reverse current of the insulating pn-junction.
- Contact resistance from silicon to the metal conductor.
- Sheet resistance of the metal line.
- Pattern quality, e.g., edge displacement and edge roughness.
- Contact resistance between test probes and bonding pads.

These individual properties cannot be determined on complete resistors. Also the cause of defectiveness can only be cleared up systematically on test structures, which are produced simultaneously with the resistor. In Figure 6 the following layers of the test structure are used:

01	diff1	Red	Doped region
10	pass1	Blue	Contacts between metal line and doped region
11	pass2	Turquoise	Aperture of the passivation on the bond pads
20	metall1	Green	Aluminum conductor

Using the upper left structure in Figure 6, the sheet resistivity of the aluminum line is measured. It is a four terminal structure, which is not affected by parasitic resistances of the wires or probes. Similarly, the resistivity of the doped region is measured with the second pattern in the top line.

The contact resistance between silicon and metal is measured using the third pattern in line 1. The contact is divided into small areas in order to avoid size effects as a result of current crowding. Also many contacts can be connected in series in order to measure the effective contact resistance and to evaluate the reliability at increased test currents with the first

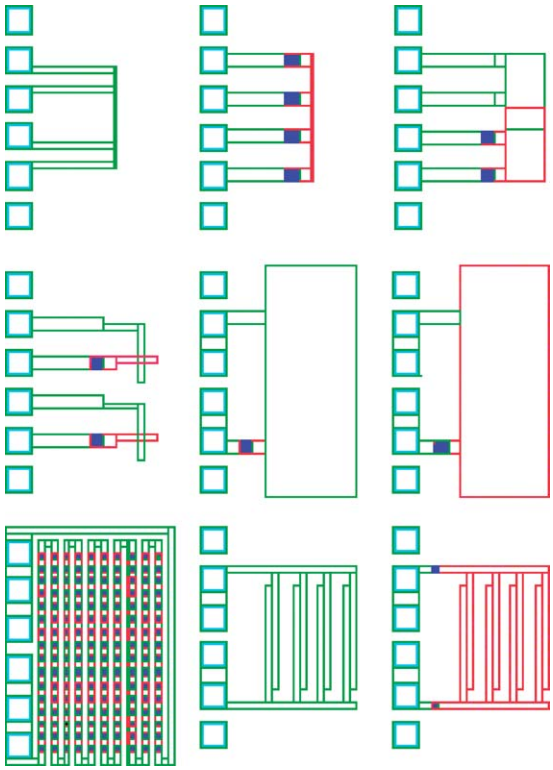

Figure 6 Test structures for monitoring structural and material parameters of implanted resistors in silicon.

structure in line 3. The structures in line 2 were developed to measure the breakdown strength and the residual current of insulating pn-transitions. In line 3 the dielectric breakdown strength of the passivation on top of the aluminum conductors is tested with the test pattern 2, while the last structure is used to check for defects between the two doped conductors.

Typically, test structures are scaled in size over a wide range because they must represent the actual product features. Also size-dependent effects such as edge displacement or underdiffusion must be taken into account. Unfortunately, in MEMS industry, many of the test structures are kept confidential as they can reveal the quality level of the fabrication facility. Also there is no comprehensive standard for BMM or SMM structures, which is equivalent to the microelectronic standards defined by the NIST.

1.17.3.3 Test Structures for Fault Detection

On microelectronic systems two basic types of faults can be distinguished. One is catastrophic faults, which lead to complete nonfunction. The second is

parametric faults, which can be regarded as parasitic elements, which can change voltages, currents, or the transient behavior. For mechanical elements of MEMS, complete failure is often a result of fractured structures or of nonreleased structures (Table 3). When functional parameters are affected, in most cases the mass, the stiffness, or the damping factor are out of range. In these cases the static as well as the dynamic behavior will be affected significantly. Therefore, it is possible to conclude from functional misbehavior back to physical defects of the micromechanical elements. Mir *et al.* (2000) proposed failure modeling in order to analyze fault effects on the functionality or on parameters, which can be measured. To that purpose, a physics-of-failure model and a subsequent simulation using the finite element method will be powerful tools to evaluate the effectiveness of possible test concepts. An example is the influence of vacuum quality on the damping properties of a resonant structure and therefore on the natural frequencies and the quality factor of the vibration (Table 4).

Table 4 lists the possible parametric faults in the mechanical and the electrical domain of micromachined thermal MEMS. Geometry and structural features as well as material properties are mainly affected by the fabrication process. As a result, the coefficients that determine the properties of the electrical or mechanical element will be affected. Examples are stiffness, mass, capacity, or resistance. On the behavioral level, properties such as resonance frequency, offset, and sensitivity can be monitored in tests.

Beroulle *et al.* (2001) worked out a scheme to conclude from relatively simple tests on system level to physical defects of the electrical or mechanical structures (Table 5). Unfortunately, such a concept has some limitations:

- The basic failures will be detected only with indirect methods.
- Measurement of resonance frequency or sensitivity requires physical stimulation.
- For complementary metal oxide semiconductor (CMOS) integrated MEMS the electrical properties on the physical level will only be accessible when adequate test points are integrated into the design. This requires a consequent design-for-testing concept.

Table 3 Catastrophic faults for CMOS-compatible suspended thermal MEMS due to manufacturing defects

Electronic structure faults (gauge)	*Mechanical microstructure faults*
Short faults	Break
Polysilicon, one level	Outside gauge
Polysilicon, two levels	Around gauge
Between poly-silicon and metal	Including gauge
Metal, one level	
Metal, two levels	
Open faults	Locking faults
Polysilicon level	Nonreleased microstructure
Metal level	Stiction
Polymetal contact	Cavity protuberances

1.17.4 Functional Testing

1.17.4.1 Wafer-Level Testing

A silicon-integrated microsensor exhibits electrical input connections for parameterization, programming, and power supply. The typical output is made up by the sensor signals and in most cases also by some status information. Microsensors need a physical stimulus to generate the measurand. In practice, sensors will need more than one stimulus as a result of cross sensitivities. Typically, the dominant disturbance variable is temperature but other effects such as pressure, moisture, or mechanical stress must also be taken into account. When testing at the package level, the device is already interconnected to the signals and to the physical world, as shown in Figure 7. Therefore, in the case of complete devices, correct physical stimulation and measurement are relatively easy to accomplish.

Such a package-level test concept alone has significant disadvantages: One is the delay between fault generation and fault detection due to the time of the manufacturing cycle. The second is the higher costs of complete devices. According to an analysis by MEMUNITY and SUSS, a typical costs distribution for a MEMS device is as follows:

- Cost of die: €3.00
- Cost of wafer-level (WL) test: €0.90
- Assembly and packaging: €7.00

Hence, 70% of all manufacturing costs are because of the back-end process and only 30% because of front-end fabrication. Therefore, if a silicon die is defective, the economic loss per piece is €3. When the bad MEMS chip is further packaged, the total loss will be €10 per defective unit.

Table 4 Classification of parametric faults on micromachined thermal MEMS

Mechanical domain	*Electrical domain*
Structural properties	Structural properties of conductors
Edge quality, width, length, thickness	Width
Cativity protuberances	Length
Friction and stiction	Thickness
Missing structures	Doping profile
Partial suspension or release of structures	
Vacuum quality or pressure	
Thermomechanical material properties:	Thermoelectrical material properties:
Mass density	Resistivity of polysilicon and metal
Young's modulus	Contact resistivity
Thermal coefficient of expansion (TCE) of metal	TCR of polysilicon and metal
Heat conductivity and capacitance	Piezoresistive coefficient of Si
Beam emissivity	Seebeck coefficient poly and metal
Convection coefficient	Permittivity and loss factor dielectrics
Friction coefficient	
Variation of mechanical coefficients	Parasitic electrical components:
Stiffness, compliance	Parasitic resistances
Mass	Parasitic capacities
Damping factor/viscosity	Parasitic inductivities
System behavior:	System behavior:
Natural frequency	Offset shift
Quality factor	Sensitivity change
Nonlinearity	Impedance-level change

Mass out of range	Sensitivity or resonance frequency
Damping coefficient out of range	Sensitivity or quality factor
Cavity protuberances	Nonlinear behavior
Structure break or nonreleased	Sensitivity

Source: Beroulle *et al*. (2001).

Another aspect is the time, which it takes to feed back the failure information into the wafer production process. Failure analysis of a packaged device is tedious. The silicon chip must be unpacked without producing defect artifacts. Also, assembly and packaging is not performed in a clean room where the wafer was processed but in a factory at another site or even in another company. It will then take weeks to months to feed back the error information into the wafer fabrication. Therefore, the data will not be up-to-date and cannot influence the quality level of the wafers immediately.

Early-stage testing of microsystems on unpackaged devices is an important factor in a modern test strategy. It has been demonstrated for non-MEMS integrated circuits (ICs) that the WL testing of devices is a more

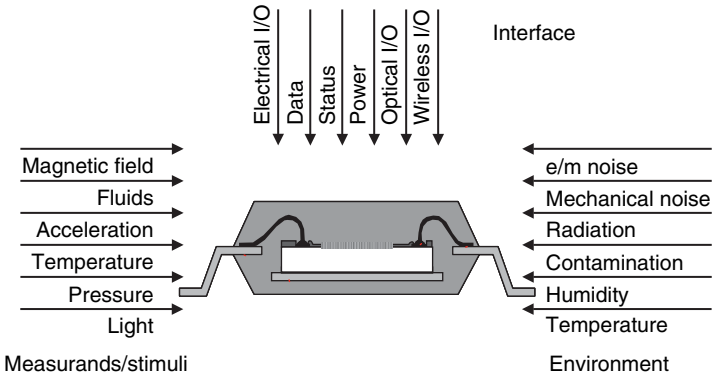

Figure 7 Signals and stimuli during the package-level testing of microsystems.

efficient strategy than the testing of single bare dies. Functional testing at the die level for known good dies requires expensive adapters and would be much more costly than the 10% costs portion of WL tests. A comparison of WL testing and package-level testing of MEMS is shown in **Table 6**. It should be noted that modern test strategies take advantage of both test concepts in order to optimize throughput, accuracy, dependability, and information gain altogether. This is the reason why testing and calibration costs are relatively high compared with the manufacturing costs.

In the following sections, the available technical solutions of testing MEMS on WL stage will be evaluated.

1.17.4.1.1 Wafer probe stations

Because the housing process is one of the most expensive steps during the fabrication of a device, most microsystems are partially tested on WL before the back-end process. A system for wafer testing will consist of four main components. They are as follows:

- The probe station.
- Single probes or a probe card for electrical interconnection to the device.
- A hot chuck that keeps the wafer accurately at a constant temperature level and
- The electronic measurement equipment.

The wafer is loaded manually or by an automatic transport system on a chuck of the wafer probe station and is fixed by a vacuum. There are fully automatic systems on the market, which are mainly used for mass production monitoring; semiautomatic ones for development purposes, and manual ones for research or rare usage (**Figure 8**).

Table 6 Comparison of wafer-level and package-level MEMS tests

Test level	*Wafer level*	*Package level*
Physical stimulation	Not possible for all measured variables	Easy, as all interfaces are present (electrical, mechanical, fluidic, optical)
Test equipment	With physical stimulation expensive Sequential testing	Test adapter costs can be high Expensive multichannel ATE
Measurable variables	I/O variables Electrical parameters on intermediate system levels (requires suitable test points)	Normally only I/O variables after internal signal processing Test modes optional if implemented
Tested elements	Specific tests of silicon element without interference of package	Test of complete microsystem, including packaging effects
Purpose	Measures basic functional properties MEMS process metrology and control Eliminates defective dies with reduced costs	System test Measure customer-relevant features Functionality and reliability Burn-in
Test time	Fast tests Allows fast control loops to the microfabrication processes	Slow tests Aimed at stability and long-term behavior

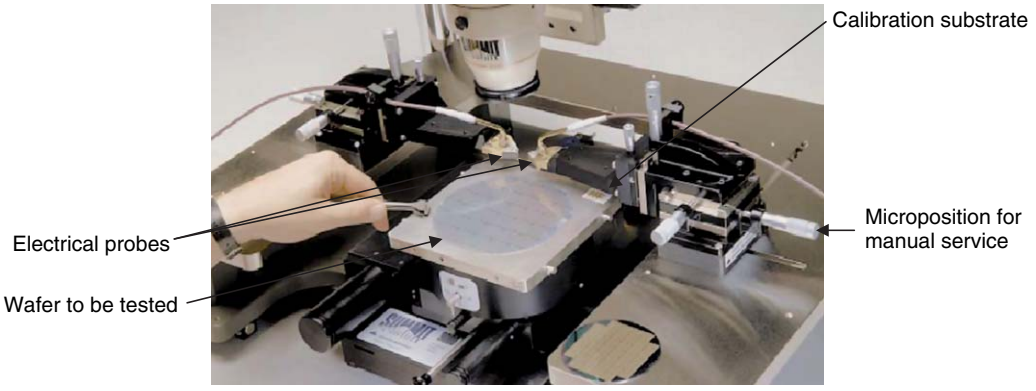

Figure 8 Close-up of a manual wafer probe station on the square chuck with independent vacuum control, which holds a calibration substrate (Impedance Standard Substrate (ISS), back to the right), and a test wafer (to the front) simultaneously. (Photo courtesy: Cascade Microtech.)

1.17.4.1.2 Temperature control

Usually electrical parameters such as impedances or transfer functions are measured using a wafer probe station. Some probes also allow applying a DC voltage between signal and ground. As many electrical properties of silicon structures are highly temperature sensitive, control of the temperature during WL testing is crucial for the accuracy of sensors. A special version of chucks, called temperature chucks, allow for a control of the temperature of the wafer and thus of the device under test (DUT) (**Figure 9**). This is accomplished by electrical heating of the backside of the chuck. For cooling, special air or liquid cooling channels or Peltier elements are integrated into the chuck. The typical test temperature range is between −65°C and 200°C, and special equipment ranges up to 300°C. To achieve a uniform temperature over the wafer, a low thermal resistance of both the chuck and the wafer backside is necessary, and also a high throughput of the cooling liquid is needed.

With a thermal chuck, reasonable care must be exercised to match the thermal expansion coefficients of the wafer and the chuck. Furthermore, the thermal expansion in the z-direction must be controlled very precisely. Otherwise, it would open the electrical contacts of the tips or, worse, could destroy the tips. Usually, special tips are applied to allow some thermal expansion.

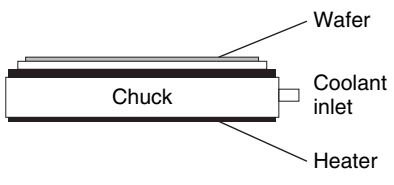

Figure 9 Schematic of the setup of a thermochuck.

1.17.4.1.3 Needle probes and microwave probes

To contact the DUT electrically to the measurement system, wafer probes with special needle-like contact elements are used (Wallitzer *et al.* 2001) (**Figure 10**).

A well-designed probing system also includes the die pad pattern and high-quality transmission line interconnections in order to minimize all errors as much as possible (**Figure 11**; see ground–signal–ground (GSG) versus ground–signal (GS) pads in Section 1.17.5.2.5.(v)).

The probes will indent into the metallic layer of the contact pads. The maximum allowed bending of the probes usually is very small. Thus, special care has to be taken to provide an extremely high planarity of the wafer adjustment to guarantee a good electrical contact with the probes, and to avoid breaking of the tiny needles. The contact of the probes to the pads usually is performed with the help of advanced micromanipulators and monitored by a microscope to check the correct alignment between probes and contact pads and to control the correct distance (**Figure 12**).

1.17.4.1.4 Device bias considerations

Power may be supplied through the analyzer's (e.g., VNA, vector network analyzer) bias ports, which combine the DC and radio frequency (RF) signals together at the measurement ports using bias tees. If the performance of the analyzer's internal bias tee is inadequate, or if the analyzer does not provide one,

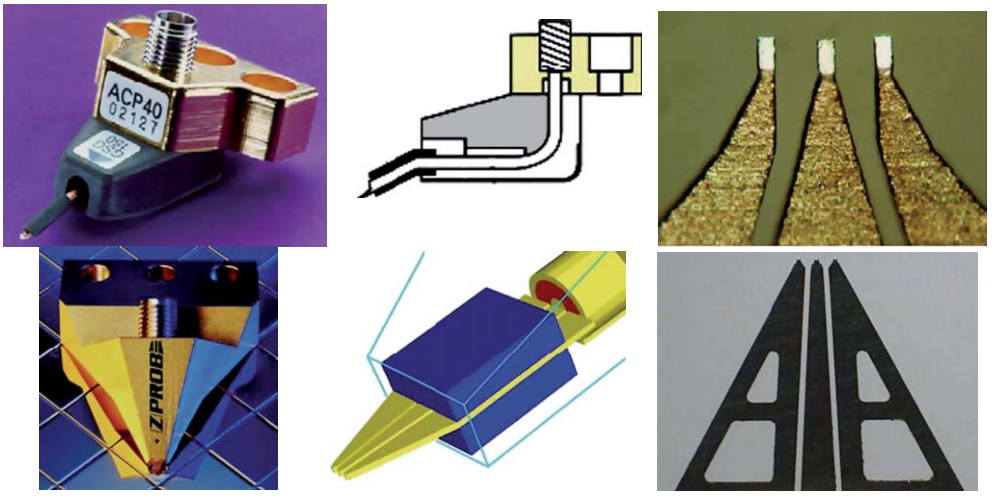

Figure 10 Close-up of a microwave probe used to electrically contact pads of a microelectromechanical systems (MEMS) die on wafer level. (Photo courtesy: Cascade Microtec.) *On the left*, microwave probe with SMA-type electrical connectors; *center*, schematic diagram of the construction of the probe; *right*, close-up view of the tips. (Photo courtesy: SUSS MicroTec.)

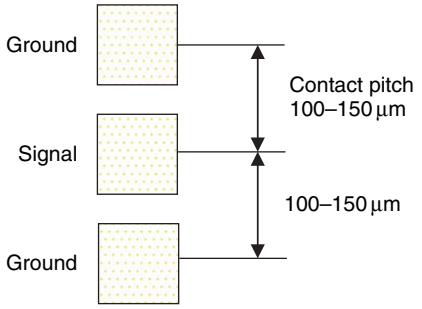

Figure 11 Typical coplanar microwave pad pattern (ground–signal–ground) for each die contact.

then an external bias tee may be preferred. A bias tee is a three-port network with the properties of a diplexer. That is a wide-bandwidth port, which is coupled to the bias port via a low-pass filter and to the RF port through a high-pass filter. Important selection parameters of a bias tee are crossover frequency, bandwidth, current and power rating, resistance and loss, and connector type.

The series and shunt resistances of the bias tee will be significant when measuring individual devices where a precise bias point is desired. For moderate to large currents, the series voltage drop will make a

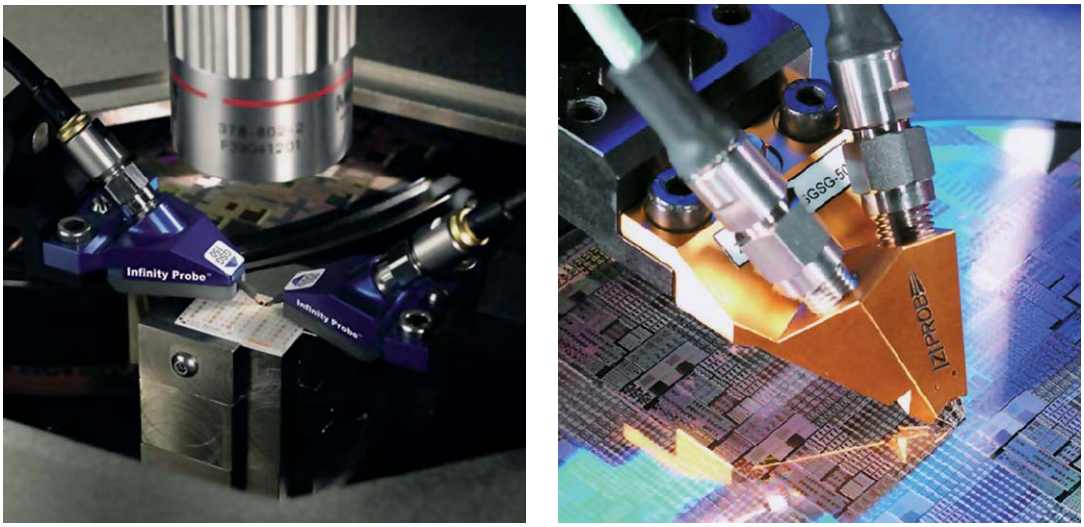

Figure 12 Close-up of microwave probes and cables on positioners, which provide planarity adjustment and cable restraint. *Left*, measurement of a calibration standard; *right*, devices on the wafer. (Photo courtesy: Cascade Microtech and SUSS MicroTec.)

change from the expected bias voltage. Actual device currents will vary from the expected ones due to the current path provided by the shunt resistance. This resistance is high, but not high by the standards of parametric measurements with currents possibly ranging from 1 fA to 100 mA. Probes, cables, and probe stations designed specifically for DC parametric measurements are generally preferred for these cases.

1.17.4.2 WL Physical Stimulation

To evaluate sensor functions or cross sensitivities of the devices, additional environmental loads are required, such as temperature, pressure or gas loads, or magnetic fields. Biotechnological and microfluidic devices frequently need additional duct systems for media. Examples will be given in the next sections.

For the WL test of integrated MEMS, three basic strategies are possible (**Table 7**). The conventional WL test of the analog and digital circuits of MEMS is identical to the WL test of ICs and will only be treated here with respect to RF testing and calibration. Physical stimulation on WL is a new technology, which is very prospective but also has limitations (**Figure 13**). The third concept aims at replacing physical stimulation by electrical excitation (**Table 7**).

This section evaluates the possibilities and requirements of physical testing of MEMS on the WL. Due to the rapid increase of the MEMS components market, also the suppliers of test equipment increased their product portfolio significantly. Consequently, wafer probing of MEMS with physical stimulation has already become the state of the art in several applications.

In **Table 8** a comparison has been made for the physical properties, which can be tested on the WL of MEMS. For many of the relevant sensor types commercial solutions exist, by which physical stimulation with the measured property is possible. Also WL test solutions for micromirror actuators and RF-MEMS are available. Unfortunately, for all the devices, strong cross sensitivities can appear, which must be taken into account. The dominant cross sensitivity of almost all devices is temperature, but also the pressure in the environment or in the device can affect the function (**Table 8**). Furthermore, several on-wafer tests are possible, which are specific for mechanical structures. These will provide information on structural features and will not characterize the full functional behavior. According to **Table 9** geometry, the topology and the binematic and dynamic behavior are tested.

Table 7 Comparison of wafer-level (WL) test strategies for MEMS

Method	*Advantage*	*Disadvantage*
Electrical testing of the analog–digital circuitry	Standard wafer probing	Only partial test of system
Physical stimulation	Realistic and comprehensive testing	Requires WL equipment
Electrical stimulation of the sensor structure	Test efficiency eliminates need for stimulation equipment	Requires design for test

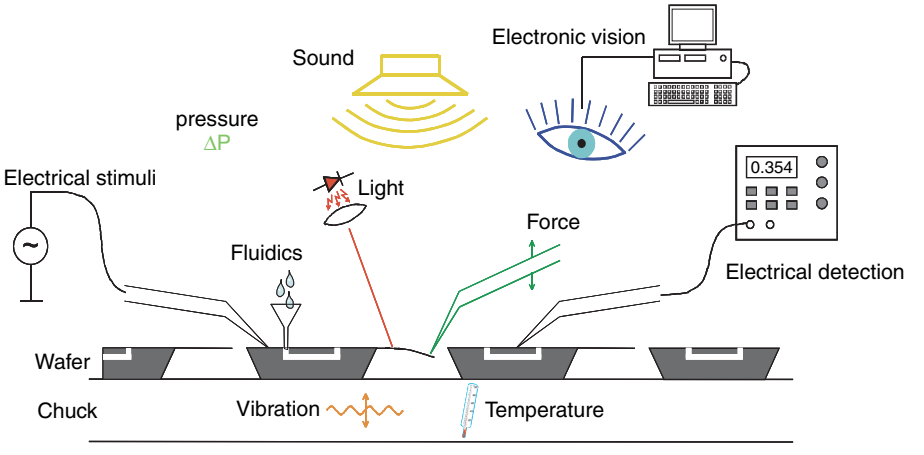

Figure 13 Examples of physical stimulation for the wafer-level testing of microelectromechanical systems (MEMS) (SUSS).

Table 8 Physical properties of MEMS, which can be tested on wafer level (WL) and dominant cross sensitivities, which must be taken into account

Device type	*Physical property*	*Main cross sensitivity*
Temperature sensor	Temperature	–
Pressure sensors	Pressure	Temperature Environmental pressure
Gas sensors	Gas composition Flow rate Pressure	Temperature
Microbolometer	Radiation power per area	Temperature
Acceleration sensors	Acceleration	Out-of-axis acceleration Mechanical stress Pressure
Gyroscopes	Yaw rate	Out-of-axis acceleration Mechanical stress Pressure
Silicon microphones	Sound pressure	Temperature
RF MEMS	Resonance frequency	Temperature, pressure, vibration, and acceleration
Micromirrors	Angular deflection	Vibration

Table 9 Additional test equipment for MEMS wafer-level test

Analysis type	*Test equipment*
3D mechanical motion analysis	Laser vibrometer or interferometer
Feature recognition	Camera systems with automated image processing
Topology analysis and profiling	Optical test systems, interferometers

1.17.4.2.1 Concepts of WL test equipment

The three basic test concepts will be explained on the example of a pressure sensor. The basic transducer element of a pressure sensor is a diaphragm, which is deflected by the pressure difference between both sides. Pressure sensors can either measure an absolute pressure using a reference cavity or a differential pressure between two pressure supplies. The working principle requires resistive strain gauge structures in order to measure the stress induced in the silicon membrane. The pressure range of silicon sensors extends from several millibars to approximately 100 bar. Measurement of some functional parameters of the sensors such as sensitivity requires a physical stimulus and that the mechanical structure be provided with a defined pressure. The available methods to apply pressure to wafers are summarized in **Table 10**:

- Use of a pressure probe on the wafer topside in addition to the electrical probes.
- A chuck that can supply a pressure or a vacuum on the wafer bottom side; or
- Operation of the complete prober station inside a pressure or vacuum chamber.

Each of these concepts has specific fields of application. Also the achievable accuracy as well as the equipment and the test costs varies significantly as compared in **Table 10**.

- Both the pressure-probe module (**Figure 14**) and the pressure chuck have the advantages that only limited changes must be made to standard equipment. Both are also limited with respect to pressure range and accuracy.
- When the complete equipment is mounted inside a pressure chamber (**Figure 16**), the system will be very versatile and many options are possible such as additional temperature control. The pressure can be controlled in a range between rough vacuum and high pressures. Such systems will be expensive, as only motorized or fully automatic wafer probers allow efficient working.

1.17.4.2.2 WL test with a stimulation via probes or via chuck

With a pressure-probe module as shown in **Figure 14**, a gas pressure is applied from the topside. A representative pressure range is from atmospheric pressure to 7 bar. An option for temperature control of the gas from ambient to 125°C is important. It must be used to prevent cooling of a sensor's diaphragm, which would lead to a strong signal disturbance. Pressure modules can be used with manual, semiautomatic, and fully automatic wafer probers.

Table 10 Methods and features of pressure sensor testing on the wafer level

Pressure application method	*Pressure probe*	*Pressure chuck*	*Pressure chamber*
Schematic			Function	Probe on the wafer topside under impact pressure	Pressure from backside	Complete equipment inside pressure chamber
Control of cross sensitivity	Optional temperature control ambient to 125°C	Optional temperature control	Optional temperature control
Limitations	Very flexible, upgradeable	Limited pressure range, vacuum testing	Very versatile, many options
Sensor types	Absolute and differential sensors	Individual chuck pattern for each wafer pattern	Few limitations
Pressure ranges	Pressure range up to 7 bar	Rough vacuum to low overpressure	Vacuum to high pressure 50 bar
Prober type	Used with all probers	Used with all probers	Motorized or fully automatic wafer prober
Cost	Good price performance ratio	Low priced	Expensive

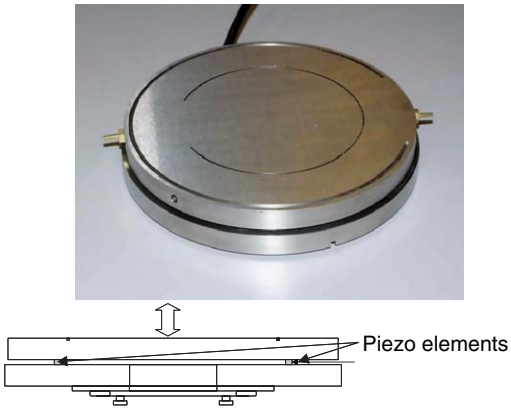

Figure 15 Acceleration chuck for wafer probing of acceleration sensors. *Upper*, photo; *lower*, drawings are a schematic cross section. (Photo courtesy: SUSS.)

In automobiles, acceleration sensors are widely used for comfort, safety, and security applications. The relevant range spans from less than 1 *g* to hundreds of *g*. For WL stimulation an acceleration chuck has been developed, which generates out-of-plane vibrations of the wafer (**Figure 15**). According to the manufacturer (SUSS) typical acceleration values are 3–5 *g* at 500 Hz, 14 *g* at 1 kHz, and more than 50 *g* at 2 kHz. In this frequency range, deflections between 100 and 200 µm are generated, which still can be tolerated by compliant probe tips.

1.17.4.2.3 WL testing in a pressure/vacuum chamber

For wafer probers that are mounted inside a pressure chamber, only motorized or automated systems are sensible. Typical data of commercial systems with a pressure chamber are as follows (SUSS):

- Regulation of pressure in a range from rough vacuum to 50 bar.
- Controlled temperature by a thermal chuck from −65°C to 250°C.

- Nonaggressive gas loads or controlled humidity are possible.
- Wafer sizes up to 200 mm.
- Eight probe manipulators with four RF probes up to 65 GHz, four to eight DC probes or alternatively probe cards can be equipped.

Many MEMS devices need to be tested in vacuum or with a special well-controlled atmosphere. The most important of these are RF-MEMS, optical switching micromirrors, resonator elements, and inertial sensors including accelerometers and gyroscopes. Also microbolometers for IR imaging, pressure sensors, chemical sensors, and many MEMS designed for aerospace applications must be tested at low pressures. If the testing has to be performed on WL, a special vacuum station is needed. Such a device encloses an entire probe station with micromanipulators in a vacuum chamber (**Figure 16**).

A vacuum probe station must be fully motorized either with manual or computer control. The control provides the x–y-stage movement, the platen z-lifting and lowering, x–y-microscope movement, and manipulator x–y–z-movement. Depending on the vacuum chamber, a pressure range from high vacuum (10^{-7} mbar) up to atmospheric pressure can precisely be regulated (**Figure 16**).

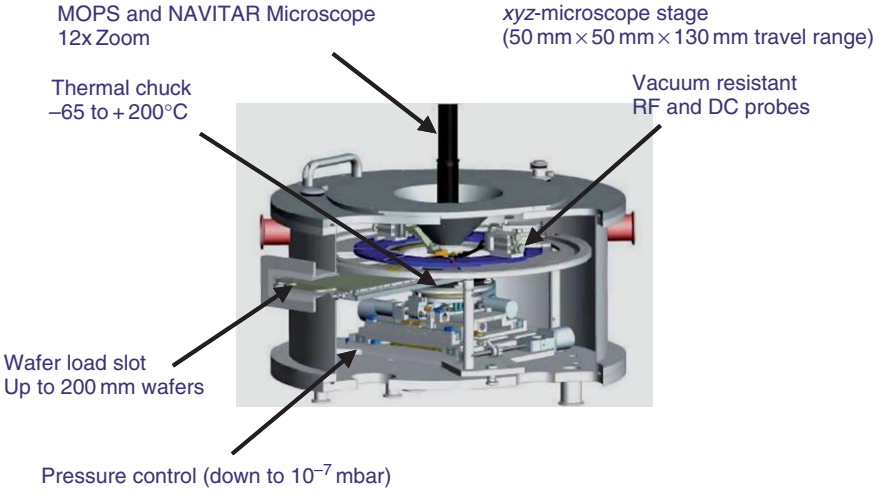

Figure 16 *Above*, Vacuum probe station; *below*, vacuum chamber of a low-pressure semiautomatic probe station. (Photo courtesy: SUSS.)

1.17.4.2.4 Applications of WL testing

1.17.4.2.4.(i) Gas sensors MEMS gas sensors are becoming more and more important due to legislative restrictions as well as due to safety and comfort requirements. There is an increasing demand to monitor exhaust and hazardous gases such as CO_X, NO_X, and others in automotive, industrial, or domestic applications. Using a vacuum/low-pressure vessel and mass flow controllers, contact-free and exact dosage of gases down to the parts per million range is possible.

An economic alternative is to supply the gases to wafers bearing gas sensors using a gas nozzle in combination with the electrical probes (**Table 10** and **Figure 14**). Unfortunately, this only allows quantitative measurements of limited accuracy and should be restricted to nontoxic media.

1.17.4.2.4.(ii) RF-MEMS For MEMS operating at high frequencies, testing in a vacuum environment is mandatory. For mechanical switching devices, the vacuum will avoid sticking effects. Also the vacuum will prevent damping of mechanical structures and electrical signals caused by the viscosity of the air. Elimination of a gas can also minimize acoustic interference within the cavities. For such tests a semiautomatic vacuum prober with a sufficient number of manipulators and RF probes is recommended. Probes for frequencies up to 100 GHz are available. Also many applications require an additional thermal chuck for temperatures from −65°C up to 250°C. Additional features of such test equipment, which are already in use, are as follows:

- Laser trimming capability
- Mechanical motion analyzer

1.17.4.2.4.(iii) MEMS infrared arrays Microbolometers are used to measure the temperature distribution of objects emitting IR radiation. For testing, such devices are exposed to IR radiation with controlled wavelength via an IR transmission window. The IR radiation is generated with IR black bodies, which are mounted on a shutter. Also the temperature of the wafer must be controlled. Here the test assembly is mounted into a vacuum environment to prevent heat transfer by convection. For the sensor wafers, special probe cards are used with front-end electronics on top and close to the tips in order to suppress wiring artifacts.

1.17.4.3 Electrical Failure Detection and Self-Test

1.17.4.3.1 Detection of faults by electrical measurements

Many manufacturing defects in MEMS devices will lead to topological or geometric deviations from the intended structures. In many cases, faulty structures can be detected by methods such as automated microscopic inspection using image processing and pattern recognition software. In order to avoid too many different tests, it is desirable to detect defects using electrical measurements on the WL. A very efficient strategy is the detection of faults by electrical stimulation. This concept has been tested by Dumas *et al.* (2006) on bending beams, which were produced by BMM and which are used as magnetic Lorentz force sensors. The possible classes of defects after free etching as well as their causes in the process are listed in **Table 11**.

The principal questions to be answered are as follows:

- Which physical phenomenon or property is sensitive to the defect?
- How can it be stimulated electrically?
- Which reaction can be detected electrically?

To check the feasibility of electrically stimulated tests, physical modeling of the defect and subsequent simulation using the finite element method may be applied. In this way the sensitivity to typical defects is evaluated. For the reported magnetic sensor there are two phenomena, which are affected by the etch defect:

(1) In case of an incomplete etch release, the heat conduction from a beam will be increased and also the effective thermal mass will be higher. As a result, the time constants of heating and cooling will be affected as well as the temperature rise per amount of heat.
(2) A second effect is that a free beam will have characteristic resonance frequencies, which will be changed by fixing the structure.

In the first case the beam must carry a coil, which can be heated by an electrical pulse while the coil's

Table 11 Classification of defects in the deep-release etching of beam structures

Structural defect	*Cause*
Fully released	Etch okay
Pointwise fixed	Etching almost complete
Strongly fixed	Partial etching
Not released	No etching

Source: Dumas *et al*. (2006).

transient resistance change is monitored. In the second case the beam is subjected to a harmonic stimulation by repeated heat pulses. At a characteristic frequency resonance occurs and can be detected using the strain gauge structures, which are normally used for deflection measurements. Also other micromachined sensor structures have been successfully tested such as accelerometer paddles, which are also sensitive with respect to transient thermal behavior and resonance frequency (**Table 12**).

In principle, an electrical test is possible to detect certain defects even after full processing and encapsulation. Nevertheless, this concept requires design for testing and is only feasible for a certain portion of all possible failures.

1.17.4.3.2 Built-in self-test

In many cases stimulation of a microsystem by the property to be measured, such as pressure or acceleration, is not convenient due to practical reasons. Physical testing often becomes very demanding when it must be performed on the WL at high or low temperatures and when the device is already in the use phase. Therefore, the concept of the built-in self-test (BIST) has been developed.

Several years ago band-gap references were introduced for selfcalibration of operational amplifiers or analog–digital converters. Besides calibration, BIST can also be used to detect whether a device is defective or if it has failed. In the case of MEMS, such a concept requires provisions to stimulate the sensing structure internally. Although BIST is still more a concept, it has already been used in industrial MEMS (Charlot *et al.* 2001), **Table 13**. One of the successful techniques is the impulse response method in combination with pseudo-random testing (Rufer *et al.* 2005). BIST usually requires that a monolithic MEMS device will be integrated with the test circuitry.

1.17.5 Calibration and Compensation

In this section all errors which limit the accuracy of a NWA measurement will be discussed and the most used calibration and verification methods will be presented.

There are three sources of errors, which limit the accuracy of any measurements: systematic errors, statistical or random errors, and drift errors (**Figure 17**). Statistical errors are caused by a low signal-to-noise ratio during the measurement and by a nonrepeatability of the measurement system. They can be minimized with averaging or adequate filtering of measurement data.

Systematic errors are assumed to be time invariant and thus predictable. They are mainly caused by imperfections in measurement equipment and setup. Systematic errors are fully eliminated by calibration. It is inevitable to use calibration in most systems that interface with the real world. Unfortunately, testing

and calibration is time-consuming and accounts for a large portion of the product generation costs.

Individual calibration of microsystems is used to reduce the effects of individual variations in the characteristics due to variations and drift in the fabrication process over time.

Most microsystems are calibrated using accurate operational test measurement at the end of the fabrication process. The calibration is done either on the hardware or on the software level. For hardware calibration, the characteristics of the device are changed by a trim process using a laser or similar techniques. For software calibration, the calibration data are stored in a nonvolatile memory in the device.

Both hardware and software calibration are limited by drift errors, which arise due to a change of the system performance after the calibration has been done. Drift errors are caused primarily by temperature variation and by aging. They are eliminated by a proper recalibration. A new approach uses an online calibration technique of microsystems similar to those implemented on analog-to-digital converters. Such an online calibration is performed continuously during operation of the device and should not interfere with the normal operation of the system, apart from making it more accurate.

1.17.5.1 Vector Network Analyzer

The VNA has become the workhorse of most on-wafer measurements above 1 GHz. This is because at high frequencies direct measurements of voltage and current become difficult and so the stimulus–response approach has been developed for the high-frequency regime. For getting the best on-wafer measurement results, a solid understanding of measurement system components and their interaction is required. Due to drift of the internal electrical parameters of any VNA and due to variations of the electrical contact of the DUT to the VNA, the measurement system including the VNA must be calibrated before any meaningful measurement.

A VNA measures vector ratios of reflected or transmitted energy to the energy incident upon the DUT. As a stimulus–response measurement, a VNA measurement determines the properties of devices rather than the properties of signals. Signals will be measured using instruments such as oscilloscopes or spectrum analyzers.

The block diagram (**Figure 18**) shows the key elements of the VNA. The RF source at the top provides the stimulus a_1 or a_2 for the DUT. A forward/reverse

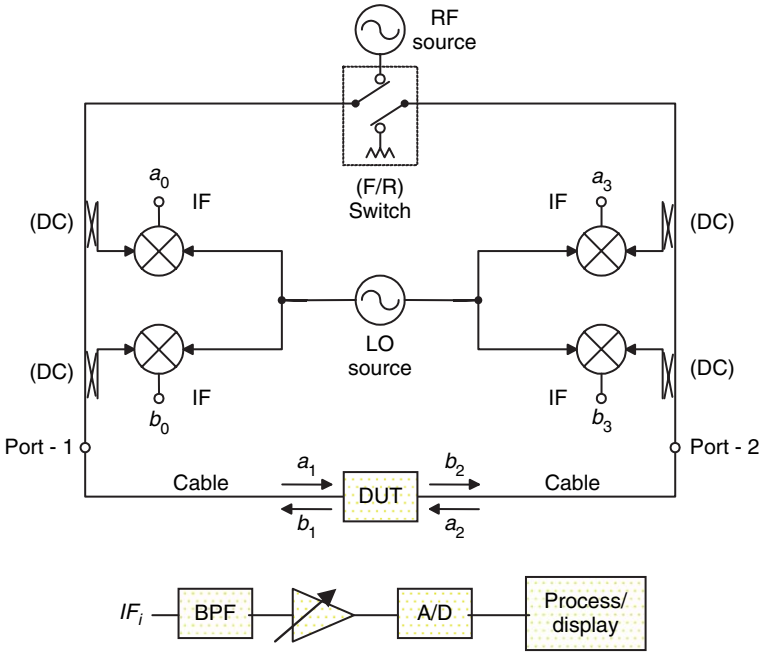

Figure 18 Main hardware blocks in a vector network analyzer (VNA).

(F/R) switch directs the RF energy to either DUT port. The test set uses directional couplers (DCs) or bridges to pick off the forward (a_1, a_2) and reverse (b_1, b_2) waves traveling to and from each port, and down-converts these signals to four intermediate frequency (IF) sections (a_0, a_3, b_0, b_3). Each IF section IF_i band pass filters, amplifies, and digitizes (A/D) the signals for further digital processing and display.

A significant challenge in stimulus–response analysis is to define exactly where the measurement system ends and the DUT begins. In on-wafer VNA measurements, this boundary is known as the reference plane of the measurement and will often be located at the probe tips. Ideally, the system will measure the characteristics of whatever is connected to the measurement reference plane. A typical wafer probing VNA setup is shown in **Figure 19**.

If we ignore any nonideal behavior of the cables, couplers, mixers, and so forth, then the ratios of wave amplitudes (a and b) inside the machine correspond directly to the so-called S-parameters of the DUT. For example:

$$\frac{b_0}{a_0} = S_{11} \text{ and } \frac{b_3}{a_0} = S_{21}$$

of the DUT.

1.17.5.1.1 Impedance measurements

S-parameters are just one type of network representation used for linear, small-signal AC analysis. A reflection ratio at a device port, with all other ports terminated, such as S_{11} or S_{22}, is also known as a reflection coefficient. The load impedance, Z_L, is related to the reflection coefficient, Γ, by the bilinear transform pair as follows:

$$Z_L = Z_0\left[\frac{1+\Gamma}{1-\Gamma}\right] = r + jx, \quad \Gamma = \frac{b_i}{a_i} = \frac{Z_L - Z_0}{Z_L + Z_0}$$

where Z_0 is the reference impedance of the measurement system. S-parameters can be converted to, e.g., Z-parameters (or to y-parameters, h-parameters, etc.) and back:

$$S_{11} = \frac{(Z_{11}-1)(Z_{22}+1) - Z_{12}Z_{21}}{(Z_{11}+1)(Z_{22}+1) - Z_{12}Z_{21}}$$

$$Z_{11} = \frac{(1+S_{11})(1-S_{22}) + S_{12}S_{21}}{(1-S_{11})(1-S_{22}) + S_{12}S_{21}}$$

$$S_{12} = \frac{2Z_{12}}{(Z_{11}+1)(Z_{22}+1) - Z_{12}Z_{21}}$$

$$Z_{12} = \frac{2S_{12}}{(1-S_{11})(1-S_{22}) + S_{12}S_{21}}$$

$$S_{21} = \frac{2Z_{21}}{(Z_{11}+1)(Z_{22}+1) - Z_{12}Z_{21}}$$

$$Z_{21} = \frac{2S_{21}}{(1-S_{11})(1-S_{22}) + S_{12}S_{21}}$$

$$S_{22} = \frac{(Z_{11}+1)(Z_{22}-1) - Z_{12}Z_{21}}{(Z_{11}+1)(Z_{22}+1) - Z_{12}Z_{21}}$$

$$Z_{22} = \frac{(1+S_{22})(1-S_{11}) + S_{12}S_{21}}{(1-S_{11})(1-S_{22}) - S_{12}S_{21}}$$

Figure 19 Two typical radio frequency (RF) device characterization setups are shown above. On the left are vector network analyzers; in this case an Agilent PNA system. Cables from the test set ports route over the probe station to a pair of microwave probes, which are aligned through the microscope or camera system onto calibration substrates and test devices. The right sides show the monitor of the PCs, which controls the prober and runs the calibration and measurement software. (Photos courtesy: Cascade Microtec. and SUSS MicroTec.)

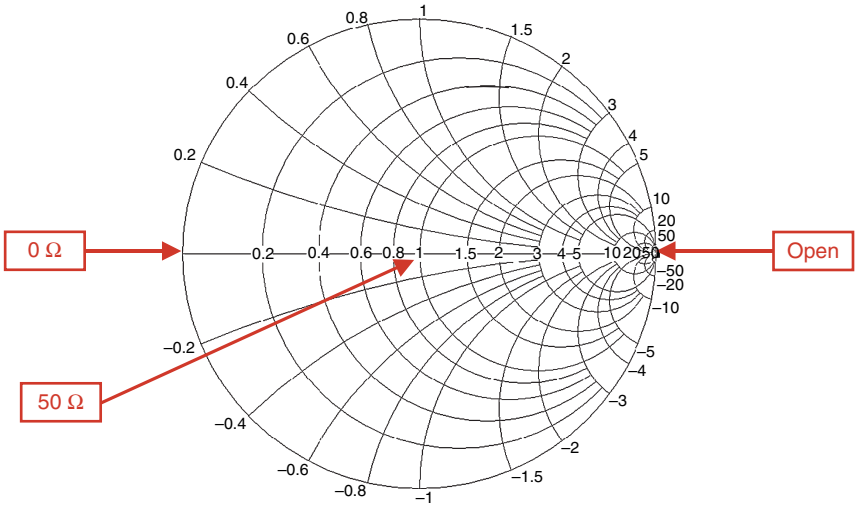

Figure 20 The Smith chart is a polar graph of the reflection coefficient Γ with grid lines showing normalized impedance values Z_L/Z_0.

Typically the VNA automates the display of a wide variety of formats: Smith chart, polar, and linear and log magnitude formats. The Smith chart (Figure 20) is a polar graph of the reflection coefficient Γ with grid lines showing the normalized impedance values Z_L/Z_0. All passive impedances are represented in a compact unit circle reflection format.

The Smith chart is very useful in microwave theory, as it visualizes the influence of a reactance or susceptance (Figure 21). The Smith chart can be used like a roadmap for matching purposes.

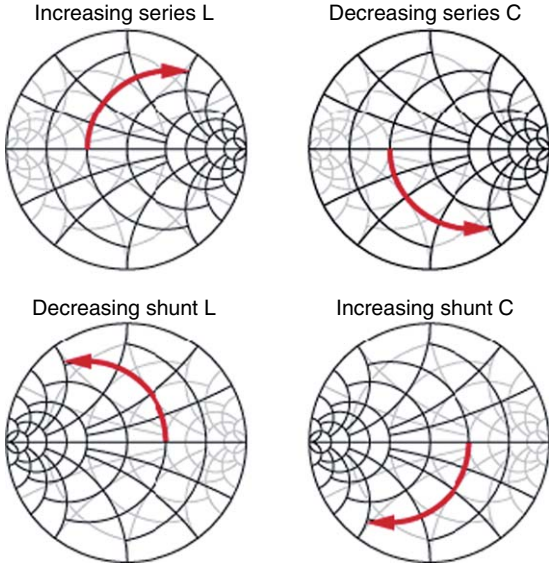

Figure 21 The paths of circuit elements in the Smith chart: The graphs demonstrate how shunt and series reactances change the circuit reflectance on the Smith chart.

1.17.5.2 Calibration Techniques

This section introduces the concept of calibration or systematic error correction of VNA.

1.17.5.2.1 VNA calibration fundamentals

VNA calibration is the process of measuring devices with known or partly known characteristics and using these measurements to establish the measurement reference planes. VNAs rely on calibration for accuracy even in measurements with the reference plane defined at the instrument front panel connectors or at the ends of cables. Calibration also corrects the imperfections of the measurement system. These imperfections include not only the nonideal nature of cables and probes but also the internal characteristics of the VNA itself.

The VNA is calibrated in much the same manner that the zero function on an ohmmeter subtracts out the resistance of the test leads. On an ohmmeter, when the zero function is activated, it stores a resistance measurement, which is then subtracted from all future measurements. The obvious error model is simply a resistance in series with the test port.

Where the ohmmeter's calibration simply used a short circuit (connecting the test leads together) to determine the extra resistance term in the error model, a VNA uses multiple calibration standards – typically open circuits, short circuits, loads, and through (thru) connections.

A VNA does the same thing as the ohmmeter but uses a more complex error model with several terms for each frequency point. The measurement system is

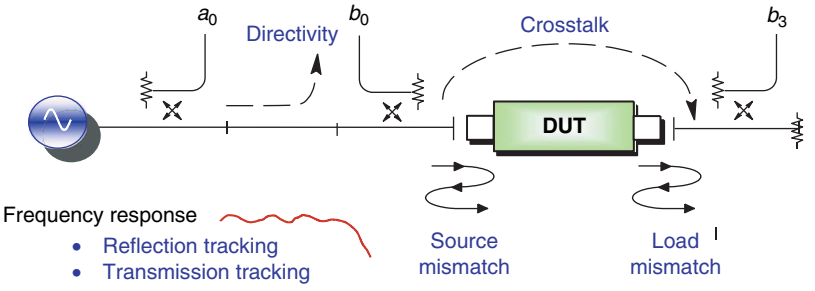

Figure 22 Six error terms are needed for the forward model. (Drawing courtesy: Agilent Technologies.)

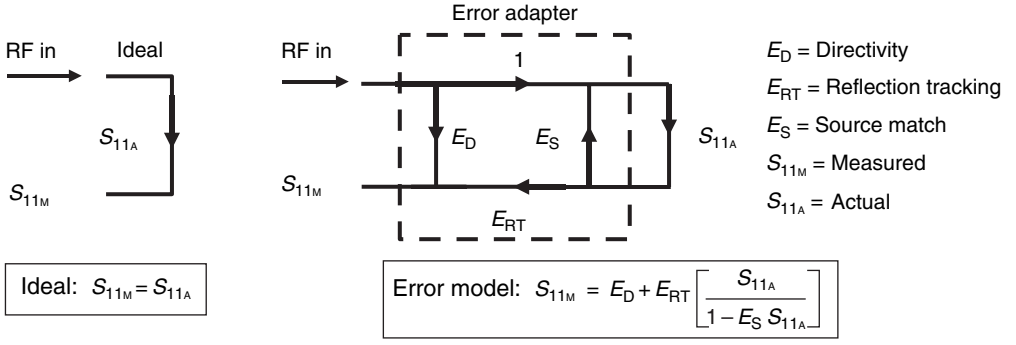

Figure 23 One-port model of reflection. (Schematic courtesy: Agilent Technologies)

described as an ideal VNA with an error adapter network that models all of the system's nonidealities: directivity of the couplers, imperfect match looking back into the reflectometer (test set ports), imperfect frequency response of the reflectometers and the transmission between ports, and the cross talk between ports (**Figure 22**).

b_0/a_0 gives the measured value S_{11M} of the actual reflectivity S_{11A} of the DUT. **Figure 23** shows the one-port error model in detail. The actual reflectivity S_{11A} is modified by the directivity E_D of the VNA, which leads to some signal b_0 without any reflected signal from the DUT, by a not fully source match E_S of the VNA cable, which together with S_{11A} might cause some standing waves, and by the reflection tracking E_{RT}, which causes a damping of the signal together with a phase shift. The damping and phase shift of the forward signal can be fully considered also in a proper choice of E_S and E_{RT}; thus, without any restriction we can set the forward signal path of the error adapter equal to 1.

To solve for these error terms, we measure three standards in the calibration to generate three equations for the three unknowns. This equation system is then solved at the end of the calibration routine, and we get the complex values of E_D, E_S, and E_{RT}. The corrected reflectivity S_{11A} can then be calculated from S_{11M} by the following equation:

$$S_{11M} = E_D + E_{RT}\left[\frac{S_{11A}}{1 - E_S S_{11A}}\right]$$

Figure 24 shows the effect of calibration of a measured one-port S_{11}. The source mismatch leads to a standing wave pattern in the uncalibrated data, which is effectively eliminated by the calibration. The full error model for a VNA is shown in **Figure 25** and the corresponding signal flow graph in **Figure 26**.

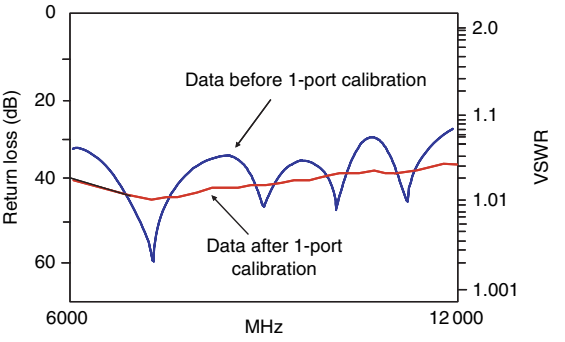

Figure 24 Measured return loss and voltage standing wave ratio (VSWR) of a device under test (DUT) before and after a one-port calibration. (Figure courtesy: Agilent Technologies.)

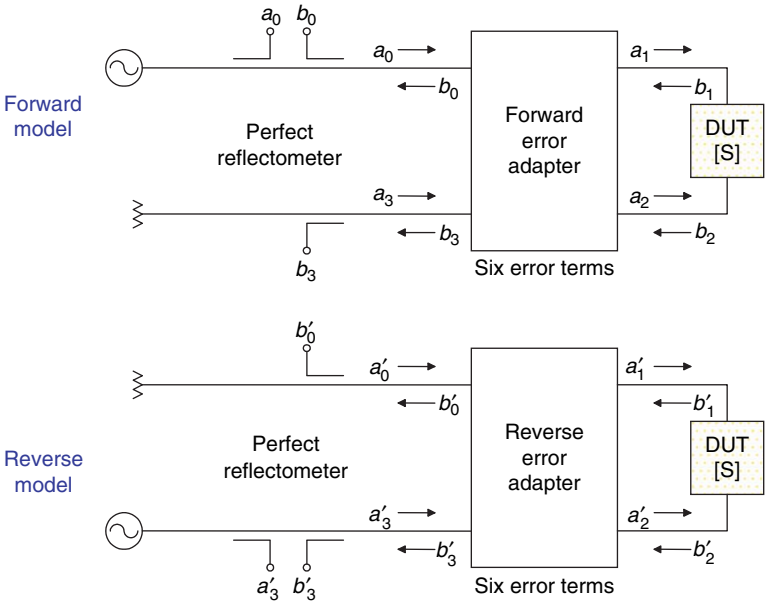

Figure 25 Error model for a typical network analyzer. All errors are modeled using an error adapter in front of an otherwise perfect system.

The full error model, shown in **Figures 25 and 26**, results in 12 unknown error terms. To solve these error terms, we measure 12 standards in the calibration to generate 12 equations for the 12 unknowns. The corrected four S-parameters of a two-port DUT (S_{11A}, S_{12A}, S_{13A}, S_{14A}) are then calculated from the measured values (S_{11M}, S_{12M}, S_{13M}, S_{14M}) by (Agilent)

$$S_{11A} = \frac{\left(\frac{S_{11M}-E_D}{E_{RT}}\right)\left(1+\frac{S_{22M}-E_{D'}}{E_{RT'}}E_{S'}\right)-E_L\left(\frac{S_{21M}-E_X}{E_{TT}}\right)\left(\frac{S_{12M}-E_{X'}}{E_{TT'}}\right)}{\left(1+\frac{S_{11M}-E_D}{E_{RT}}E_S\right)\left(1+\frac{S_{22M}-E_{D'}}{E_{RT'}}E_{S'}\right)-E_{L'}E_L\left(\frac{S_{21M}-E_X}{E_{TT}}\right)\left(\frac{S_{12M}-E_{X'}}{E_{TT'}}\right)}$$

$$S_{21A} = \frac{\left(\frac{S_{21M}-E_X}{E_{TT}}\right)\left(1+\frac{S_{22M}-E_{D'}}{E_{RT'}}(E_{S'}-E_L)\right)}{\left(1+\frac{S_{11M}-E_D}{E_{RT}}E_S\right)\left(1+\frac{S_{22M}-E_{D'}}{E_{RT'}}E_{S'}\right)-E_{L'}E_L\left(\frac{S_{21M}-E_X}{E_{TT}}\right)\left(\frac{S_{12M}-E_{X'}}{E_{TT'}}\right)}$$

$$S_{12A} = \frac{\left(\frac{S_{12M}-E_{X'}}{E_{TT'}}\right)\left(1+\frac{S_{11M}-E_D}{E_{RT}}(E_S-E_{L'})\right)}{\left(1+\frac{S_{11M}-E_D}{E_{RT}}E_S\right)\left(1+\frac{S_{22M}-E_{D'}}{E_{RT'}}E_{S'}\right)-E_{L'}E_L\left(\frac{S_{21M}-E_X}{E_{TT}}\right)\left(\frac{S_{12M}-E_{X'}}{E_{TT'}}\right)}$$

$$S_{22A} = \frac{\left(\frac{S_{22M}-E_{D'}}{E_{RT'}}\right)\left(1+\frac{S_{11M}-E_D}{E_{RT}}E_S\right)-E_{L'}\left(\frac{S_{21M}-E_X}{E_{TT}}\right)\left(\frac{S_{12M}-E_{X'}}{E_{TT'}}\right)}{\left(1+\frac{S_{11M}-E_D}{E_{RT}}E_S\right)\left(1+\frac{S_{22M}-E_{D'}}{E_{RT'}}E_{S'}\right)-E_{L'}E_L\left(\frac{S_{21M}-E_X}{E_{TT}}\right)\left(\frac{S_{12M}-E_{X'}}{E_{TT'}}\right)}$$

Each actual S-parameter is a function of the four measured S-parameters. Thus, the VNA must perform a forward and a reverse sweep to update each S-parameter. The calibration functions allow the user to store measurements of standards, compute the error models, and automatically apply corrections to DUT measurements. Corrected VNA measurements are sometimes referred to as de-embedded. **Figure 27** shows as a comparison the uncorrected, response calibrated, and full two-port calibrated insertion attenuation of a filter.

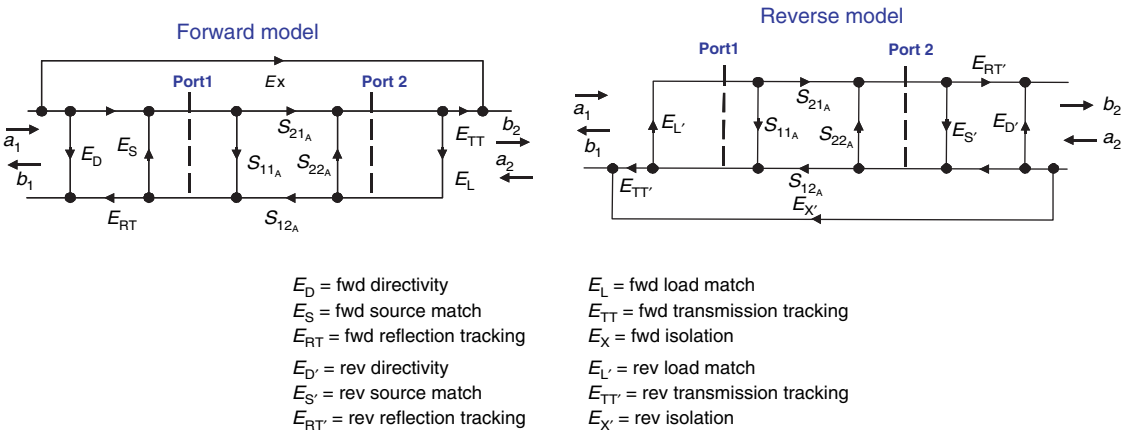

Figure 26 Signal-flow diagram of the error model for a typical network analyzer. (Schematic courtesy: Agilent Technology.)

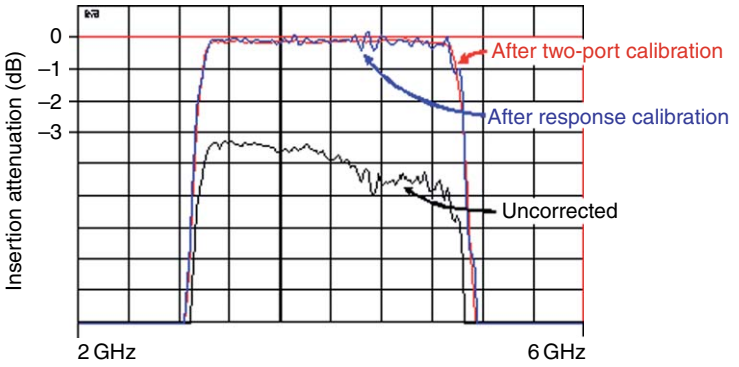

Figure 27 Response calibration versus two-port calibration of filter insertion attenuation. (Schematic courtesy: Agilent Technology.)

1.17.5.2.2 Calibrated VNA accuracy

As with any corrected measurement, the absolute accuracy of a calibrated VNA measurement is determined by the techniques and completeness of the error model used as well as by the accuracy of the description of the reference devices (calibration standards), and by the repeatability of the measurement system.

Improper calibration will introduce errors. The impedances used in the calibration must be accurately known and entered. Assumption of ideal behavior of standards is a recipe for errors, but worse things can happen. For example, the improper entry of a description of a short-circuit or open-circuit standard will lead to useless results that may not always be obviously wrong. The calibration routine of the VNA will accept everything that is entered. Accurate descriptions of the electrical behavior of the various calibration standards must be supplied to the VNA.

Corrected measurements rely on the repeatability of the measurement system. Just as an ohmmeter cannot correct a changing resistance of its test leads or drift in the ohmmeter circuitry, a VNA cannot correct for random errors such as noise or dynamic range, cable repeatability, or instrument drift. Any change in the measurement due to, for instance, drift of the VNA test set, thermally induced cable length changes, or even the effects of noise due to VNA dynamic range can invalidate the correction. Sensitivity of cable electrical performance (such as phase delay), of the microwave probe contact (such as ohmic resistance), or even of the calibration elements by environmental changes is a significant element of quality and suitability for VNA use.

VNA error models are based on the use of *S*-parameter representations of network properties. *S*-parameters are signal-flow- and transmission-line-based. Only a single mode of propagation at the device terminals is assumed. Situations that violate this assumption such as using waveguides that can propagate multiple modes, radiation, or parasitic coupling

between networks other than at the device terminals are not properly handled. If a second mode, radiation, or extra parasitic does not change for any and all devices being measured then it will drop out with the calibration. These extra modes, however, usually show a behavior that is DUT-dependent and the VNA calibration will not account for these effects. A well-designed probing system with good quality transmission-like interconnections will minimize these errors as much as possible (**Figure 11**). An extensive discussion of VNA calibration and accuracy is given (e.g., NN Calibration and Accuracy Factors – Summit High – Frequency Probe Station Reference Manual. Cascade Microtech, part number 103–375A).

1.17.5.2.3 VNA calibration options and standards

If not calibrated, the VNA will measure the uncorrected *S*-parameters (**Figure 28**). Uncorrected parameters are very convenient to measure, but not very accurate and, thus, rarely used. A response calibration is simply a vector magnitude and phase normalization of a transmission or reflection measurement. Thus, it removes frequency response errors. It is sometimes used when highest accuracy is not required (**Figure 29**).

Typically, a full calibration of all the error parameters is used as a reference or to assure the highest accuracy (**Figure 30**) (Rytting 1986). For a two-port full error calibration each port must be connected to some well-known standards, like an open (O), a short cut (S), and a load (L). Additionally, both ports must be connected using a through connection. A full calibration removes all errors concerning directivity, source match, load match, reflection tracking, transmission tracking, and optional, also cross talk.

Figure 28 Uncorrected vector network analyzer (VNA) measurement.

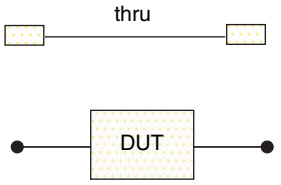

Figure 29 *Above*, Response calibration; *below*, measurement.

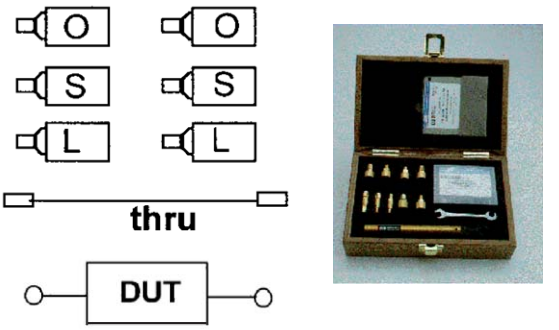

Figure 30 Full two-port calibration elements. *Left*, schematic; *right*, calibration standards (SOLT) for SMA adapters (Agilent Technologies).

1.17.5.2.4 Calibration standards

On-wafer calibration standards most often are precision thin-film resistors, short-circuit connections, and 50-Ω transmission lines fabricated either on the wafer containing the DUT or on a separate calibration substrate (typically alumina). High-performance load resistors are trimmed to within 0.1% (SUSS MicroTec) of their desired DC-value (usually 50 Ω).

A true thru standard does not exist for on-wafer measurements because probes cannot directly connect to each other and must instead use a very short transmission line as a thru standard. **Figure 31** shows typical short-load-thru (ISS (impedance standard substrate) family, Cascade Microtech) and short-open-load-thru (SOLT) (CSR family, SUSS MicroTec) substrates.

It is important to note that some specific electrical behavior of the standards depend on the probe pitch used. The calibration data are therefore supplied with the probe, rather than being a single value for a standard as would be the case for coaxial standards where there is no ambiguity about what connections can be made to it. Calibration data are normally specified for a specific probe spacing used with a particular impedance standard substrate, and is only valid for a particular probe–calibration standard combination. The contact pattern, e.g., GSG or GS (see **Figures 11, 38 and 39**), will also impact calibration data. Important for a wide application range of a calibration standard is a good temperature stability of the load resistance and a high accuracy of the characteristic impedance of the through standard over a wide frequency range (see **Figure 32**).

On-wafer standards, fabricated on the same wafer as the DUT, are sometimes desirable since the probe-to-standard transition can be designed to be very similar to the transition to the DUT. This is helpful

Figure 31 A calibration substrate has multiple repeated patterns of Thru-Short-Load Standards (*left*, impedance standard substrate (ISS) family, Cascade Microtech), Thru-Short-Open-Load (*right*, CSR family, SUSS MicroTec), and alignment marks for setting proper probe separation. A set of transmission lines is also provided for Thru-Reflect-Line (TRL) Calibration.

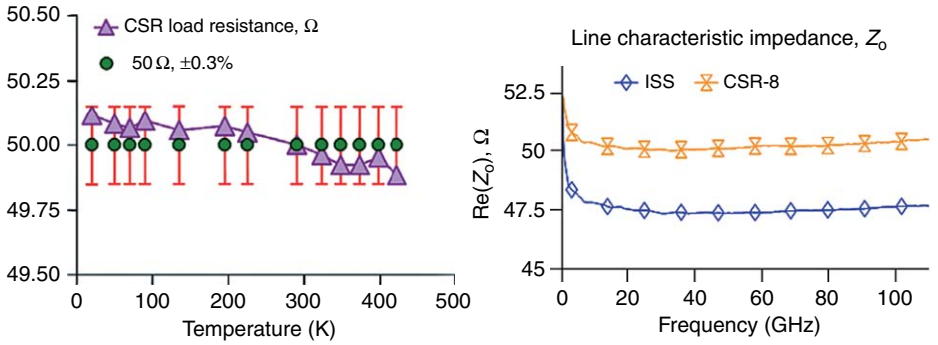

Figure 32 Typical temperature stability of load resistance and accuracy of the thru standard of coplanar calibration substrates (Geissler, Rumiantsev *et al.* 2006).

at frequencies above 20 GHz since a primitive transition may introduce extra parasitic elements or modes, which, since they are occurring at the probe-tip reference plane, may not be corrected by calibration. In many cases these transition errors may be de-embedded using simple lumped element equivalent circuit models (Walker and Williams 1997).

The use of off-wafer standards for calibration is very convenient and calibration results have been demonstrated, which are comparable to results obtained by using the special on-wafer standards methods recommended by the US NIST. In cases where the transition on-wafer is dramatically different to that of the calibration standard substrate, such as on silicon substrates, the use of a set of dummy pads on-wafer allows the removal of additional parasitic elements of the pads. Algorithms to remove pad parasitic are discussed (e.g., Van Wijnen).

1.17.5.2.5 Short-Open-Load-Thru calibration

By far the most commonly used method is the SOLT calibration (**Figures 33 and 34**). This calibration is the combination of 2 one-port short-open-load calibrations with additional measurements of a thru standard to complete the two-port calibration.

The SOLT standard elements are reasonably well modeled with simple lumped elements: open-circuit capacitance, short-circuit inductance, load inductance, and thru delay (and loss). All of the standards must be fully known and specified. This is very difficult to achieve for highly reflective standards (open, short) at higher frequencies,

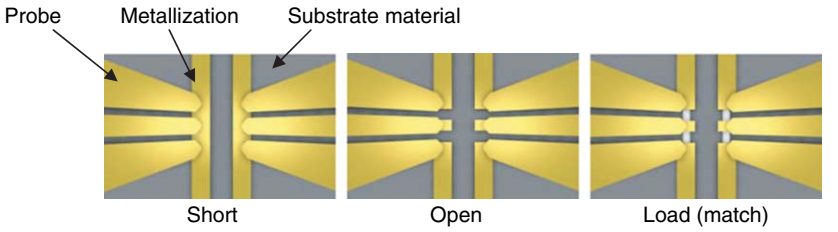

Figure 33 Close-up view of coplanar lumped calibration standards. (Figure courtesy: SUSS.)

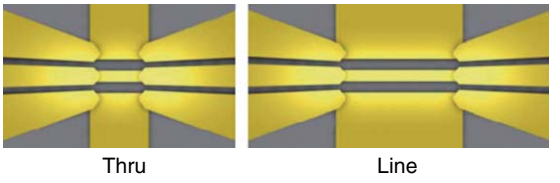

Figure 34 Close-up view of coplanar distributed calibration standards. (Figure courtesy: SUSS.)

thus rendering SOLT impractical for measurements above 20 GHz.

1.17.5.2.5.(i) Advanced calibration methods

An alternative to the SOLT calibration is the SOLR (short-open-load-reciprocal) calibration (Ferrero 1992). This algorithm is similar to the SOLT calibration for one-port corrections, but the redundant information available in the standards set allows the reciprocal standard to be any reciprocal two-port network. No other knowledge of the standard is required to complete the calibration. The SOLR algorithm is thus very powerful when only nonideal thru standards are available, like orthogonal probes, excess thru line length, glossy, or mismatched thru lines, or incompatible port geometries (pitch). However, all reflection standards should be fully defined, like SOLT, limiting calibration accuracy to 20 GHz.

The thru-reflect-line (TRL) calibration algorithm uses the characteristic impedance of a transmission line as the reference for calibration (see **Figure 34**) (Engen and Hoer 1979). Line pairs differing only in length are measured along with a reflect standard that is known only to the sign of the reflection coefficient. The line length difference must not be near 180° of phase since a half wavelength transmission line mimics a zero length line and provides no additional information. In practice a line pair will only provide useful results over a 20–160° phase difference range. Wider bandwidths require multiple line lengths to provide suitable phase differences over a wide frequency range.

In the TRL calibration (and its variations), the thru line must be fully known to allow the measurement reference plane to be moved to the probe tips from the midpoint of the thru line. In some applications using on-wafer standards, the DUT is effectively embedded at the thru midpoint, eliminating the need for this reference plane change. The TRL calibration process itself does not determine the characteristic impedance that is the reference for the resulting *S*-parameters. Additional assumptions and measurements may be used to determine the Z_0, and renormalize the *S*-parameters to 50 Ω (for example).

TRL calibration requires programmable probe positioners for fully automatic calibration. Dispersion, skin effects, losses, and fabrication tolerances of planar lines as well as requirements for multiple lines and probe repositioning significantly reduce the application and the frequency range of TRL at the WL.

The line-reflect-match (LRM) calibration was developed to overcome the limitations of the TRL calibration. Instead of using a set of different lines, the lumped match (load) element is used for calibration. However, good calibration accuracy can be guaranteed only if using purely resistive, highly symmetrical 50-Ω loads, which is impossible to fabricate at WL. Therefore, the accuracy of LRM significantly decreases as in-pair asymmetry of the load standard and measurement frequency increase.

A variation of the LRM, the line-reflect-reflect-match (LRRM) calibration provides calibration accuracy comparable to the NIST multiline TRL algorithm described below without the need for changing probe separation (Davidson *et al.* 1990, Pence 1993). The standards used for LRRM are identical to those used for SOLT but without the requirement for careful specification of the short and open standard behavior (see **Figure 33**). In LRRM, only the thru line delay (and loss for longer lines) and load standard must be specified. By using only one Match standard any ambiguity in load inductance between ports is eliminated. However, LRRM applies assumptions about the match. Namely, the match measured on one port is assumed

to behave identically on the other port. This can lead to an error in the return loss measurement (S_{11} and S_{22}) when the two ports are not actually the same, for instance, if the measurement setup includes bias tees, splitters, etc. (Wartenberg 2002).

Another modern variation of the LRM is the extended line-reflect-match (LRM+) (Scholz *et al.* 2004). LRM+ defines the measurement system reference impedance for each port individually overcoming limitations of the LRRM calibration procedure. Therefore, asymmetrical setups can be accurately calibrated with LRM+. This also applies to calibration with test chips (customized calibration elements, embedded on the wafer), as LRM+ is the only calibration method that does not assume that load pairs have identical values. Additionally, LRM+ calibrates the system to the DUT, including parasitic influences from contact pads, which means pad de-embedding is no longer required (see **Figure 37**). The accuracy of LRM+ has been verified using independent standards from NIST. Over a frequency from DC to 110 GHz, LRM+ consistently outperformed all other WL calibration methods available (Doerner and Rumiantsev 2005, Rumiantsev *et al.* 2006).

1.17.5.2.5.(ii) NIST multiline TRL Research by the Microwave Metrology Group of the US NIST has advanced the quality of rigorous on-wafer VNA measurements. The focus of this work has been the development and application of a multiline TRL calibration algorithm using the full redundancy of the standards. While normal TRL selects line pairs for applicable frequency ranges, the NIST multiline TRL uses a continuously varying optimally weighted average of all the data (Marks 1991, Williams *et al.* 1991). **Figure 35** compares the quality of the most-used on-wafer calibration techniques up to 110 GHz.

1.17.5.2.5.(iii) Measuring calibration standards The process of completing the calibration entails placement of probes on standards and directing the VNA measurement system to acquire data. This process is somewhat error prone as it is not always easy to determine if the standard is properly connected.

While uncalibrated or raw *S*-parameters from a VNA are often far from accurate, they can be used to help verify proper contact with the calibration standards. The raised probe open measurement does not have any contact issues and can be used as a reference. The measurement of a short standard will show ideally a 180° phase rotation of the reflection coefficient. This can be seen as a rotation of the raw data

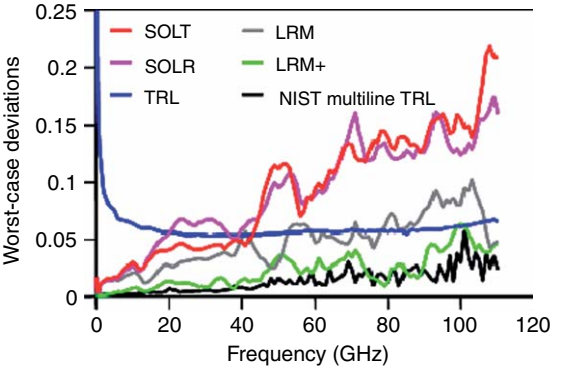

Figure 35 Comparison between the worst-case measurement deviations of a vector network analyzer (VNA) calibrated using different calibration techniques. (Figure courtesy: SUSS.)

Smith chart constellation or a shift in a phase display occurring when the probe makes contact. In practice, second-order terms in the error box will also somewhat impact the actual change of observed reflection, but the shift will be very noticeable and provide a good indication confirming visual identification of proper alignment and contact.

The load standard shows a significant reduction in the magnitude of the uncorrected reflection coefficient when contact is made. Contact with a 50-Ω load will tend to reduce the Smith chart display toward the center dot. Particularly at higher frequencies, the various reflections from adapters, cable connectors, and probes can degrade the overall return loss of the load standard. The measured reflections will normally be reduced by more than 10 dB when the load is in contact. Smaller reductions are signs of poor system return loss that may require correction.

The thru line measurement will exhibit the matching characteristics of the load and will also show an increase in the raw S_{21} transmission measurement.

1.17.5.2.5.(iv) Calibration verification It is a good practice to perform one or more verifications after completing every calibration. The verification of proper calibration kit entry and the correct measurements of the calibration standards can be demonstrated by measuring a long open circuit or a long transmission line. The reflection coefficient of the long open circuit should exhibit a smooth monotonic inward spiral on the Smith chart. The long transmission line verification standard should show a linear phase in the transmission response. Some common verification standards are shown in **Figure 36**.

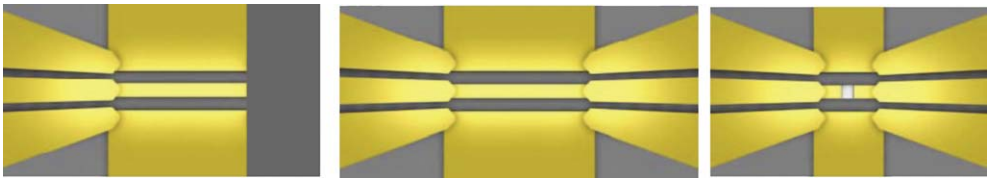

Figure 36 Typical on-wafer verification elements. In many cases measurement of such structures will catch the most common errors and problems. (Figure courtesy: SUSS.)

The remeasurement of a calibration standard is useless for verification, as only the repeatability of the measurement will be revealed. A VNA cannot recognize the errors caused by using incorrect impedance standards. A load resistor of the wrong value will not be recognized: it will be accepted as 50 Ω. The VNA will even accept interchanged open and short standards without complaint. Either mistake will result in significant measurement error.

Measurement of calibration standards for the advanced calibrations routines where standards do not have to be fully specified is useful for verification. Examining the open that is used for the reflect standard in a TRL or LRM calibration can identify problems. After calibration, the open may not have perfectly zero return loss. The probe in air will actually have slightly less loss than the probe in contact with the wafer, so in addition to some negative capacitance a small amount of return gain from the calibrated open may be observed.

The thru line standard is a useful verification element for an SOLR calibration. Again the verification should reflect expected behavior so this is only useful when the behavior is predictable. The SOLR can calibrate successfully even with a highly reactive and complicated frequency response of the reciprocal thru, which will not be predictable. However, a good line standard will exhibit attenuation with square root of frequency dependence consistent with thin-film transmission lines. Excess line length beyond the probe contacts will act like capacitive stubs resulting in increased attenuation at higher frequencies. Linear transmission phase would be expected unless the standard has dispersive characteristics.

A gold standard device – a device that has been characterized using a (hopefully) known good test system – is another way to validate a test system. However, it is difficult to validate a calibration and measurement method this way. Slight differences in calibration reference planes may appear as significant errors. Differences in circuit bias or power supplies can also appear as errors in the microwave measurement. A gold standard can, however, be an effective and simple test for qualifying a new system that uses identical equipment and methods as a reference measurement system.

1.17.5.2.5.(v) Ground–signal–ground vs. ground–signal pads After probe positioning and calibration errors, the most significant inaccuracy in microwave probing is associated with parasitic coupling at the probe tip (**Figure 37**).

A GSG interface terminates field lines effectively, but GS pads allow the open side fields to terminate on the wafer ground plane or chuck. The degree of this coupling is dependent on substrate thickness and pad spacing.

An undesirable mode of propagation where all topside conductors form a microstrip with the bottom of the wafer can occur in these structures. The best way to deal with this problem is usually to minimize the excitation of that mode. The GSG pad configuration excites the undesired microstrip mode less than the GS configuration. A reasonable rule is to avoid GS pads for good results above 10 GHz.

1.17.5.2.5.(vi) GS probing parasitics **Figure 38** depicts a GS probe tip, two connection pads, and a DUT, along with the main reactive parasitics of the connection. The ground is the backside of the wafer, the wafer chuck, or a high conductivity substrate such as silicon.

The transmission line uses the inductances in series with the DUT and the corresponding bridging capacitors. The resistor Z_{absorber} can be used to absorb energy in the undesired mode. This attenuates energy propagating up the ground, which could resonate with the probe holder.

Proper selection and use of a microwave probe will allow the parasitic C_{SProbe} and C_{GProbe} to be small and repeatable. However, differing pad sizes or conductor geometries on test structures can cause C_{GDut} or C_{SDut} to be different from one structure to another, or from the calibration standards. Only when these values are equal for calibration standards and measurement devices will these parasitics be removed by

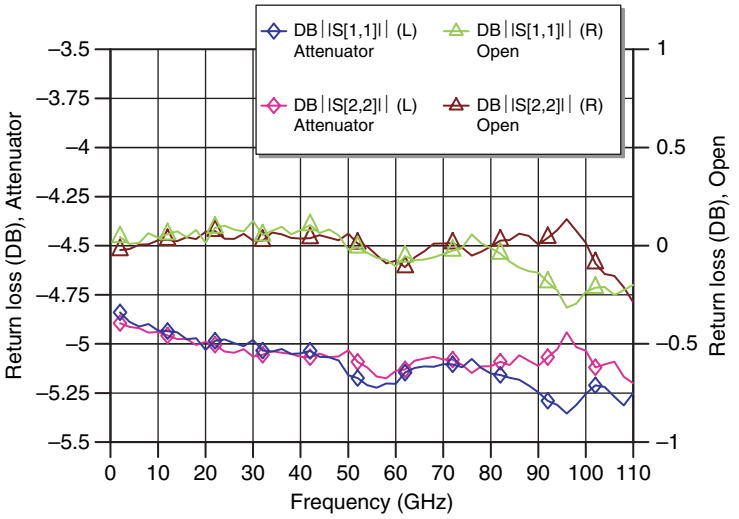

Figure 37 Verification example of the wafer-embedded extended Line-Reflect-Match (LRM+) calibration procedure using a symmetrical series attenuator and a symmetrical open elements on SiGe:C up to 110 GHz. (Source: Scholz R, Korndoerfer F, Senapati B, Rumiantsev A 2004 Advanced technique for broadband on-wafer RF device characterization. *63rd ARFTG Conference. Digest*, pp. 83–90, June 2004.)

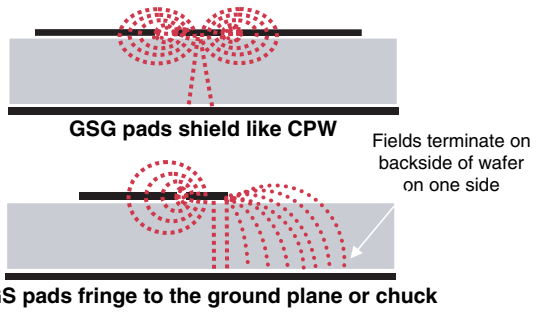

Figure 38 *Top*, ground–signal–ground pads shield electrical fields to the ground plate; *bottom*, ground–signal pads fringe to the ground plane or chuck.

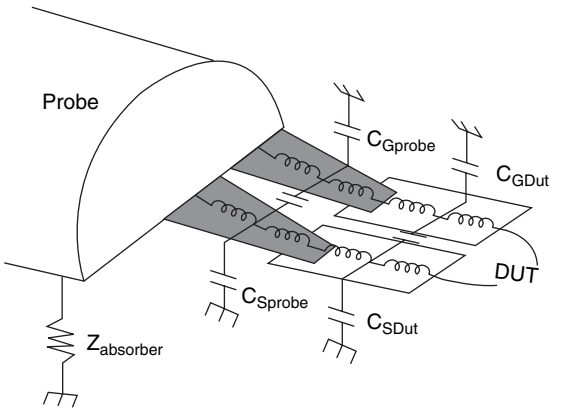

Figure 39 Ground–signal (GS) probing parasitic elements. C_{SDut} and C_{GDut} must be the same as the calibration standards. (Figure courtesy: Cascade Microtech.)

VNA calibration. But changes in metal configuration will often occur. For measurements above 10 GHz, the GS configuration is inadequate and the superior shielding of GSG is preferred.

1.17.5.2.5.(vii) Cable sensitivity Correcting the network analyzer measurement through a glossy cable is similar to the correction we subconsciously use to see an image through a dirty window. We correct for the attenuation due to dirt on the window as well as reflections from the window's surfaces. It is important that the cables be highly repeatable as well as reasonably low loss, so that there is enough dynamic range after looking through and correcting for the lossy cable. Calibrated measurements of a short-circuit standard before and after the cable has been significantly flexed, shown in **Figure 39**, demonstrates the importance of measurement repeatability. The resonance at about 20 GHz would significantly distort further DUT measurements. When troubleshooting the responses of a VNA, it is useful to keep in mind that impedances that vary rapidly with frequency cannot be due to errors near the DUT. When wafer probing there is insufficient electrical length on the wafer or in the probes to cause resonances or impedances that change rapidly with frequency.

1.17.5.2.5.(viii) Troubleshooting **Table 14** may be helpful in troubleshooting VNA measurement problems.

Table 14 Troubleshooting table for NWA measurements problems

Symptom	*Likely problem*	*Try*
Measurements do not repeat at any frequency	Cables or adapters are loose or faulty	Calibrate in coaxial with and without cables and adapters
	Analyzer fault	Calibrate in coaxial directly at test set port
	Probe contact fault	Verify probe contact visually or at DC
	Probe head fault	Calibrate in coaxial at probe connector; if good, replace probe head
	Oscillating DUT	Use different bias condition to verify; change low-frequency DUT terminations
Measurement noisy at all frequencies	Insufficient averaging or too large IF bandwidth	Increase averaging or decrease IF bandwidth
	Poor ramp sweep repeatability	Use step mode
Measurement noisy at certain frequencies	Sweeper band switching	Increase averaging, use step mode. Change sweep rate
	Loose connection	Tighten connectors
	Faulty probe resonating	Check open stub on ISS – should be a smooth inward spiral
Measurement noisy at high frequencies only	Poor return loss at high frequencies	Measure ISS load with corrections off – should be at least 10 dB below the open or short trace
DUT measurements noisy at low frequencies only, or Transistor S_{21} compresses at low frequencies (passive elements OK)	DUT is being biased by rectified RF, or RF is compressing DUT gm	Reduce RF power level, add device input port attenuation, use power slope
Passive element, reflection coefficient outside Smith chart	Incorrect calibration coefficients	Adjust calibration coefficients
	Poor probe placement on standards	Use alignment marks to improve placement accuracy

1.17.6 Testing for Quality Assurance and Reliability

1.17.6.1 Reliability Testing

1.17.6.1.1 Definition of reliability parameters

Reliability $R(t)$ is typically defined as the probability that a device will still be functional after operation over the time interval $\{0, t\}$. In this context, the absolute time, the number of missions, the operating cycles, or even the mileage of a car can be taken as a measure of time. The complementary property of reliability is the failure probability $F(t) = 1 - R(t)$. Starting from a certain number of specimens N, the reliability is a function of the failed specimens n according to

$$R(t) = \frac{N-n}{N} \text{ or } F(t) = \frac{n}{N} \qquad [1]$$

Typical MEMS components cannot be repaired. Hence, the reliability of MEMS can only decrease over time. For electronic components frequently the mean time to failure (MTTF) is used to specify a lifetime parameter. MTTF is defined as the integral over the actual reliability function from zero to infinity.

$$\text{MTTF} = \mu = \int_0^\infty R(t)\mathrm{d}t \qquad [2]$$

In the case of a normal distribution, the MTTF is equivalent to 50% failed, i.e., MTTF $= t_{50}$. A certain portion of MEMS will have failed after some time. Therefore, specific lifetimes can be given for each failure probability, e.g., t_5, t_{10}, and t_{50} for failure portions of 5%, 10%, and 50%, respectively. For reliability engineering in most cases the exponential distribution as well as its more generalized form, the Weibull distribution, is used.

In the case of an exponential distribution, MTTF is taken at 63.2% failures, i.e., MTTF $\approx t_{63}$. The Weibull curve is characterized by a lifetime parameter, which is also taken as $T \approx t_{63}$ but is not identical to the MTTF.

For the failure rate, the definition in **Table 15** is valid. It can be regarded as the relative number of

Table 15 Distribution functions used in reliability engineering

Distribution function	*Failure probability* $F(t) = \int_0^t f(\tau)d\tau$	*Failure rate* $h(t) = \frac{f(t)}{1-F(t)}$
Exponential	$F(t) = 1 - e^{-\lambda t}$	$h(t) = \lambda = const.$
Weibull	$F(t) = 1 - e^{-\left(\frac{t}{T}\right)^b}$	$h(t) = \frac{b}{T} \cdot \left(\frac{t}{T}\right)^{b-1}$

failures per time in relation to the components that are still functional at that time. The failure rate can vary over time. In the case of an exponential distribution it is constant.

In the production phase of MEMS, engineers wish to achieve failure rates and failure portions that are as low as possible. Zero defects is a modern quality management strategy. On the contrary, sufficient failures are necessary in the development phase in order to monitor the reliability level and to give the development engineer optimization criteria. When the Weibull curve is verified experimentally, this is called end-of-life test.

For electronic components several definitions of failure are possible, which can be used specifically, which are as follows:

(1) Nonfunction of a component as well as open or short connections are hard failures.
(2) One of the most relevant failure criteria is deviation from specified functional parameters such as sensitivity, offset, and noise.
(3) Other criteria such as visual appearance, cracking, or a deteriorated surface finish can be taken as failures by definition.
(4) Criteria such as residual strength of a bond are useful in order to gain quality measures even when the MEMS device has not yet failed.

1.17.6.1.2 Real failure behavior of MEMS

Under operating conditions MEMS devices will not fail at a constant rate over their design lifetime. This behavior is represented graphically by the so-called bathtub curve (**Figure 40**). Over the life cycle three phases are distinguished.

In an early period, the failure rate is rather high, but it decreases over time. When early failures are analyzed, in many cases samples exhibit defects, which have led to the premature failures. The defectiveness is a result of inadequate fabrication processes. These processes generate a portion of devices that are functional but unreliable. In operation, these will fail first and the inferior portion of the produced lot will die out after some time.

According to the reliability theory, in the second phase the failure rate should be constant as failures here are only caused by chance when a local fluctuation of stress parameters exceeds the material's strength. The rate of these failures will increase

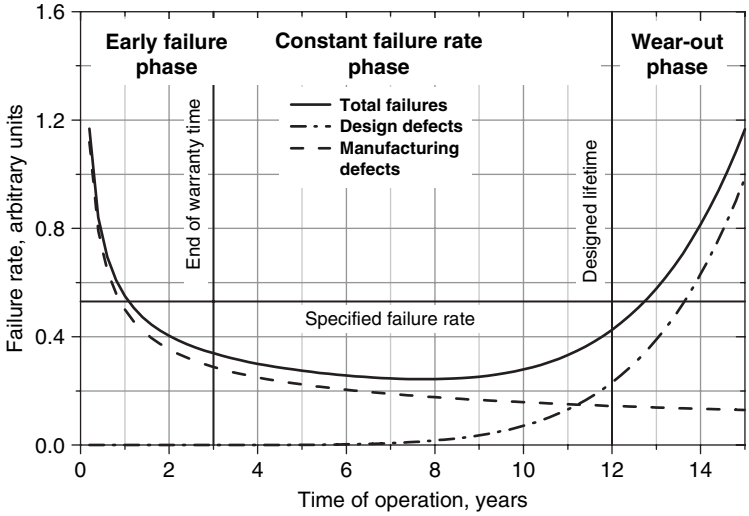

Figure 40 Schematic of the bathtub curve of failures of electronics hardware.

when the damaging conditions become more severe, e.g., when the temperature is increased.

In the last phase the failure rate will again increase due to wear-out processes. Wear-out reduces the ability of components to withstand the environmental loads. Therefore, the probability of failures is increased. Wear-out in MEMS is caused by phenomena like fatigue, corrosion, aging, or electrical degradation of dielectric layers.

The characteristic reliability behavior in the different phases of the bathtub curve is compared in **Table 16**. Clearly, different test strategies are necessary in the reliability management of MEMS. One has to distinguish between the designed reliability, which is tested by end-of-life-tests, and the manufactured reliability, which must be verified by tests monitoring the production.

Table 17 lists typical reliability data, which have been gathered from the data sheets of renowned MEMS manufacturers. A wide range of FIT values is characteristic of MEMS components.

1.17.6.2 Reliability Test Methods

Failures of an electronic component will occur when there are external, environmental loads or when the device is stressed by internal conditions due to operation. Several investigators (Guettler 2004) came to the conclusion that temperature is the dominant influence on the reliability of electronics. In mobile systems many other factors such as vibration, humidity, and lack of cleanliness will significantly contribute to failure causes (**Figure 41**).

Furthermore, operation of MEMS will lead to an increasing number of failures due to degradation (wear-out) by the use conditions. The individual conditions making up the load profile are very much application specific. Also the mechanisms can interact, making the problem rather complex. Loads that are most relevant to failures of MEMS are as follows:

- Temperature
- Temperature changes, including shock
- Mechanical shock and vibrations

Table 16 Characteristics of failures over the lifetime of MEMS

Phase	*Failure rate, tendency*	*Portion of specimens*	*Failure cause*	*Examples*	*Weibull exponent*
Early failures	Medium, decreasing	Defective ones, die out	Manufacturing defects	Defective solder Joints	$b < 1$; e.g., $b = 0.5$
Constant failure rate	Low, constant	Small, but possibly all	Random failures by fluctuations	Dielectric breakdown	$b = 1$
Wear-out failures	High, increasing	Aged ones	Design lifetime exceeded	Fatigue of interconnections	$b > 1$; e.g., $b = 2-10$

Table 17 Characteristics of failure rates of MEMS

Microsystem sensor	*Technology*	*Computed failure rate in FIT*[a]	*Confidence level, $1-\alpha$(%)*	*Temperature for failure rate (°C)*	*Use conditions*
Pressure	Sensor IC	18	60	25	Industrial
		44	90

- Internal operating conditions (U, I, P)
- Environment, humidity, and climate
- Chemical agents

For verification, comparable loads must be imposed on the MEMS using standardized tests. Each of the tests will stimulate specific degradation processes and failure modes in the devices. Thus, many different laboratory tests are necessary to verify the expected operational reliability. In **Table 18**, a matrix summarizes the influence of these tests on specific failure modes of MEMS.

Testing must fulfill a number of prerequisites in order to provide the engineer with realistic results:

- The test conditions must be similar to operational conditions.
- All of the relevant failure modes must be stimulated.
- Test times must be sufficiently long.
- The data must exhibit sufficient statistical significance.

Some of the most relevant test standards for electronic components have been released by the Electronics Industry Association (EIA) as well as by the JEDEC as listed in **Table 19**.

A typical test procedure comprises the following steps:

(1) Visual inspection
(2) MEMS-specific functional test with parameter extraction
(3) Reliability testing
(4) Functional testing
(5) Decision whether the qualification goal is achieved

It is important that the degradation of functional parameters be monitored. Also other failure criteria can be applied in accordance with the predefined specifications. For reliability tests, the number of samples to be examined and the tolerable number of failures are specified according to EIA/JESD STD 47. Typically, three lots, each consisting of 77 components, must be used for temperature/environmental tests and three lots, each with 39 components, for mechanical tests. For production lots no failures are allowed. These tests numbers are applicable only for qualification of production lots but not in the development phase. There a sufficiently representative number of failures is desirable in order to determine lifetime parameters.

Successful lot qualification testing alone will not verify that the MEMS are reliable. The reliability results acquired during the technology qualification of the MEMS must be taken into account. The mathematical procedure is described in EIA/JESD STD 47. When a production lot of MEMS is qualified, N_{lot} is the lot size and M_{lot} is the number of lots to be tested, e.g., $N_{\text{lot}} \times N_{\text{lot}} = 77 \times 3 = 231$. No failures are allowed, so $c \overset{!}{=} 0$. The qualification is based on the data basis of the generic technology qualification. Due to statistical reasons, the complete database that has been gathered for a specific technology must be used even though it comprises many individual device types. N_{tq} is the generic lot size and $c = n$ is the number of failures in technology qualification:

$$\frac{\chi^2_{(c=n)}}{N_{\text{TQ}}} \overset{!}{\leq} \frac{\chi^2_{(c=0)}}{M_{\text{lot}} \times N_{\text{lot}}} \text{ or } \chi^2_{(c=n)} \overset{!}{\leq} \frac{N_{\text{TQ}} \times \chi^2_{(c=0)}}{M_{\text{lot}} \times N_{\text{lot}}} \quad [3]$$

The χ^2-value of the technology qualification must be smaller than the test value computed from Section 1.17.3.1 in order to clear the sample for production. The necessary degree of freedom ν is computed according to $\nu = 2 \cdot (c + 1)$. A second parameter is the confidence level $1 - \alpha$. α is the significance level. Typical confidence levels in reliability physics are $1 - \alpha = 90\%$ and $1 - \alpha = 60\%$. χ^2-values are taken from statistical tables or are computed using a spreadsheet program.

1.17.6.2.1 Field reliability

One of the most important questions in reliability engineering is the lifetime of the products in the application environment. After a certain time of operation in the field, some of the products will fail. Reliability is the probability of function after

some time. The Weibull distribution in **Table 15** describes failure probability and reliability using the parameters b and T. These parameters must be made available by testing; n is the number of failures. Based on data from the qualification, a prediction for field application is possible in accordance with ISO 16750. The significance level α represents the probability of error, i.e., of failure despite a no-failure prediction. Typically, a minimum lifetime in the field t_{field} must be guaranteed and is therefore a specified value. Testing N devices over a time t_{test} without failure, a lifetime ratio $L_v = t_{\text{field}}/t_{\text{test}}$ can be defined. The reliability is then calculated according to ISO 16750:

$$R(t_{\text{field}}) \geq \alpha^{\frac{1}{NL_v^b}} \quad [4]$$

Vice versa, it is possible to compute the necessary defect-free test time according to:

$$t_{\text{test}} \geq \frac{t_{\text{field}}}{f}\left[\frac{\ln\alpha}{N\ln R}\right]^{1/b} \quad [5]$$

In this formula, an empirical acceleration factor between field and test has to be used, according to $f = t_{\text{test}}/t_{\text{field}}$. This factor must be determined experimentally or it is computed based on physics-of-failure models such as the Arrhenius equation or the Coffin–Manson law. Time can be defined in terms of hours as well as operation cycles or even miles.

For assemblies and modules integrating microsystems, specific standards will be applied. In the field of environmental tests, IPC standards as well as European standards IEC 60068-2, Environmental Testing, and ISO 16750 Road Vehicles-Environmental Conditions are examples. Generally, their physical test conditions are similar to the JEDEC standards.

It must be emphasized that a universal test set of general validity cannot be defined. Rather it is the first step toward a correct and complete product specification to analyze the real operating conditions in the application and to design the test program on this basis. Nevertheless, the use of best-practice test sets for specific MEMS applications like medicine or automotives can be a good starting point.

1.17.6.2.2 Failure analysis

Reliability tests must be accompanied by various failure analysis methods in order to understand the basic physical failure mechanisms. Helpful tests are as follows:

- Electrical testing
- Test of mechanical strength
- Chemical analysis of reactions products, corrosion residues, and impurities
- Measurement of thermal resistance

The investigations must be performed in the micro- to nanorange concerning dimensions and concentrations. The most relevant methods are compared in Table 20 like:

- Microscopy with light or electron beam
- Spectroscopy with electrons or X-rays for microanalysis
- Ultrasonic microscopy
- X-ray microscopy and tomography
- Test chips

1.17.6.3 Electrostatic Discharge

Electrostatic discharge (ESD) testing of MEMS is very important as these devices integrate micromechanical structures, analog and digital circuits, thin films, and CMOS memories. In a dry environment, typical human operations like walking, sitting, or working on an insulated ground will lead to electrostatic voltages up to 35 kV; in a humid atmosphere, the voltages are reduced to a maximum of 1500 V. Discharge onto the pins of a component will lead to high transient voltages and currents, which can damage internal structures. Two principal types of test have been standardized for the ESD of electronic components. The human body model (HBM) simulates the ESD of a person while the machine model (MM) tests the ESD of an equipment. For both tests, sensibility classes have been defined (Tables 21 and 22).

The test equipment must fulfill certain requirements with respect to rise time, peak current, and resonance frequency in order to perform correct tests (Table 23).

The test procedure is specified in the following list:

(1) Verify the test signal
(2) Perform parameter test and functional tests at ambient temperature
(3) Test at elevated temperatures
(4) Test with positive and negative pulse of all pin combinations; lot size is three components
(5) Perform parametric and functional tests
(6) Proceed with next voltage level

When the electrical parameters are out of the specified range, this will be the ESD failure criterion.

1.17.6.4 Burn-in, Run-in, and Nondestructive Testing

The idea of burn-in and run-in is based on the bathtub curve. The early failure rate of MEMS devices is significantly higher than the steady-state failure rate. This is caused by a certain portion of devices, which are not perfect and will fail during operation earlier than flawless MEMS components. During burn-in, devices will be operated at high temperatures preferably under conditions comparable to those of the application. Parametric and functional tests must be performed during burn-in. The mathematical basis of burn-in is the Weibull curve. The failed portion is

$$F(t) = 1 - e^{-\left(\frac{t}{T}\right)^{b}} \textit{ and the failure rate is}$$

$$h(t) = \frac{b}{T} \uparrow \left(\frac{t}{T}\right)^{b-1}$$

After a certain burn-in test time, a significant portion of the defective devices will fail. The remaining samples that are shipped to the customer will have a higher apparent reliability than the original batch. Due to high equipment costs, 100% burn-in test of large lots of MEMS devices is often not possible. A second aspect to use burn-in is the use as an indicator of the actual reliability level. When the early failure rate rises significantly, this indicates that also long-term reliability problems are imminent.

Model	*Voltage*	I_{peak}	*Rise time, short circuit*
Human body	4000 V	2.40–2.96 A	2–10 ns

A value of $b = 0.5$ is a representative datum for electronic components and MEMS. Hence, burn-in can be a very effective method to monitor the quality level or to eliminate a portion of the bad samples by testing.

An important third aspect of burn-in is the stability of microsensors, i.e., regarding their electrical parameters. After manufacturing, many of the material properties affecting the electrical behavior are not yet stabilized, such as the resistance of thin films, the stress of metal layers, or the curing degree of encapsulation polymers. Packaging processes can have a strong influence on long-term functionality and drift of microsystems (Fischer *et al.* 2005). In order to save money, fabrication processes are optimized with respect to a high throughput. Therefore, transient processes will not have the required time to accomplish a final status. Consequently, the first material changes will be rapid enough to accomplish the product, which can be handled within seconds or minutes. The end status of the process is only reached after hours or days. Therefore, parameters defining the accuracy such as offset, zero point, or linearity cannot attain their final values in a microsensor directly after fabrication. The burn-in of the system at high temperatures can finalize the kinetic processes and therefore produce stable system properties over the use period. As a device is operational during burn-in, the functional test can also be used to monitor the parameter drift.

Nevertheless, the burn-in test strategy is avoided if possible due to several drawbacks, which are listed in **Table 24**. The main applications lie in fields with small lot sizes and very high-reliability requirements like in aerospace or medical technologies.

In some cases microsystems will exhibit defects, which can impair reliability or functionality. Many defects are caused by inadequate fabrication operations such as assembly or packaging. Nondestructive testing (NDT) is a method of risk elimination of the final product by defect visualization. The three most important NDT methods are visual inspection, X-ray inspection, and scanning acoustic microscope. The main advantages of NDT are that 100% inspection is possible and that no specimens will be lost during testing. As X-ray and ultrasonic testing will also reveal hidden flaws, these are of great importance in MEMS technology.

1.17.7 Test Standards

No special family of standards exists, which was specifically defined for microsystems technology. In typical applications, MEMS are regarded as electronic components and will be subjected to the respective standards and test procedures. A number of international organizations have regulated the field of components.

The American JESD standards and the JEP documents define the properties and quality requirements as well as methodologies for testing and statistical procedures. A part of the standards and technical papers published by JEDEC is free for download. More standards for electronic components have

Table 24 Advantages and drawbacks of burn-in of MEMS

Advantages	*Disadvantages*
Effective in elimination of defective samples	Costly equipment
Shorter quality control loops than for field failures (a week rather than years)	As an end-of-line test still forms wide control loop (hours are desirable)
Good early reliability indicator	Established mainly for thermal phenomena
Improve long-term stability of electrical parameters	High effort for 100% test of large series
Monitor off-set and zero-point drift	Temperature-driven, not for all damaging phenomena

been published in cooperation with the Electronics Industry Alliance (EIA) and are partly available from JEDEC.

In the field of manufacturing technology for electronic assemblies, a comprehensive set of standards was published by the IPC. It has been established worldwide and is used almost independent of specific markets. IPC standards are primarily aimed at printed circuit board assemblies. They specify methods, procedures, tests, and product requirements from the materials level up to the module level. A subset of the IPC publications is free for electronic download.

A major application field of MEMS is electronics for cars. The large equipment suppliers have formed the Automotive Electronics Council (AEC) who worked out a set of standards, AEC-Q100 to AEC-Q200 on the basis of modified JEDEC/EIA standards. Many AEC standards have been made free to the public.

Furthermore, many environmental tests have been defined by ISO standards and by European EN standards. Typical reliability test methods and tests for electromagnetic compatibility (EMC) have been defined and are widely used.

1.17.8 Conclusions

In the field of MEMS, testing is indispensable at all stages of the product generation cycle. It is very important to use efficient and versatile test strategies in order to accomplish fast, economic and dependable verification results with respect to functionality and reliability. These requirements are some of the strong drivers towards wafer-level-testing, which allows verification during intermediate fabrication stages but which also requires very costly equipment. Other future test concepts like built-in self-test or self-calibration are very prospective for MEMS but will require strong research efforts.

Acknowledgment

For his fruitful discussions and qualified remarks, the authors want to thank Mr. Rumianntsev from SUSS Microtec, who took over the proof-reading of the text.

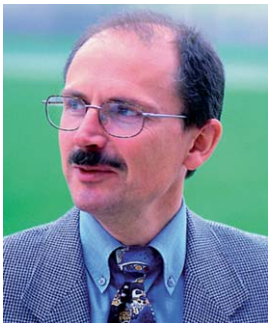
Leonhard Reindl received his Dipl.-Phys. degree from the Technical University of Munich, Germany in 1985 and the Dr. sc. techn. degree from the University of Technology, Vienna, Austria, in 1997. From 1985 to 1999 he was a member of the microacoustics group of the Siemens Corporate Technology Department, Munich, Germany, where he was engaged in research and development on SAW convolvers, dispersive and tapped delay lines, ID-tags, and wireless passive SAW sensors. In the winter of 1998/99 and in the summer of 2000, he was guest professor for spread spectrum technologies and sensor techniques at the University of Linz, Austria. From 1999 to 2003 he was a university lecturer for communication and microwave techniques at the Institute of Electrical Information Technology, Clausthal University of Technology. In May 2003, he accepted a full professor position at the laboratory for electrical instrumentation at the Institute for Micro System Technology (IMTEK), Albert-Ludwigs-University of Freiburg.

His research interests include wireless sensor and identification systems, micro energy harvesting, surface and bulk acoustic wave devices and materials, as well as microwave communication sensor systems based on SAW devices. He holds 35 patents on SAW devices and wireless passive sensor systems and has authored or coauthored approximately 130 papers in this field.

Leonhard Reindl is an elected member of the Administrative Committee (AdCom) of the IEEE Ultrasonics, Ferroelectrics and Frequency Control Society. He is a member of the Technical Program Committee of the IEEE Frequency Control Symposium and the IEEE Sonics and Ultrasonics Symposium. He is also engaged in technical committees of the German VDE/ITG Association, and served as chairman for the German conference Sensors and Measurement Systems 2006.



Jürgen Wilde received a Diploma degree in Materials Science from the University of Erlangen-Nuremberg, Germany, in 1982. In 1989 he received a Ph.D. for his work on The Properties of Microstructured Bonding Wires and their Processing for Electronics from the Technical University of Clausthal, Germany. Subsequently, he worked as a research fellow and group leader in the DaimlerChrysler research institute in Frankfurt, Germany. His research was aimed at influencing design, materials, and fabrication processes on the performance and reliability of mechatronic systems. Since 1999 he has been holding the Chair for Assembly and Packaging at the University of Freiburg's Department of Microsystems Engineering in Germany. He teaches graduates and undergraduates giving lectures on Assembly and Packaging, Quality Management, Testing and Qualification, Systems Integration, and Reliability. He is a member of the VDI/VDE Society GMM, where he is chairman of the Board 5.5 Assembly and Interconnection Technology. His publication list comprises approximately 80 papers in the field of assembly, packaging, and materials science for electronic devices like sensors and microsystems. His current research is dedicated to new methods for accuracy prognosis, reliability verification, and testing of microsensors in automotive applications.

Craig Stewart has worked in the fields of microwave and fiber optic devices, communications, semiconductors and semiconductor equipment. He qualified with a first class honors degree in Electrical Engineering from Glasgow University and

then undertook research in guided wave optics and acousto-optic interactions. In 1975 he moved to the Plessey Allen Clarke Research Centre (Caswell) where he spent seven years working on optical fiber measurements, passive optical devices and acousto-optic signal processing. There followed a transfer to the Plessey Component Group and management assignments in various group companies as well as a short period studying business methods in Japan. On returning, he joined the Plessey Three-Five Group in 1984, a company formed to address the emerging market for III–V semiconductors. Initially tasked with formulating a marketing strategy, he then assumed responsibility for engineering development to establish viable processes and product portfolio, finally moving once again into sales and marketing management for the company. During this period, he first became familiar with on-wafer measurements, both as a customer for Cascade Microtech products and as the sponsor for an internal Plessey development program on ceramic based wafer probes. In 1988 he left Plessey and spent a short period with a cable equipment company before joining Cascade Microtech in 1990 with responsibility for European sales and applications support. Initially the market need was confined mostly to RF measurements on III–V semiconductor devices and Cascade was able to establish the premier position in the field. As the need for on-wafer measurement tools expanded into the mainstream semiconductor industry the need for complementary precision DC measurements emerged with consequently increased sales, applications and service responsibilities. In October 2006, Craig left Cascade Microtech to pursue other business interests although he is still active in semiconductor and communications technology and management via Candim Consulting.

1.18 Multiphysics and Multiscale Simulation

J. G. Korvink, A. Greiner, and Z. Liu, Department of Microsystems Engineering-IMTEK, University of Freiburg, Freiburg, Germany

1.18.1 Multiphysics Simulation and Design Optimization

The microelectromechanical systems (MEMS) design process is highly iterative in character. This is because design constraints tend to become more precise as each design evolves, and because complexity issues emerge only as a design takes shape. Computational tools aim at alleviating this aspect by providing two key capabilities:

- A high level of predictability of the physical processes in a given design realization
- A method to modify a design in the direction of optimality

For the second capability, the first is of course a prerequisite. In this chapter we describe some recent techniques that contribute to more powerful tools both for multiscale multiphysics simulations and toward the ultimate goal of automatic design optimization.

We have grouped the continuum approaches together and described them first, and have followed this up with the particle simulation approaches for soft matter simulations.

As dimensions reduce and soft matter becomes more relevant to MEMS, we see a gradual increase in the use of particle-based methods, and their emergence in commercial tools.

1.18.1.1 Multiphysical Essence of MEMS Simulation

Modeling denotes the process of developing an appropriate mathematical description of a particular system. Simulation is the process of using this description to actually compute the behavior of the system analytically or numerically.

Originally, silicon-based sensors and actuators constitute the basic building blocks of MEMS, and integrated MEMS employ materials and processing techniques originally designated for integrated circuits. Despite the inherent reference to electrical and mechanical phenomena, the field of MEMS has grown to encompass a much broader application range, including microsystems exploiting electrical, mechanical, thermal, magnetic, fluidic, selected chemical, and biological effects and possible coupling among these fields (Romanowicz 1998, Senturia 2000). In addition, a much wider range of material technologies has become established, including metals, polymers, and ceramics.

1.18.1.1.1 Classification of coupled physical fields in MEMS

In MEMS, certain measurements and outputs are detected in the bulk of MEMS devices, and others only on their surface. The same is true of coupled physical phenomena. For example, sensor effects are modeled by equations that are either coupled through domain effects, where a number of physical models are active within the same region and influence each other, or through common boundaries for the case where uncoupled models operate in nonoverlapping adjoining regions. This is relevant to a large number of physical models. We seek to clarify the basic operating principles of MEMS and to characterize the influence of coupling effects in MEMS devices. This classification is not the only possible one but provides an overview of the coupling effects in MEMS.

1.18.1.1.2 Domain-type multiphysical coupling

The electro-thermo-mechanical interaction is a commonly used coupling effect in MEMS. This coupling effect is also called domain coupling because the physical phenomena of coupling occurs completely in the material domain. For example, the energy of an electrical current passes through a material and is partially dissipated into heat. At the same time, the gradient of temperature causes thermal stress and results in structural deformation. This is a natural sequential coupling effect, which can be observed in daily life. In fact, there are fully coupled effects between electrical, thermal, and mechanical signals due to the nature of associated materials. If the independent variables, such as stress, electrical field, and temperature, and the dependent variables, such as strain, electrical displacement, and entropy, are chosen, then the coupling effects can occur between strain–stress as the elastic compliance, strain–electric field as the inverse piezoelectric effect, strain–temperature as thermal expansion, electrical displacement–stress as piezoelectric effect, electrical displacement–electrical field as permittivity effect, electrical displacement–temperature as pyroelectric effect, entropy–stress as piezocaloric effect, entropy–electrical field as electrocaloric effect, and entropy–temperature as heat capacity effect (Nathan and Baltes 1999).

On the one hand, it is possible to observe how the independent variables are coupled with each other, based on these coupling effects. On the other hand, a certain coupling may have very small amplitude when compared with other couplings. For example, the value of elastic coefficients may change only in a very small interval (<1%) when retrieved under constant entropy or isothermal conditions. In this case, the coupling effect can be decoupled and the accuracy of the numerical solution will still agree well with measurements.

1.18.1.1.3 Boundary-type multiphysical coupling

The electrostatic microactuation of a parallel plate structure is a widely used technique in MEMS. One electrode is typically a movable beam while the other electrode is fixed and separated by an air gap, which is within the micrometer range. This electromechanical interaction is a typical boundary coupling effect since the electrically induced mechanical loading is significant with regard to the electrical and mechanical interface. It is clear from the Poisson equation that the electrical force is perpendicular to the material boundary. Then the mechanical deformation of the structure alters the distribution of the electrical potential, thus changing the distribution of the surface charge density and hence the electrostatic forces acting on the structure. The self-consistent solution for both the mechanical deformation and the electrical potential distribution is coupled through the

interface of two energy subdomains. It is especially tricky to compute self-consistency when the pull-in in electrostatic actuation occurs.

1.18.1.2 Coupled FEM Simulation

The primary goal of using numerical simulation for MEMS development is to enable and to accelerate the design compromise. It is also an important aid in improving the understanding of some physical processes, given that the model is correct. Of course, simulation is not a replacement for experimental evidence, and it cannot eliminate a hardware development cycle. It also does not make sense to pursue modeling without measured material property data. This necessity cannot be overemphasized.

1.18.1.2.1 PDE expression of physical field

Physical effects can be described by partial differential equations (PDEs). A PDE relates an unknown scalar or a vector-valued function $u[x_i]$ to its partial derivatives for space and time:

$$F\left[x_1, x_2, \ldots, x_n, u, \frac{\partial u}{\partial x_1}, \ldots, \frac{\partial^k u}{\partial x_1^{k_1} \cdots \partial x_n^{k_n}}, \ldots\right] = 0 \quad [1]$$

The order of a PDE is given by the derivative of the highest order k present in eqn [1], and it is referred to as quasi-linear when all the highest order derivatives appear in a linear relationship. For most of the commonly used second-order PDEs, the characteristic at a point x_i is determined by the coefficients of the second derivative term. We speak of elliptic equations when all eigenvalues of the coefficient matrix have the same sign, of hyperbolic equations when the eigenvalues have differing signs, and of parabolic equations when the matrix is singular. Only by appropriately specified boundary conditions, such as Dirichlet, Neumann, and Robin boundary conditions, a unique solution of the PDE is defined (Morton and Mayers 1994).

1.18.1.2.2 Numerical simulation of single PDE using FEM

In most cases, analytical solutions to the partial differential questions are possible only for a linear PDE with certain simple geometries and boundary conditions. For arbitrarily shaped geometries there can be no closed-form solutions. Then a PDE has to be solved numerically using suitable approximations. In this chapter we use the standard weighted Galerkin finite element method (FEM) to discretize a PDE and obtain approximate solutions.

In the FEM, the choice of weighting and approximation functions in the discretized weak form of the corresponding PDE has an important influence on the solution. In general, the FEM procedure includes deriving a PDE weak form, choosing an approximation function, meshing the computational domain, assembling the stiffness matrix and load vector, adding boundary conditions, and solving a linear algebraic equation. For more detailed discussions about the accuracy and the efficiency of FEM solutions, see Zienkiewicz *et al.* (2005). Here we merely discuss some key points that are very important to obtain reasonable numerical solutions in various MEMS field simulations.

Mechanical analysis involves solving the Lamé equation with the given displacement and force boundary conditions. In deformation analysis, it is usual to choose a linear finite element to discretize the computation domain in order to balance the computational cost and accuracy. This is especially important for 3D simulations. If only the numerical solution of the displacement is needed, then the linear finite element is sufficient in most cases, whereas this is not true anymore if the strain or stress distribution needs to be checked. For a 2D beam that is rigidly fixed at one end and is loaded by a force at the other end, the numerical solution of stress with linear finite element shows a major difference (generally >15%) in comparison to the analytical solution. The discrepancy cannot be compensated using more refined meshes. This phenomenon is called self-locking in beam analysis. The reason for this excessively stiff behavior can be attributed to the missing approximate basis function describing the bending terms using a linear finite element. Similar problems can also be met when solving thin plate and shell problems that have large rotations and small strain. One of the simplest remedies is to use a high-order finite element. However, the computational cost of the high-order finite element is much more than that of a linear finite element. An efficient method to obtain an accurate stress solution is to use a nonconforming element. The nonconforming quadratic complement element approximates the solution by the standard linear interpolation function and a nonconforming quadratic function. The nonconforming degrees of freedom (dofs) are condensed at the element level so that dofs of the element stiffness matrix are the same as for the linear element after static condensing. The nonconforming

element improves the accuracy of stress distribution significantly, and there is no significant increase in the computational cost when compared with the linear element.

Electrostatic analysis involves solving the Poisson equation to compute the distribution of the electrostatic potential and electric field in a given domain. The accurate calculation of electrostatic fields is very important in order to simulate microdevice behavior, such as capacitive sensors and electrostatic microactuators. Generally, the Lagrange element, which has potential dofs only on the element nodes, is used. The electric field is calculated through the numerical solution of the potential. In this case, the accuracy of electric field is not as good as the potential. When the solution of the Poisson equation has a singular character caused by a nonsmooth boundary or an inhomogeneous material distribution, the accuracy of the electric field is not good. Hermite-type elements can be used in which both the potential and the electric field are dofs. However, the Hermite type of high-order element is sometimes awkward to use when solving the electrostatic problem, which includes material interfaces. On the nonsmooth points, the distribution of the potential is continuous but the electric field is not continuous. So the numerical solution with standard Hermite-type element is oversmoothed compared with the exact solution. In order to find a remedy for the oversmooth problem of Hermite-type high-order elements, releasing of derivative dof is required. It is well known that on the material interface the potential and electric displacement is continuous, but the electric field is not continuous. The jump of the electric field depends on the ratio of material dielectric coefficients. So only one unknown of electric on the interface should be used when using the standard discretization method. One simple remedy is to rescale the element stiffness matrix before assembling into the global stiffness matrix, by the relationship of the electric displacement. The transformation is completed on the element level and the sum of dofs does not increase when compared with the standard method.

Like the electrostatic problem, there is also a material interface problem when solving the electromagnetic problem based on the Maxwell equations. Based on a standard Lagrange element, the electric and magnetic fields and fluxes are determined indirectly by solving a scalar and vector potential. At the same time, the curl of electric field and the divergence of magnetic flux should be zero. It is well known that the tangential components of electric field and magnetic field are continuous across the material interface, and the normal components of magnetic flux and electric displacement are continuous across the material interface. The difficulty in the modeling of field strengths caused by discontinuities in the properties of the media can be overcome by using edge elements. An edge element has the property of ensuring the continuity of tangential field components across an interface between different media, while leaving the normal field components free to jump across such interfaces. Hence, edge elements can be used for modeling an electromagnetic field along the interfaces between two different media. It can provide sufficient continuity for the electromagnetic field with a conforming-type element.

In acoustics, sound pressure waves are often sinusoidal. Associated with a sound pressure wave is a flow of energy. The acoustic wave is extremely sensitive to changes in material properties, such as mass, elasticity, and viscosity of the propagation medium. Similar numerical discretization ideas as used for the electrostatic and electromagnetic problem can be used to deal with the material problem. Meanwhile, there is another problem regarding acoustic simulation with the standard Lagrange element, which uses polynomials as approximate basis. Since the basis solution of the acoustic problem can be expressed using superimposed sine functions, fine enough number of finite elements should be used to interpolate the high-frequency wave solution. Coarse meshes cannot reflect a sound wave. The basic reason for this problem is the limited approximation accuracy of the polynomial function for the high-frequency waves. Bubble elements have shape functions, which are zero at the boundaries of the mesh element, and have a sine or a cosine function in the middle of the mesh element. Combined with a linear basis, the bases used in the bubble elements are more suitable to simulate wave phenomena with coarse meshes when compared with the standard Lagrange element.

Fluid problems are also a challenge for the FEM. The challenges arise from two aspects. The first is the consistent interpolation of the velocity and the pressure, and the second is the stable discretization of a pure convection operator. For the first problem, a general rule to obtain a consistent discretization is that the number of pressure dofs should never exceed the number of velocity dofs. When solving incompressible Navier–Stokes equations (NSEs), this demand should be valid independently of the number of elements used to discretize the computational

domain. In order to satisfy this criterion, a generally accepted rule is that the order of approximation of the pressure must be one lower than the order of approximation of the velocity. So if the velocity is approximated by a linear polynomial, the pressure is approximated by a constant in each element and so on. For the second problem, nonstandard Galerkin FEM, such as streamline upwind Petrov Galerkin (SUPG) method, can be used to obtain a solution without nonphysical oscillations.

1.18.1.2.3 Numerical simulation of coupled PDEs using FEM

Until now we have merely discussed the numerical simulation of isolated physical effects that are described by a single PDE, but neglecting all coupling effects with other state variables. However, MEMS devices achieve their functionality through coupling of different physical effects. In the following, we introduce coupling simulation based on boundary and domain coupling effects. The treatment is far from being complete but intends to illustrate some possibilities to accurately simulate coupling mechanisms in MEMS.

1.18.1.2.4 Sequentially coupled method

The sequentially coupled method is typically used in boundary-coupled problems. It is also called partitioned analysis of coupled problems (Felippa 1999), and it was first used to solve the fluid–structure interaction problem. The numerical solution of the structural deformation and fluidic field is implemented separately, and the coupling effect is transmitted through the fluid–structure interface. This means that different programs can be called as black boxes separately, and the finite element meshes need not coincide at the interfaces (http://www.ansys.com/). The decomposition is driven by physical or computational considerations for sequentially coupled methods. Another case using the sequentially coupled method is the loosely coupled problem. For the electrothermal problem, a loosely coupled effect exists if the electric current is not influenced by the change in the temperature. The electric current is first calculated and then solved for the temperature distribution. The advantage of using several programs lies in exploiting the know-how contained in each program, enabling research effort to concentrate on the development of coupling mechanisms and solution strategies, especially since there are many commercially available general-purpose modeling tools, which are extensively used for MEMS simulation. However, the coupling between the different programs has to be performed via external files. This generates a dependency on the data formats of the different programs. The applicable solution strategies for coupled simulations are limited to decoupled iteration schemes, because the coupling Jacobian matrix is not available. At the same time, the sequentially coupled method is not straightforward when extended to more than two fields, because no general staggering iteration can guarantee the convergence for a variety of physical coupling characteristics in MEMS.

1.18.1.2.5 Fully coupled method

In practical MEMS simulation, many coupled problems are fully coupled. It is natural that one discretizes the coupled PDEs directly. In fully coupled discretization, a unified mesh is used in the whole computational domain and each nodal point has the same dofs, which includes unknowns from all the coupled PDEs. With the standard FEM, the off-diagonal submatrices of the global discretization matrices describe the coupling effect and associated relation (http://www.femlab.com).

1.18.1.2.6 Linearization of nonlinear PDEs

For most of the coupled problems in MEMS, the nonlinearity comes from coefficients or material properties that contain a dependent variable or from certain terms in PDEs that have a dependent variable of degree 2 or higher order. Nonlinear PDE sets should contain at least one nonlinear PDE.

In order to solve a system of nonlinear equations, an iterative procedure is necessary. In general a suitable initial estimation is given, and then linearized nonlinear equations are solved based on a previous solution until a converged solution is obtained. Generally there are two ways to derive the iterative method. First, one can discretize the nonlinear PDEs and then solve the nonlinear equation system. An alternative is to linearize the nonlinear PDEs and then to discretize the resulting linear equations (Belytschko *et al.* 2000, Gockenbach 2002). Sometimes both approaches are identical. The second approach is conceptually easier than the first one, and therefore it is widely used in MEMS simulation.

When linearizing the nonlinear PDEs, the nonlinear terms are treated using the Taylor expansion, leaving only the linear terms. This is called the Newton method. Alternative linearization is constructed by the so-called Picard iteration method.

The nonlinear terms are linearized in which all the nonlinear unknown terms are replaced with an iterative solution from the last time step. An important question with respect to these two iterative methods is how to give a good initial estimate. It is well known that the Newton method converges fast (quadratically) when the initial value is in the neighborhood of the converged solution. However, if the distance between the initial value and the converged solution is too large, the Newton method may converge slowly or may even diverge. The Picard iteration seems to have a larger convergence region, which means that it does not need as accurate an initial estimate. However, Picard iterations converge much slower than the Newton method (linearly). A possible strategy to balance the stable and fast convergence is to use Picard iterations first with an initial value and then use Newton iterations when the iteration residual is smaller than certain value.

In strong nonlinear problems, the convergence of nonlinear iterations may be very sensitive to the quality of the initial value even though one is using combined Picard and Newton linearization. In this case, the robustness of the iterative property can be improved using the continuation method (Allgower and Georg 2003). The continuation method defines an easy problem and the original problem that one actually wishes to solve. The solution of the easy problem is gradually transformed to the solution of the hard problem by tracing this path. The path can be defined by introducing an additional scalar parameter that can weaken the nonlinearity of the original problem.

1.18.1.2.7 Time-dependent solvers

The discretization of the time-dependent PDE results in a system of ordinary differential equations (ODEs). In order to solve this system of equations any classical method for solving ODEs can be used. In general one can distinguish between explicit and implicit methods, and between one-step and multistep methods. In the FEM, the time derivative can be replaced by a forward difference discretization (or method of lines):

$$M\left(\frac{U_{k+1}-U_k}{\Delta t}\right)+KU=F \qquad [2]$$

where k denotes the present time-level and $k+1$ the next time-level. A method is called explicit if the term KU is taken only at the time level k. When KU is also taken at the new time level $k+1$, the method is called implicit.

In the explicit method, one still has to solve a system of equations if the matrix M is not lumped. In the case of a lumped M matrix, the solution implies only the inversion of a diagonal matrix and the explicit method is relatively cheap. A disadvantage of the explicit method is that the time-step length must be restricted based on the Courant–Friedrichs–Levy (CFL) condition in order to obtain a stable solution. For a stiff ODE, the size of the time step in the explicit method can be so small that the overall computation is not efficient anymore. For the implicit method, it may be unconditionally stable for well-defined problems. The accuracy requirement is the main reason to restrict the size of the time step.

In coupled problems, which include both time-dependent PDEs and steady PDEs, the matrix M becomes singular. Differential algebraic equations (DAE) have to be solved after the space discretization of the coupled PDEs. This is also the case where there is a big difference in magnitude of the solutions of the coupled time-dependent problems so that the matrix M is almost singular. One has to note that DAEs are different from ODEs, although a general DAE can be transformed into an ODE theoretically by variable substitution. The variable-order, variable-step size backward differentiation formula (BDF) is an efficient method to solve a DAE problem. Solving DAEs is also an important step in the coupled optimization method (COM) for fully coupled physical fields discussed later on in this text (Ascher and Petzold 1998).

1.18.1.3 Mesh Adaptation

In MEMS, an efficient coupled field simulation procedure depends on many detailed numerical strategies. In the FEM, a good mesh is a very important issue, which influences the efficiency and the accuracy of the numerical solution (Thompson *et al.* 1985). When users have limited experience in the properties of the coupled physical fields, it is nearly impossible to decide upon a suitable mesh to discretize the computational domain in advance. In this case, mesh adaptation can bridge the gap. Basically, dynamic mesh adaption can be implemented in two general ways, i.e., adaptive mesh refinement (AMR) (Costa and Alves 2003) and adaptive moving mesh (AMM) (also called the r-adaptive method) (Cao *et al.* 2003). The mesh is locally remeshed in the AMR method, thereby capturing the important part of the

solution. This method is usually accompanied by a relatively complicated data structure updating procedure. For the AMM method, numerical solution of the moving mesh is based on a moving mesh PDE. The nodal points are moved throughout the region to best approximate the solution globally.

The AMR method is suitable for domain-type coupled problems in MEMS. When using the FEM to solve a PDE, there are two major AMR methods available, the h-method and the p-method. For the h-method, the mesh is refined or coarsened by adding or deleting mesh grids according to a local error analysis. For the p-method, the mesh is fixed and the order of a finite element is varied to implement a high-order approximation locally. There have been extensive studies on the h-method and p-method, both of which have shown good efficiency for both steady-state and time-dependent problems. The key point of the AMR method is to define a remeshing strategy. This guarantees the quality of the finite element solution and smoothens the expressions of the material domain, while keeping a reasonable number of design variables. Generally, an error estimator is used to determine the adaptation strategy, since the exact solution of the direct problem is unknown. For a single physical field problem, such as a linear elastic mechanical problem, the error estimator by Zienkiewicz and Zhu can be expressed as a least square approximation between the approximated nodal stress and the smoothened stress in the Gaussian points for all finite elements. Since the solution range for different physical fields can have difference in magnitude of several orders, the error estimators for coupled problem cannot be based on the numerical solution directly. One strategy is scaling the numerical solutions based on the first calculation. User can also provide an initial guess based on the physical meaning of the unknowns of the coupled PDEs.

In the AMM method, the mesh topology is kept unchanged but the mesh grid points are concentrated inside the physical domain where the solution of the physical problem has large gradient or large solution variations (Beckett *et al.* 2001). Compared with the AMR method, the AMM method does not require complicated data structures for mesh refinement. Furthermore, the AMM method does not need to interpolate the numerical solution between different levels of mesh refinement. For the boundary coupled problem, the AMM method coincides with the arbitrary Lagrangian–Eulerian (ALE) method, which is popularly used in the fluid–structure interface problem. In a Lagrangian formulation, the update of a mesh follows the change of the computational domain. The advantage of a Lagrangian expression for a moving mesh is that it can retain a sharp material interface when the mesh is deformed properly. However, one of the challenges of using a Lagrangian-type formulation is that the mesh can become severely distorted or can overlap itself. So after the computational domain is updated, the mesh points inside the domain should be smoothly adjusted using the AMM method. Of course, it can also be possible to use both the AMR and the AMM methods during simulation, e.g., when the domain and boundary couplings exist on different subdomains in one simulation.

1.18.1.4 Multiphysics Design Optimization

Microsystem components are hard to design, because manufacturing technology significantly constrains our creative possibilities, and the sensitive regions where sensor and actuator effects are active are usually not neatly lumped but extend over large portions of a device, making system design approaches hard to apply. Currently, very few automated design methods are available for MEMS (Sigmund 2001a, b, Yin and Ananthasuresh 2002). To establish such methods, a number of numerical components must be in place so that together they can form an integrated design and optimization tool. Here we introduce an integrated structural topology optimization method for multiphysics in MEMS.

1.18.1.4.1 Structural layout optimization

The optimization of structural layout potentially has a great effect on the performance of a structure through parameters such as weight, volume, stress distribution and dynamic response, etc. Generally, structural layout optimization can be classified into three categories: size, shape, and topology optimization.

For size optimization, only simple geometrical parameters, such as the thickness of a plate or the length of a bar, are chosen as the design variable. The shape of the structure is fixed throughout the optimization procedure. For shape optimization, the design strategy to improve the performance of the structure is to adjust the shapes of structural boundaries. The default hypothesis is that the topology of the structure or the connections of the structure remain unchanged. Therefore, shape optimization

cannot answer topological questions. The topology optimization method is a suitable and an efficient methodology in this case.

When compared with size and shape optimization, the topology optimization method is an advanced method, which can obtain an optimal topology, shape, and size at the same time (Rozvany 2001). The continuous topology optimization method has been used to design the layout of structures since the development of the homogenization method (Bendsoe and Kikuchi 1988, Bendsoe and Sigmund 2003). Based on the ground structure method, an initial design domain is discretized by finite element meshing. According to this fixed meshing, an optimal topology can be obtained without guessing an initial topology of the structure. It should be noted that the topology optimization method is equivalent to an inverse problem (first kind is Fredholm integral equation), which considers the material parameter distribution for coupled problems. There is no general theory to obtain a stable solution for this kind of inverse problem. Numerical regularization is generally used in most cases.

1.18.1.4.2 Simultaneous simulation and optimization method

To date, topology optimization has covered several applications, such as functional materials, micro sensors, and compliant actuators, in MEMS design. As an example, let us consider electrothermal microactuator, which is actuated through resistive heating and thereby thermal expansion effects, modeling of electric, thermal, and elastic fields, and then calculates the sensitivity from these three fields to implement the structural optimization iteratively. Numerical instabilities during the optimization procedure, checkerboard patterns and mesh dependency, have been overcome based on the numerical filters or the homogenization method. Geometrically nonlinear deformation, which generally occurs as a snap through or buckling phenomenon in an electrostatic actuated switch, is also a research topic in nonlinear topology optimization. However, further application of structural topology optimization in MEMS is impeded by the complexity of the optimization algorithm itself and the difficulty in finding a unified expression for the optimization procedure for diverse coupled problems in MEMS. For example, there are many surface-type coupling effects in MEMS, such as the structure actuated using electrostatic force. It is known that the deformation of the structure also influences the magnitude of the electrostatic force and vice versa. During structural optimization the electrostatic force is design-dependent. It means that the force is simultaneously changed following the change of the structural boundary in the material frame during the procedure of optimization. Here an efficient and accurate expression of these forces is a key point and has also been a challenging problem to date.

Traditionally, topology optimization is based on the sequentially COM. Specified physical problems can be discretized and solved first, and then sensitivity based on the discretized numerical solutions can be calculated. This is a discretize-then-optimize approach. Another optimization strategy is the COM. One can establish coupled physical equations and an optimization equation at the original PDE level, and then discretize these coupled PDEs together by a numerical method. This is an optimize-then-discretize approach. Here we describe the first as the sequential optimization method (SOM) and the second as the COM (Arora and Wang 2005).

The COM has several advantages when compared with the SOM. First, in the SOM, it is obvious that the effect of an optimization iteration is strongly dependent on the accuracy of their discretized physical problems, because the discretized solution of physical problems is often a noisy or a discontinuous approximation of the initial problem. Numerical errors pollute the quality of sensitivity and influence the convergence. For the COM, the sensitivity, which connects the physical equations and the optimization equation, is calculated by the true physical relationship without any numerical discretization error. So it is often less noisy and more accurate than the discretized optimization method. Second, in the SOM, the state variables are treated as implicit functions of the design variable. Then the design sensitivity analysis should include the derivative terms of the state variables and the design variables. In the COM, the state variables are set independent of the design variables, i.e., the state and design variables are defined in a composite vector. One of the distinguishing advantages of the method is that the derivation of the sensitivity is relatively straightforward. This is especially true when one wants to implement structural optimization in which the state variables are controlled by multiphysical problems. For example, equilibrium equations could come from mechanics, electrostatics, and thermoelectric effects. The state variables include displacement, electrostatic field, thermal stress, etc. The coupling effects include surface coupling of

mechanism and electrostatics, and domain coupling of mechanics and thermoelectric effects. In this case, the sensitivity analysis of the SOM is extremely complicated, and the expression of the COM is much simpler for coupled problems. Then one question is how to establish a relationship between the decoupled state and design variables. One of the possibilities is to derive a corresponding optimization equation based on the specified objective and to solve the fully coupled equilibrium equations and optimization equations simultaneously.

Typically, the element density-type method, such as the solid isotropic microstructures with penalization (SIMP) method, is used to implement structural topology optimization (Allaire *et al.* 2004). However, the expression of the structural layout is nonsmooth because piecewise constant density values are used to express the material domain. Even though this does not cause serious numerical problems for the structural optimization problems, nonsmooth expression of material leads to unexpected results for other types of structural optimization, such as thermal problems (Yoon and Kim 2006). One of the simplest remedies to overcome the problem of nonsmooth expression of a material is the nodal density-type method, where material density is interpolated smoothly with nodal density values. In MEMS simulation, the actuation force is normally either a body force or a surface force. During structural topology optimization, these two kinds of forces are referred to as design-dependent loads, which mean that the load vectors change with the evolution of the structural layout. With either the element- or the nodal density-type method, there is no explicitly defined material boundary. So the implementation of a design-dependent load is not straightforward (Du and Olhoff 2004, Hammer and Olhoff 2000). Basically, the level set method is shape optimization method. Because of its ability to merge holes during the optimization, it has recently become popular in structural topology optimization. When compared with the density-type method, one of the distinguishing advantages of the level set method is the material boundary with zero-level set contours; therefore the design-dependent load is easily implemented during the optimization procedure.

1.18.1.4.3 Derivation of the optimization equation

In this section we introduce the use of the level set method to transform a typical optimization procedure to a coupled PDE expression. We first introduce how to establish a coupled simulation and optimization for a single mechanical and electrostatic field problem, so that the structural optimization procedure can be solved as a pseudo-time-dependent coupled PDE problem. Then we extend this procedure to the electromechanical-coupled optimization problem in MEMS.

A typical structural topology optimization problem for 2D compliance minimization can be written as:

$$\begin{aligned} \text{Min:} \quad & c[\phi,\varepsilon] = \int_{\Omega} \frac{1}{2} E[\phi]\varepsilon^{\mathrm{T}} D\varepsilon \, \mathrm{d}\Omega \\ \text{s.t.} \quad & \nabla\cdot(E[\phi]\sigma) = f \\ & \int_{\Omega} H[\phi]\mathrm{d}\Omega = \mathrm{Vol}^{*} \end{aligned} \qquad [3]$$

where Ω is the design domain, u is the displacement field calculated using the linear elastic equilibrium equation, ε is the strain tensor, σ is the stress tensor, E is the design variable and is defined by the level set surface ϕ as $E[\phi] = H[\phi] + (1 - H[\phi])E_{\min}$, where $E_{\min}$ is a small number, such as 0.001, to avoid singularity of the stiffness matrix, D is the elasticity matrix in which the material Young's modulus is E_0, and Vol^{*} is the material volume constraint in the deign domain.

The level set function $\phi[x]$ is an implicit function for a given domain Ω with smooth boundary, which satisfies the following (Osher and Fedkiw 2002):

$$\begin{aligned} &\phi[x] > 0, \quad x \in \Omega^{+} \text{ (material)} \\ &\phi[x] = 0, \quad x \in \partial\Omega \text{ (boundary)} \\ &\phi[x] < 0, \quad x \in \Omega^{-} \text{ (hole)} \end{aligned} \qquad [4]$$

The area constraint condition, which is typically used in compliance minimization design, is presented. To derive the level set equation, which moves the material boundaries, we combine the objective function and constraints together by using a Lagrangian formulation, and then derive a corresponding Euler–Lagrangian equation (Nocedal and Wright 1999). Using the Lagrangian multiplier λ, we can rewrite problem [3] as

$$\mathcal{J}[\varepsilon,\phi,\lambda] = \int_{\Omega} \left(\frac{1}{2} E[\phi]\varepsilon^{\mathrm{T}} D\varepsilon + \lambda \left(H[\phi] - \frac{\mathrm{Vol}^{*}}{\mathrm{Vol}^{\Omega}} \right) \right) \mathrm{d}\Omega \qquad [5]$$

where Vol^{Ω} is the area of the entire design domain. From classical calculus, we know that the extrema of functional [5] is attained at the position where $\mathcal{J}' = 0$. To obtain the level set equation, which uses a level set surface to express the structural topology implicitly, we need to calculate the variation of the level set surface. Only the normal velocity of the material boundary influences the change of the shape. The

tangential velocity will not influence the deformation of the geometry, merely its parameterization (Sapiro 2001). We assume that the zero level set contour $\phi = 0$ moves only in the normal direction. For an infinitesimal variation δl, which is along the normal direction $\vec{n}$, a new zero-level set is ϕ' and we have

$$\begin{aligned}\delta\phi|_{\phi=0} &= \phi'[x] - \phi[x] = \phi[x + \delta l \cdot \vec{n}] - \phi[x] \\ &= \nabla\phi \cdot (\delta l \cdot \vec{n}) = |\nabla\phi|\delta\end{aligned} \quad [6]$$

where the normal vector $\vec{n} = \nabla\phi/|\nabla\phi|$. For problem [5], the variation of the level set surface on the material boundary can be expressed as

$$\delta_\phi \mathcal{J} = \int_\Omega \left(\frac{1}{2}(1 - E_{\min})\varepsilon^{\mathrm{T}} D\varepsilon + \lambda\right)\delta[\phi]|\nabla\phi|\delta l \, \mathrm{d}\Omega \quad [7]$$

The corresponding Euler–Lagrangian equation at the extreme value point is

$$\left(\frac{1}{2}(1 - E_{\min})\varepsilon^{\mathrm{T}} D\varepsilon + \lambda\right)\delta[\phi]|\nabla\phi| = 0 \quad [8]$$

In most cases, it is impossible to solve eqn [8] directly. One general technique is to solve set equation numerically

$$\frac{\partial\phi}{\partial t} - \left(\frac{1}{2}(1 - E_{\min})\varepsilon^{\mathrm{T}} D\varepsilon + \lambda\right)\delta[\phi]|\nabla\phi| = 0 \quad [9]$$

The auxiliary variable t is used as pseudo-time. The method is also referred to as gradient descent flow. In the case of a well-posed optimization problem, the solution converges to a local minimum based on different initial values. In this way the 2D compliance minimization topology optimization problem can be transformed into the following coupled plane stress equation and time-dependent reaction diffusion equation

$$\begin{aligned}\nabla\cdot(E[\phi]\sigma) &= f \\ \frac{\partial\phi}{\partial t} - \left(\frac{1}{2}(1 - E_{\min})\varepsilon^{\mathrm{T}} D\varepsilon + \lambda\right)\delta[\phi]|\nabla\phi| &= \alpha\,\Delta\phi\end{aligned} \quad [10]$$

with a suitable initial condition ϕ_0. Here an artificial diffusion term $\alpha\,\Delta\phi$ is added to overcome numerical oscillations during the evolution of the level set surface. The coefficient α is proportional to the mesh size and the reaction term. The Lagrangian multiplier is expressed as

$$\lambda = \frac{\displaystyle\int_\Omega \left(\frac{1}{2}(1 - E_{\min})\varepsilon^{\mathrm{T}} D\varepsilon\right)\delta^2[\phi]|\nabla\phi|\mathrm{d}\Omega}{\displaystyle\int_\Omega \delta^2[\phi]|\nabla\phi|\mathrm{d}\Omega} \quad [11]$$

Here we call the first equation in eqn [10] as the state equation for the direct problem and the second equation as the optimization equation for the structural optimization problem.

For the electrostatic problem, one of the most commonly used objective functions is the stored potential energy inside a design domain. The electrical energy can be expressed as $\mu[\phi]\nabla V^{\mathrm{T}}\nabla V/2$ where V is the electrical potential, ∇V is the electric field vector, μ is the dielectric permittivity, which is defined by a level set surface ϕ as

$$\mu[\phi] = \mu_{\mathrm{mat}} H[\phi] + (1 - H[\phi])\mu_{\mathrm{air}}$$

where μ_{air} is the dielectric permittivity of the air and μ_{mat} is the dielectric permittivity of the design material. The equilibrium equation, which controls the electrostatic problem, is the Poisson equation. Following a similar procedure as for the mechanical problem, a maximization of the electrostatic energy problem can be expressed as

$$\begin{aligned}\text{Max:} \quad C[\phi, \nabla V] &= \int_\Omega \frac{1}{2}\mu[\phi]\nabla V^{\mathrm{T}}\nabla V \, \mathrm{d}\Omega \\ \text{s.t. } \nabla\cdot(\mu[\phi]\nabla V) &= 0 \\ \int_\Omega H[\phi]\mathrm{d}\Omega &= \mathrm{Vol}^*\end{aligned} \quad [12]$$

A fully coupled PDE expression of topology optimization for the electric potential energy problem with area constraint can be similarly expressed as

$$\begin{aligned}\nabla\cdot(\mu[\phi]\nabla V) &= 0 \\ \frac{\partial\phi}{\partial t} - \left(\frac{1}{2}(\mu_{\mathrm{mat}} - \mu_{\mathrm{air}})\nabla V^{\mathrm{T}}\nabla V + \lambda\right)\delta[\phi]|\nabla\phi| &= \alpha\,\Delta\phi\end{aligned} \quad [13]$$

where

$$\lambda = \frac{\displaystyle\int_\Omega \left(\frac{1}{2}(\mu_{\mathrm{mat}} - \mu_{\mathrm{air}})\nabla V^{\mathrm{T}}\nabla V\right)\delta^2[\phi]|\nabla\phi|\mathrm{d}\Omega}{\displaystyle\int_\Omega \delta^2[\phi]|\nabla\phi|\mathrm{d}\Omega} \quad [14]$$

Hence as for the mechanical problem, an artificial diffusion term is added to the right-hand side of the second equation in eqn [13].

During the procedure, the amplitude and the direction of the electrostatic force will change with the update of the topology of the structure and its deformation. Hence we have a coupled optimization problem. There are two different methods to solve this surface coupling problem: the sequentially coupled solver and the directly coupled solver. To

implement structural optimization with the coupled method, the directly coupled solver is used to calculate the structural deformation. The design domain is shown in **Figure 1**. There are two subdomains. Subdomain 1, the upper strip of the beam marked in black, has specified constant material properties. Subdomain 2 is the optimization domain and is white in **Figure 1(a), 1(c), and 1(e)**. Here we discuss three different load cases. In the first case, a fixed load vector is added on the middle point of the upper surface of the whole domain. In the second case, the electrostatic force acts on the structure. In the last case, both the fixed load and the electrostatic force act together on the whole structure. The objective of structural optimization is still compliance minimization with area constraint. The material inside both subdomains is aluminum with Young's modulus of 70 GPa and a Poisson ratio of 0.33.

In the first case, we use the compliance minimization model in eqn [3]. In addition, we consider the geometrically large deformation for the elastic equilibrium equation. So the strain tensor ε has a nonlinear relationship with the displacement vector. Since we use the COM (Liu *et al.* 2005) in which the design variable ϕ and the displacement vector are independent of each other, the optimization equation is still the same as the second equation in eqn [10]. The first equation in eqn [10] is solved using a nonlinear solver for large deformation analysis. The optimized structural topology is shown in **Figure 1(b)**.

In the second load case, a consistent solution for the electromechanical problem is needed. To coincide with the fully coupled optimization method, we choose a direct coupled solver where the deformed mesh caused by the structural deformation is simulated by the ALE method (Jakobsen *et al.* 2001). The couple ALE method can be implemented using the following coupled equations:

$$\begin{aligned} \nabla \cdot (\mu[\phi] \nabla V_X) &= 0 \\ \nabla \cdot (E[\phi]\sigma) &= F_{\text{ele}} \\ \nabla \cdot (G \nabla X) &= 0 \end{aligned} \qquad [15]$$

where X represents the deformed nodal position because of structural deformation, G is the mesh monitor function, which controls a local property of the deformed mesh, V_X means that the value of the electrical potential is calculated on the deformed mesh, and

$$\mu[\phi] = \mu_{\max} H[\phi] + (1 - H[\phi])\mu_{\text{air}}$$

where $\mu_{\max}$ is a large number to approximate the distribution of the electrical potential inside the conductor. In this example $\mu_{\max} = 100$. Using the moving mesh equation (the third equation in eqn [15]), all of the displacement, force, and electrical potential boundary conditions can be implemented in the original coordinates. This method can deal with the electromechanical coupling directly before pull-in occurs. For the optimization examples we presented here, the fixed–fixed end beam in subdomain 1 is used

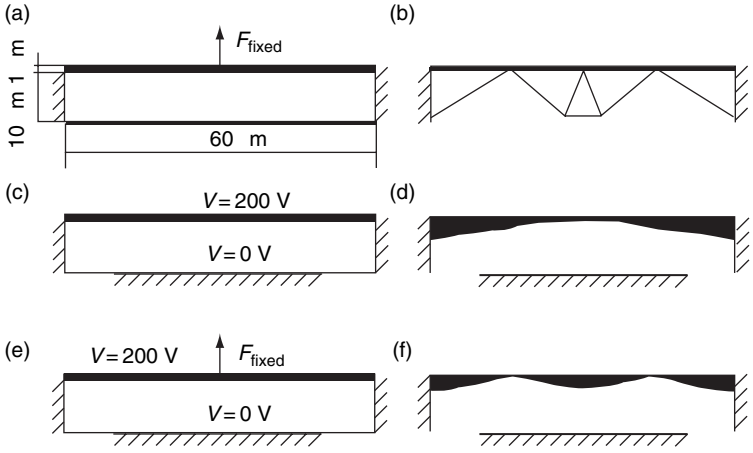


Figure 1 Compliance-minimized topology optimization of a fixed–fixed end beam and three load cases. (a) and (b) Initial design domain and optimized topology with fixed load vector; (c) and (d) initial design domain and optimized topology with electrostatic force; (e) and (f) initial design domain and optimized topology with both the fixed load vector and the electrostatic force. The beam in (a) has a stiffness of 0.019 N m^{-1} at its center point, and for the situation in (c), it has a theoretical pull-in voltage of 1700 V. In all simulations F was set to 10 μN. (Source: Lui Z, Korvink J G, Reed M L, Multiphysics for structural topology optimization. *Sensor Letters*. **4**, 191–199.)

to avoid pull-in occurring during the optimization procedure with reasonable electrical potential conditions. The coupled optimization equations are:

$$\begin{aligned}\nabla\cdot(\mu[\phi]\nabla V_X) &= 0\\ \nabla\cdot(E[\phi]\sigma) &= F_{\text{ele}}\\ \nabla\cdot(\nabla X) &= 0\\ \frac{\partial\phi}{\partial t} - \left(\frac{1}{2}(1-E_{\min})\varepsilon^{\mathrm{T}} D\varepsilon + \lambda\right)\delta[\phi]|\nabla\phi| &= \alpha\,\Delta\phi\end{aligned} \quad [16]$$

Here the mesh monitor function is the unit function so that the mesh is smoothly modified on the whole design domain. On each mesh node, there are six dofs, two displacement dofs, one electrical potential dof, two moving mesh position dofs, and one level set surface dof. However, the optimization equations remain unchanged despite the complicated coupled forward problems. The optimized result is shown in **Figure 1(d)**.

In the last case, both the fixed load vector and the electrostatic force act on the structure. So this is a multiple load optimization problem. Based on the analysis of the first two cases, the optimization equations for these two loads are the following:

$$\begin{aligned}\nabla\cdot(E[\phi]\sigma_1) &= F_{\text{fixed}}\\ \nabla\cdot(\mu[\phi]\nabla V_X) &= 0\\ \nabla\cdot(E[\phi]\sigma_2) &= F_{\text{ele}}\\ \nabla\cdot(\nabla X) &= 0\\ \frac{\partial\phi}{\partial t} - \left(\frac{1}{2}(1-E_{\min})\left(\varepsilon_1^{\mathrm{T}} D\varepsilon_1 + \varepsilon_2^{\mathrm{T}} D\varepsilon_2\right) + \lambda\right)&\\ \times\,\delta[\phi]|\nabla\phi| &= \alpha\,\Delta\phi\end{aligned} \quad [17]$$

where ε_1 and ε_2 are the strain vectors corresponding to two load cases. The optimized result is shown in **Figure 1(f)**.

1.18.2 Multiscale Simulation

Modeling and simulation of the behavior of materials in various applications of modern microsystems is a challenging task. On the other hand, high costs or restricted availability of samples for analysis requires modern microfluidic systems to operate in the picoliter regime and below. The ultimate goal is to make available simulation tools that emerge from a theoretical modeling that ranges from quantum physics of atomic-scale phenomena, covering up to continuum descriptions of macroscopic behavior, and going even further to system behavior. Such engineering tools, supporting design processes in microsystem technology, are still missing. In microsystems, the presence of length scales of several orders of magnitude requires the coupling of different tools appropriate for simulation at the respective spatial scale. The use of advanced computer-aided design (CAD) tools promises reduction in the extent of physical testing necessary to prototype a device. Activities to incorporate various physical models at different length scales (e.g., Nielaba *et al.* 2002) exist.

The simulation of complex processes in liquids and the modeling of the material properties of liquids are tasks that require resolutions on the molecular scale and below. The computational effort at the atomistic level is demanding. Consequently, atomistic approaches should undergo a coarse graining procedure. Simulating the behavior of a reasonable amount of liquid with various components in a common framework with a reasonable computational effort – as it is mandatory for the application of microfluidic systems in a design process – can be realized only by superimposing microscopic molecular dynamics (MD) approaches on coarse-grained particle dynamics methods. Typically, the microscopic MD simulation is computationally more expensive than coarse-grained particle dynamics solvers and therefore MD must be restricted to very specific parts of the whole system where an atomistic resolution is desirable. It is even conceivable that a successive coupling to continuum Navier–Stokes models is necessary. To overcome the problem of the costly particle dynamics calculation being repeated in every iterative loop of the continuum solver, a microscale simulation featuring noniterative and explicit time marching must be coupled to an equivalent model acting at a much coarser length scale. This eventually leads to a feasible simulation process for engineering CAD applications in multiscale microfluidic systems. A promising technique to fulfill the above-mentioned requirements is dissipative particle dynamics (DPD), a particle dynamic simulation technique for simulations above the molecular length scale (Hoogerbrugge and Koelman 1992), which is described in Section 1.18.2.1. A second approach to fluid dynamics that couple the DPD model to more macroscopical environments is given by the lattice Boltzmann method (Wolf-Gladrow 2000).

1.18.2.1 Particle Dynamics Methods

Molecular dynamics is the most popular particle dynamics method, and it has a long-standing tradition. Its main ingredients are the interaction potentials of the atomistically resolved particles together with an algorithm to integrate the set of differential equations for this many-body problem. In essence it is an

integration of Newton's equation of motion. Much effort has been put into the development of efficient algorithms. On the other hand the interaction potentials can be derived from first principles and their form is crucial for the properties of the simulated material.

Coarse-grained particle dynamics methods loose this direct connection to the first principles derivation of the interaction potentials. Instead, they must rely on either MD simulations or macroscopic measurements to adjust the respective parameters. Nevertheless, they benefit from the development of the efficient integration techniques for MD systems.

1.18.2.1.1 Coarse-graining microscopic methods vs refinement of continuum models

At a microscopic length scale on the order of interatomic distances in fluids or solids, MD represents an attractive simulation technique in computational fluid dynamics. However, at the length scale from 10 to 1000 nm a coarse graining of the molecular model due to rising computational costs is desirable.

There are two ways to arrive at a particle description of microfluidic phenomena: coarse graining of MD and a direct Lagrangian discretization of the equations governing hydrodynamics. The former leads to the DPD variants discussed in Section 1.18.2.1.2, while the latter is exemplarily discussed here by the method of smoothed particle hydrodynamics (SPH) (Koumoutsakos 2005).

SPH is a method for the simulation of hydrodynamic phenomena. Originally, SPH was developed to overcome hydrodynamic problems in astrophysics. Eventually it was adopted for the investigation of laboratory scale problems as well. It is a direct discretization of the macroscopic hydrodynamic equations on Lagrangian grid. The spatial derivatives are found by means of an interpolation formula. One of the biggest drawbacks of SPH is the fact that thermal fluctuations are not included in the equations of motion. For modeling flows at astronomical length scales, fluctuations most certainly do not play a role. In applying SPH to microfluidics where the dimensions are orders of magnitude smaller, fluctuations definitely do come into play. In a recent effort a generalization of SPH including thermal fluctuations has been proposed (Espanol and Revenga 2003) and termed smoothed dissipative particle dynamics (SDPD).

1.18.2.1.2 Dissipative particle dynamics

DPD, first introduced by Hoogerbrugge and Koelman (1992), is expected to be suitable for the intermediate range of length scale. Its relation to MD as well as to continuum methods has been investigated (Flekkoy and Coveney 1999, Flekkoy *et al.* 2000). DPD is a mesoscopic simulation method capable of bridging the gap between atomistic and mesoscopic simulations (Groot and Warren 1997).

In essence, DPD is a treatment of the dynamics of quasi-particles representing small sets of the liquid's molecules by stochastic differential equations similar to a Langevin approach. It combines features from MD and lattice gas methods. **Figure 2** provides a schematic representation of the context in which DPD has to be seen with respect to other simulation methods. Since its first introduction this method has been applied for the simulation of a wide range of phenomena, especially in material science. Thorough investigations have been carried out to understand the capabilities of DPD when applied to computational fluid dynamics. Recently, DPD has experienced an increasing interest of different research groups for its improvement in several aspects. Its algorithmic optimization was one focus, making it an appropriate method for application in engineering fields (Kauzlaric *et al.* 2005). The inclusion of energy and momentum conservation in the particle–particle interaction for the set of stochastic differential equations describing a DPD models is an important extension for heat flow applications. Recently, phase change models have been included, which is built on the energy-conserving DPD (DPDE) models. A solid–liquid phase transition and liquid–vapor coexistence can be modeled with DPD without turning down all the advantages of the method that come from using larger time steps than in MD.

We will briefly describe the basic ingredients of DPD. Every dissipative particle i with its position $\mathbf{r}_i$ and its momentum $\mathbf{p}_i$ or its velocity $\mathbf{v}_i$ is propagated according to Newton's law with the force $\mathbf{F}_i$ acting on a particle. Thus the equations of motion is given as follows:

$$\dot{\mathbf{r}}_i = \mathbf{v}_i \qquad [18]$$

$$\dot{\mathbf{v}}_i = \mathbf{F}_i = \sum_{j \neq i} \left(\mathbf{F}_{ij}^{\mathrm{C}} + \mathbf{F}_{ij}^{\mathrm{D}} + \mathbf{F}_{ij}^{\mathrm{R}} \right) \qquad [19]$$

where the force has three main contributions due to other particles in the flow, namely a conservative part $\mathbf{F}^{\mathrm{C}}$, a dissipative contribution $\mathbf{F}^{\mathrm{D}}$, and a fluctuating force $\mathbf{F}^{\mathrm{R}}$. The latter two are defined as

$$F_{ij}^{\mathrm{D}} = -\gamma_{ij} w[r_{ij}](\mathbf{e}_{ij} \cdot \mathbf{v}_{ij})\mathbf{e}_{ij} \qquad [20]$$

$$F_{ij}^{\mathrm{R}} = \sigma_{ij} w^{1/2}[r_{ij}]\mathbf{e}_{ij}\xi_{ij}[t] \qquad [21]$$

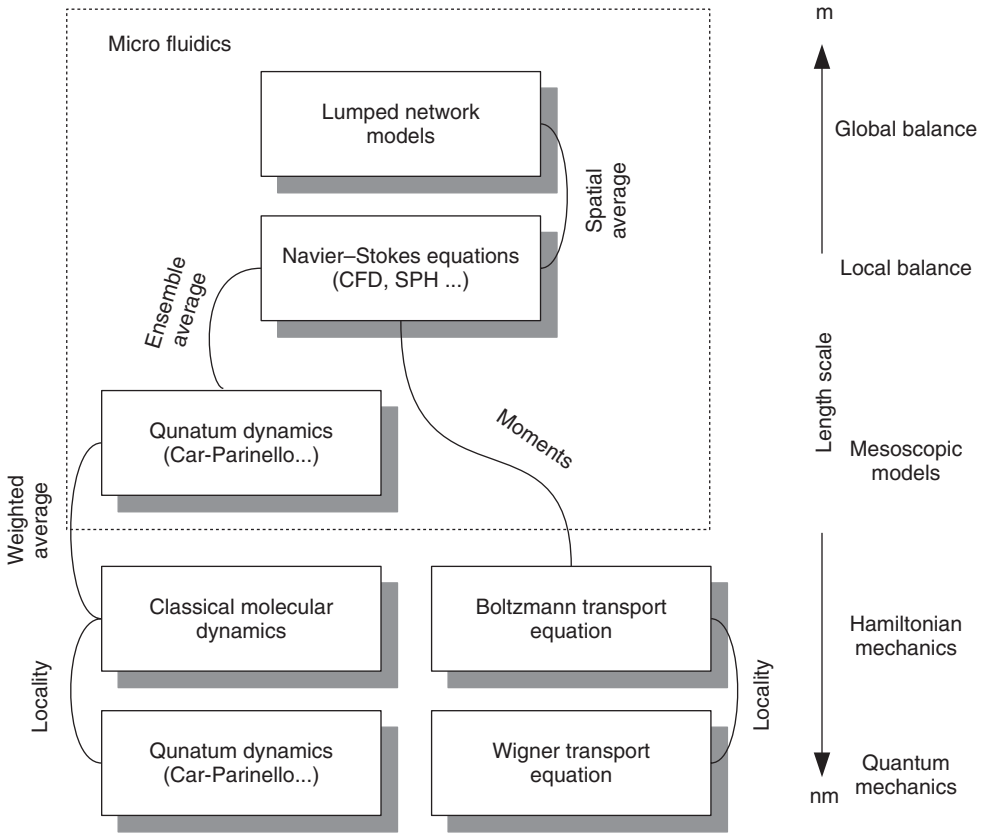

Figure 2 DPD model in the context of other simulation methods. BD, Brownian dynamics; CFD, computational fluid dynamics; DPD, dissipative particle dynamics; SPH, smoothed particle hydrodynamics. Deriving a mesoscopic technique from a microscopic one or a macroscopic technique from a mesoscopic one usually involves some sort of projection (averaging).

where γ and σ are the dissipation strength and the fluctuation amplitude, respectively. $w[r_{ij}]$ is a weighting function of the distance r_{ij} of the two dissipative particles i and j, while $\mathbf{e}_{ij}$ is the unit vector pointing from particle i to particle j, and $\mathbf{v}_{ij}$ is the relative velocity of the two particles. $\xi_{ij}[t]$ describes the Gaussian white noise according to the following equation

$$\langle \xi_{ij}[t] \rangle = 0 \qquad [22]$$

$$\langle \xi_{ij} i[t] \xi_{i'j'}(t') \rangle = (\delta_{ii'}\delta_{jj'} + \delta_{ij'}\delta_{ji'})\delta[t-t'] \qquad [23]$$

The modeling of material properties is done in DPD by adjusting the parameters entering the forces given in eqn [19]. These are γ and σ and form the conservative potential. An advantage in computational effort results only if $\mathbf{F}^{\mathrm{C}}$ is a soft repulsive potential. This allows for much larger time steps than in MD. On the other hand, the lack of an attractive part in $\mathbf{F}^{\mathrm{C}}$ does not allow for free surface flow. Hence a density-dependent part must be added to the conservative potential accounting for the excess surface energy in order to describe liquid–gas interfaces. Since this is an extension of the simple DPD model to many-body behavior, it is termed as MDPD in the literature (e.g., Paganobarraga and Frenkel 2001).

So far we treated only isothermal DPD even with its extension to MDPD. To include thermal properties of the material the internal energy of the individual dissipative particle and its interactions with the translational dofs should be taken into account. The internal energy as an example for the extension of the DPD to DPDE (e.g., Pastewka *et al.* 2006) devises a way for the introduction of various other dofs. Clearly, their equation of motion should be coupled to those of the existing dofs, and is a task for material modeling. With the extension to

MDPDE, the phase description of phase transitions has become possible, which makes this method also very attractive in engineering applications when compared with direct numerical treatment of the hydrodynamic equations.

1.18.2.1.3 Applications of DPD

The area of applications for DPD is growing very rapidly. Its range for different simulation tasks is listed as follows. A discussion on mesoscopic dynamics of colloids can be found in Dwinzel *et al.* (2002), the treatment of binary fluids and immiscible fluids is reported in Coveney and Novik (1996) and Dwinzel and Yuen (2000), the rheology of dense colloidal suspensions can be found in Boek *et al.* (1997), and many more. The important step was the derivation of a thermodynamically conservative interacting force from a given free energy density, which allowed for the implementation of phase coexistence and the description of phase boundaries (Paganobarraga and Frenkel 2001). The implementation of DPDE was a very important development to make the model applicable for phase transitions (Boneyt Avalos and Mackie 1997). Newer developments overcome the limitations of DPDE with respect to the time steps in simulations (Pastewka *et al.* 2006), and thus allow for its application to the study of complex fluids. There are recent investigations on the applicability of DPD in the framework of micelle formation (Schulz *et al.* 2004), which makes it a promising candidate for the task of bridging the gap of length and time scales for the simulation of ionic liquids as well, even if there are still strong implications for the applicability of the method. In Pool and Bolhuis (2006), the failure in the prediction of a critical micelle concentration by an error of thirteen orders of magnitude was exposed impressively. We noted that there is a need for further developments to make DPD applicable in specific materials systems, especially when it comes to difficult rheological properties (Kauzlaric *et al.* 2003a, b, 2004).

In **Figure 3** the filling of a bending specimen mold was simulated. Experimental findings reported on the jetting behavior around the obstacle in the flow field. This was exactly reproduced by the DPD simulation,

Figure 3 Filling simulation of a bending specimen mold performed by dissipative particle dynamics (DPD).

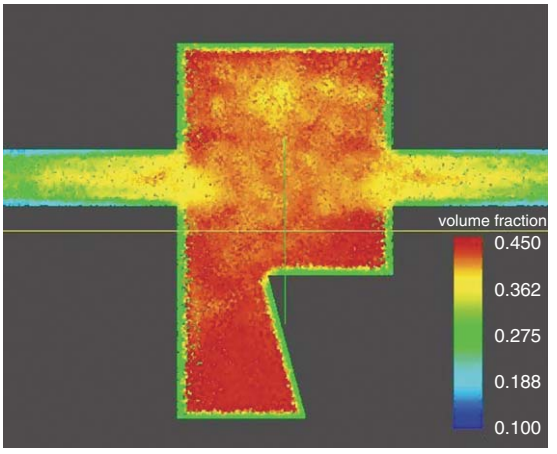

Figure 4 Characteristic powder distribution in micropowder injection molding.

while a conventional simulation tool failed in the prediction of jetting. A very important information in powder injection molding is the ceramic or metal powder distribution after the molding process. A homogeneous mold mass is subject to demixing due to the shear rates occurring in the molding process. **Figure 4** shows that by the extension of the DPD model a direct prediction of the powder concentration is possible.

1.18.2.2 Kinetic Models

Kinetic theory, as opposed to particle dynamics, starts from a different point of view for a system of many dofs. A state of N particles is given by its $3N$ coordinates r_i and its $3N$ momenta p_i to give $6N$ dofs. Instead of solving the coupled $6N$ equations of motion, as done in a particle dynamics approach, we rather regard the system as represented by a probability density $f_N[r_1, \ldots, r_{3N}, p_1, \ldots, p_{3N}]$. The quantity f_N has the meaning of a correlation function for the $6N$ dofs. By knowing the interaction potentials of the N particles we can form the Hamilton function $H[r_1, ..., r_{3N}, p_1, ..., p_{3N}]$ and write down the $6N$ Hamiltonian equations of motion as follows

$$\dot{r}_i = \frac{H}{\partial p_i} \qquad [24]$$

$$\dot{p}_i = -\frac{H}{\partial r_i} \qquad [25]$$

This is the starting point of particle dynamics methods, for example, MD, which proceed by solving eqns [24] and [25]. Instead of doing so we can write

down the equation of motion for f_N, which in this case in treated as an observable quantity, to give

$$\frac{\partial f_N[r_i, p_i, t]}{\partial t} + \frac{\partial r_j}{\partial t}\frac{\partial f_N[r_i, p_i, t]}{\partial r_j} + \frac{\partial p_j}{\partial t}\frac{\partial f_N[r_i, p_i, t]}{\partial p_j} = 0 \quad [26]$$

For solving eqn [26] the information from eqns [24] and [25] is needed and thus there is no advantage. In kinetic models the interest is not in the full correlation function f_N, but instead in the probability of finding one particle in phase space at a certain point f_1 [**r**, **p**]. This function can be obtained by integrating f_N over all the $6(N-1)$ variables that are not of interest. Together with Boltzmann's assumption of molecular chaos, the equation of motion for a single particle distribution function then is given as follows:

$$\frac{\partial f[\boldsymbol{r}, \boldsymbol{p}, t]}{\partial t} + \dot{\boldsymbol{r}}\frac{\partial f[\boldsymbol{r}, \boldsymbol{p}, t]}{\partial \boldsymbol{r}} + \dot{\boldsymbol{p}}\frac{\partial f[\boldsymbol{r}, \boldsymbol{p}, t]}{\partial \boldsymbol{p}} = C[\boldsymbol{r}, \boldsymbol{p}, t]_{\text{coll}} \quad [27]$$

where $C[\boldsymbol{r}, \boldsymbol{p}, t]_{\text{coll}}$ is a collision term that derives from the fact that we averaged over the $6(N-1)$ dofs. Eqn [27] is called the Boltzmann transport equation (BTE). Solution techniques for eqn [27] that make use of cellular automata is briefly discussed in Section 1.18.2.2.1.

1.18.2.2.1 Approximations of the BTE

Although it is a discretization method of the BTE, the lattice Boltzmann automaton (Chen and Doolen 1998) was introduced for the purpose of solving the NSE, which in turn can be derived from the BTE via a Chapman–Enskog Expansion (CEE).

The NSE is the equation of motion of the first moment of the single-particle distribution function. An approximation of the BTE up to a finite order satisfies the NSE by design, even though it could be more general. At first, the most simplified lattice Boltzmann model still consistent with the NSE has been sought. Examples for simplifications that do not necessarily improve efficiency are the single relaxation time approximation (Bhatnagar *et al.* 1954) and models with a minimal set of dofs like the D3Q13 model (13 speeds in three dimensions) (d'Humieres *et al.* 2001). In these models, efficiency is often decreased by the introduction of instabilities. However, there is a very simple way to make even the worst model stable, e.g., through increased viscosity. By applying the scaling laws of fluid dynamics it is still possible to simulate any flow condition by choosing appropriate time steps and grid spacings for the model-dependent lowest attainable viscosity. The performance penalty is severe and can be calculated from the same scaling laws. Two flow conditions are said to be similar if their Reynolds number is identical. The Reynolds number is defined as $Re = Lv/\nu$. Here L is a characteristic flow length, v is the flow's average velocity, and ν is the kinematic viscosity. Scaling laws are useful to derive numerically tractable dimensionless equations. It is easily seen that, for a constant Reynolds number, increasing viscosity can only be compensated for by increasing either v or L. Higher velocities will typically not result in more stable solutions since the lattice Boltzmann method is an explicit finite difference scheme and has to satisfy the CFL condition (Courant *et al.* 1967). The only remaining option is to take the expensive road and decrease L. This translates to finer grid spacings and shorter time steps. Since we are interested in time-varying 3D simulations we see that lowering the viscosity by one order of magnitude leads to four orders of magnitude decline in cell update operations and three orders of magnitude decline in the number of cells. In contrast, the above-mentioned simplifications result only in small gains per update step, typically smaller than a factor of 2 in memory and computational time. This cannot be compared at all with what we gain by finding a way of lowering the viscosity by many orders of magnitude without sacrificing stability. This is done, not by introducing new concepts or models, by merely removing other types of simplification, which crept into the scheme due to the effort to relate the lattice Boltzmann automata to the NSE rather than to see it as a discretization of the BTE. A recently developed new scheme called cascaded digital lattice Boltzmann automata (CDLBA) is able to overcome all the instability issues of conventional LBA (Geier *et al.* 2006a).

1.18.2.2.2 Applications of CDLBA

The stability of CDLBA is impressively demonstrated by the turbulent flows in **Figures 5** and **6**.

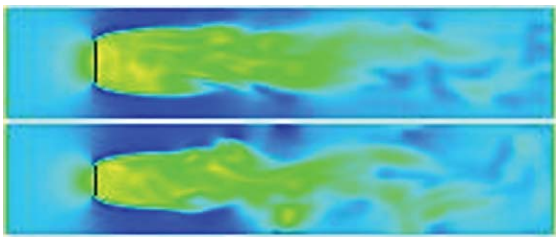

Figure 5 Top and side view of the wake field of a rectangular object in a gas flow, $Re \approx 500\,000$.

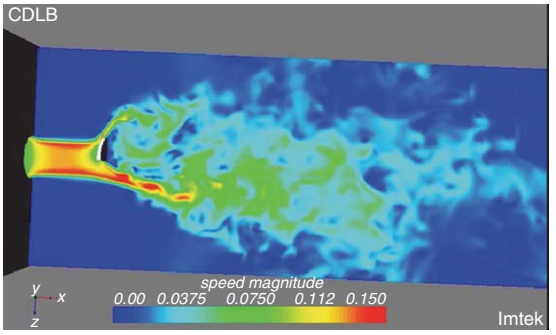

Figure 6 Arbitrarily shaped object in a gas flow from an orifice, $Re \approx 1\,000\,000$.

The flow over a rectangular plate has a Reynolds number of $Re \approx 500.000$ while the orifice flow has $Re \approx 1.000.000$. CDLBA is undoubtedly a major improvement for the calculation of flow fields in subsonic flow. In micrometer dimensions one may argue that turbulence does not play an important role. This is not true for all applications, especially when fast mixing devices are considered. In this application the onset of turbulence on short length scales is desired and the design of the respective structure can be supported by CDLBA, as it has already been done for the topology optimization of microflows (Geier *et al.* 2006b).

1.18.3 Conclusion

Whenever there is talk of automatic simulation tools, meaning that we wish to eliminate the need for a human operator, we deal either with highly linear and therefore deterministic decisions and computations or with a highly restricted application area and need to invest enormous effort to make the implementations robust.

Nevertheless, engineering design practice yearns for ever more automation as a means to become more efficient, especially in avoiding the tedious work of scanning for optimal design layouts for those cases where at least the target performance quantities are evaluable.

In our search for better tools to achieve these goals, we and others are working at cointegrating continuum and mesoscopic methods, and on extending algorithms to become more efficient and robust, and general enough to cope with the insatiable demand of MEMS engineers for design support tools in an ever-broadening application field.

Our choice for the immediate future has fallen on the level set method, treated as a coupled scalar field and tied to the rest of the physics, as a way to capture the engineering design topology. It provides a natural setting for a range of complex phenomena when performing topology optimization together with the finite element and related methods.

For soft matter physics, two particle approaches are followed: the DPD method and the digital lattice Boltzmann method. We are exploring ways to tie them together with conventional (continuum) methods, so as to achieve efficient multiscaling simulators, and we are embedding them in a topology optimization cycle, so as to bring these methods also into the design tool domain.

Acknowledgments

The authors wish to thank M. Geier, D. Kauzlaric, and L. Pastewka for their support in preparing the figures.

Biographies

Dr. Jan G. Korvink obtained his M.Sc. in computational mechanics from the University of Cape Town in 1987, and his Ph.D. in applied computer science from the ETH Zurich in 1993. After his graduate studies, he joined the Physical Electronics Laboratory of the ETH Zurich, where he established and led the MEMS Modelling Group. This was followed by a move in 1997 to the Albert Ludwig University in Freiburg, Germany, where he holds a Chair position in microsystem technology and runs the Laboratory for Microsystem Simulation. He has written more that 180 journal and conference papers in the area of microsystem technology, and co-edits the review journal *Applied Micro and Nanosystems,* see http://www.wiley-vch.de/books/info/amn. His research interests cover the modelling and simulation and low cost fabrication of microsystems.

Andreas Greiner is a senior scientist and head of the group of physical modeling at the laboratory for Simulation of the Department of Microsystems Engineering (IMTEK), University of Freiburg, Germany. He graduated in physics from the University of Stuttgart, Germany, where he received his PhD in Theoretical Physics in 1992 and where he was concerned with the simulation of carrier transport in semiconductor lasers until 1995. From June 1995 on he held several grants as a research fellow at the University of Bologna, the University of Lecce and the CNRS research center for Microoptoelectronics in Montpellier. His research interest is the multiscale modeling and simulation of micro- and nanosystems as well as process simulation.

Zhenyu Liu obtained his PhD in mechanical engineering from the Dalian University of Technology, China in 2000. From 2001 to 2002, he worked as postdoc in the Department of Microsystems Engineering (IMTEK), University of Freiburg, Germany. From 2003 he joined IMTEK as a senior scientist and group leader at the laboratory for Simulation. His research interests cover the simulation and optimization of devices in MEMS.

1.19 Systematic Synthesis Methods

G. K. Ananthasuresh, Mechanical Engineering, Indian Institute of Science, Bangalore, India

Glossary

Analysis Evaluation of a given entity or system using physics-based modeling.

Calculus of variations A branch of mathematics dealing with minimization of functionals, which are mappings from a function space to real or complex number field.

Compliant mechanisms Mechanisms that use elastic deformation to transform or transmit given motion, forces, or energy.

Design variable A variable whose value is determined by the optimization algorithm to minimize the objective function in an optimal design problem.

Functional Functional is a mapping from a function space to real or complex number field.

Governing equation A mathematical equation, usually a partial differential equation, that described a physical law that governs the behavior of a system.

Inverse problem A problem in which the results are known and we need to find the data or model parameters that would give those results.

Karush–Kuhn–Tucker conditions The first-order necessary conditions for the constrained minimum of an optimization problem involving an objective function and equality and inequality constraints.

Parametric optimization An optimization problem in which a few parameters of a model, a system, or an entity are used as the design variables.

Shape optimization A structural optimization problem where the design variables determine the shape of the structure.
Simulation Modeling and solving for the behavior of a system or an entity using physics-based mathematical modeling.
State variable A variable that describes the state of a system. For example, the displacement of each point in an elastically deforming system is a state variable.
Stiffness measure A metric to quantify the stiffness of an elastic structure.
Strain energy Energy stored in a deformable body when it is subjected to forces.
Synthesis Creating an entity or a system for desired behavior.
Topology optimization A structural optimization problem where the design variables constitute a space of possible topologies of the structure.

1.19.1 Introduction

We begin this chapter by explaining how the term synthesis is interpreted here. This is followed by a brief discussion of the issues involved in the systematic synthesis of microsystems and their components.

1.19.1.1 What Is Synthesis?

The integration of different types of miniaturized components into a single system – sometimes as a single chip and sometimes in a package – is one of the key attributes of microsystems. The coming together of numerous entities of a wide variety at a close proximity in the micron scale ushers in new opportunities as well as challenging problems in simulation and design. The simulation of microsystems, owing to focused research and development efforts in the last decade of the 20th century, is well established today. There are quite a few new software packages that are exclusively devoted to this task and several other older ones that incorporated this as a new module. The number of research papers that deal with simulation of microsystems is rapidly growing. More importantly, most of today's papers in this field include some discussion on modeling and simulation unlike those in the 1980s and 1990s. The design of microsystems is less developed in comparison. Since the terms simulation and design are often misinterpreted – not only in the field of microsystems but also in others – some clarification is pertinent at the outset. One of the unambiguous ways to interpret these is to use their equivalent terms analysis and synthesis, respectively.

Analysis is an evaluation of something that is already there or is conceived anew. We use well-known laws, principles, and phenomenological models that govern the behavior of different phenomena, pose them as mathematical equations, and finally solve them either analytically or numerically. Thus, analysis or simulation is an alternative to experimenting with an actual entity. It of course helps in design but simulation is not the design in its entirety. Synthesis is the crux of design. Synthesis is the creation of something that is not already there. When it is conceived as a creative flash by an individual, it should be assumed that the process of synthesis took place in one's mind. The same is true when a new design is put forth based on the previous experience of an individual. In both the cases, simulation is very useful to check how well a newly conceived design performs before making its prototype. Most of the features of the existing microsystem software help immensely in this respect. They also provide the feedback or the insight to change the design to improve it. Perhaps this is the reason for the confusion between the terms simulation and design or their analogs, analysis and synthesis. Just as analysis can be systematically done using mathematical models of various phenomena, synthesis too can be done systematically using the same models. But the manner in which the problem is posed and the analytical or numerical methods that help solve it are significantly different for analysis and synthesis.

Synthesis can be considered as the reverse of analysis. While analysis (i.e., simulation) helps determine the resolution of the angular rate of a particular embodiment of a micromachined gyroscope, synthesis aims at something different: what systematic procedure or a direct algorithm, as opposed to a trial-and-error approach, helps determine the overall configuration and its parameters, dimensions, and materials that give the resolution that a designer wants? Systematic synthesis procedures alleviate or completely remove the tedium of repeated and incrementally improved designs that follow the trial-and-error approach. An additional advantage is that they

may also lead to designs that would otherwise not come about from intuition, prior experience, or creativity of human designers.

1.19.1.2 Significance, Opportunities, and Challenges

It is useful to understand the differences between synthesis-based and purely analysis-based approaches to design from a mathematical viewpoint. Since most physical, chemical, or biological phenomena involved in microsystems are governed by differential equations, let us consider a differential equation – an ordinary differential equation – to keep things simple and clear:

$$D(u(x), v(x)) + cu(x)v(x) = 0 \qquad [1]$$

where D is a differential operator, $u(x)$ and $v(x)$ are some functions of the independent variable x, and c is a constant. Let $u(x)$ denote the function that determines the design, and let $v(x)$ be the state variable on which a certain response of the system directly depends. The response is the quantity that a designer wants to optimize or have at a desired value. In analysis, eqn [1] is solved for $v(x)$ when $u(x)$ (the design) is known. This is the forward problem. But it may not be straightforward to solve it. Hence, in each physical or chemical domain, there are well-developed analytical and computational methods to solve the corresponding governing differential equation. In microsystems, there is an additional interesting feature that several differential equations are coupled together because the phenomena involved in them are physically or chemically coupled. Much of the computer-aided design (CAD) software that exists for microsystems today addresses this need: how can one efficiently determine the response of a microsystem component when the design is known? Since the design is not known, whenever a new task is taken up, the software programs expect the designer to guess a design or initiate one based on prior experience or intuition. With the help of the software, the designer computes the response and tries to adjust the design to match the desired performance by trial and error and using the insight gained from numerical experiments. Arguably, this is a tedious and time-consuming process. Furthermore, there is no guarantee that an optimum design is found.

In the synthesis-based approach, the guesswork would be circumvented or minimized. Here, when the designer knows what is needed (i.e., $v(x)$ is known), eqn [1] is solved for the unknown $u(x)$. Notice that it is simply the inverse problem wherein the roles of design variable ($u(x)$) and the state variable ($v(x)$) are interchanged. It must be noted, however, that the analytical or computational methods to solve this inverse problem are significantly different from those of the forward (analysis) problem. But, if we develop such methods, which we call synthesis methods, there is no need for a trial-and-error approach to design. This makes design computations efficient.

The synthesis-based direct approach to design not only provides computationally efficient means to obtain new designs that work but also reveals valuable insights into the problem. For example, a designer could be advised about what performance is reasonable to expect for the given specifications. That is, the limits of desired performance can be understood *a priori*. An example would help to appreciate this better. Let us consider the simplest elastic system of an axially deforming bar of a given area of cross section $A(x)$ and material's Young's modulus $E(x)$ under an axial load of $p(x)$ (**Figure 1**). Let its displacement under elastic deformation be $w(x)$. If we want to design this bar to be the stiffest (i.e., it deforms the least), $w(x)$ becomes the state variable deciding the desired performance and thus taking up the role of $v(x)$ in eqn [1]. Then, $A(x)$ is the design variable. For this system, the governing differential equation is given by

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(E(x)A(x)\frac{\mathrm{d}w(x)}{\mathrm{d}x}\right) + p(x) = 0 \qquad [2]$$

In which the state and design variables appear differently. This is almost always the case. Hence, the methods to solve the forward and inverse problems are significantly different. Furthermore, in the forward (analysis) problem $A(x)$ is completely known as a function because one would have the

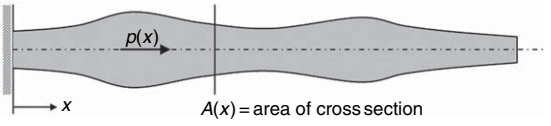

Figure 1 A simple example of an elastically deformable structure to illustrate the difference between analysis and synthesis. Is it sensible to desire displacement to the left if the force is applied to the right everywhere? The answer is no. However, this intuition proves wrong when a 2D elastic body is considered in a similar situation.

cross-section value at all points x. It is not so in the synthesis problem: we only know of or desire a certain level of response or performance or we are interested in its value for only particular values of x.

In this problem, if the stiffness is the desired performance, we know its value as given below:

$$\text{A measure of stiffness} = \int_{\Omega} p(x)w(x)\mathrm{d}\Omega \qquad [3]$$

where the symbol Ω denotes the spatial design domain of the bar that spans between 0 and L. That is, the function $w(x)$ is not known but the quantity that is controlled by it is known or it needs to be optimized for. In other situations, one may want to limit the deflection at the tip to a certain value. For example, one may stipulate in a certain application that it should move to the left (i.e., have a negative value). But if the load $p(x)$ is positive (i.e., pointing to the right) everywhere, it is not possible to achieve that with any physically meaningful $A(x)$. This is rather obvious in this simple problem. However, if this problem is considered in two dimensions (as in a planar sheet of some geometry with forces applied in one direction, say positive x, in the same plane), it is indeed possible to get the displacement in the negative x direction. So, if a trial-and-error approach is used, there is no easy way to know this in complicated design problems unless the designer has the required intuition about the problem. Similarly, one would also not know what value of the measure of stiffness (eqn [3]) is the best that can be achieved. Given that microsystems is a multidisciplinary field, it is often not practical to expect designers to have that intuition in all aspects of the problem. As opposed to this analysis-based iterative approach, when we solve the synthesis problem, often both the problems of the trial-based design iterations can be remedied to a large extent. The interested reader may refer to Ananthasuresh (2003, Section 1.2) for additional examples that explain the difference between analysis and synthesis. Much work is of course needed to gain insight into a given problem. But this will be the work done by synthesis researchers and it will not be a burden on the designers who use synthesis methods.

The above synthesis perspective toward designing the systems governed by differential equations offers unique opportunities in systematically creating designs that are not otherwise conceived by human designers. The designs obtained by the synthesis methods also aid the intuition of the designers. These points are discussed in the chapter after some of the synthesis methods are presented. First, we consider a general overview of the synthesis work done for microsystems.

1.19.1.3 Overview of the Synthesis Work on Microsystems

Many aspects of the synthesis of microsystems components and devices have been addressed in the literature. Among these, the maximum attention has been paid to mechanical synthesis wherein an elastically deforming body is designed. It is well known that most of the mechanical components of microsystems consist of elastically deforming bodies rather than rigid bodies assembled with joints. So, it is often necessary to design the geometrical form of an elastic body – be it a simple beam or a plate or a complicated 3D elastic body – so that it deforms in a desired manner under given mechanical forces. An example of such a problem is shown in **Figure 2**. The method to solve this type of problem first appeared in Ananthasuresh (1994), Ananthasuresh *et al.* (1994), Frecker *et al.* (1997), and Sigmund (1997). Comprehensive literature on this can be found in Ananthasuresh (2003) and Bendsoe and Sigmund (2003).

When forces are not just mechanical, which is often the case in microsystems, this basic method needs to be extended. For electrostatically actuated micromechanical structures, methods have been developed to design the geometry (Ye *et al.* 1998). This problem involves two coupled differential equations in the electrostatic and elastic energy domains. Similar coupled problems exist in electrothermally actuated structures (Mankame and Ananthasuresh

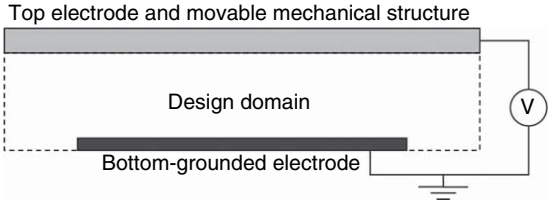

Figure 2 An example of a mechanical synthesis problem. What mechanical connection within the design domain indicated by dashed lines between the bottom grounded electrode and the top electrode would make the top movable electrode displace downward without any or minimal curving? This problem has practical relevance in micromachined polychromators. (Source: Hung E S, Senturia S D 1999 Extending the travel range of analog-tuned electrostatic actuators. *J. Microelectromech. Syst.* **8**, 497.)

2004, Moulton and Ananthasuresh 2001, Sigmund 2001a, b, Yin and Ananthasuresh 2002), magnetically actuated structures (Yoo and Soh 2005), acoustics (Bangtsson *et al.* 2003), and several others. In the case of electrothermally actuated structures, three different domains, viz., electric, thermal, and elastic domains, are coupled together.

When the material under consideration is *active*, it also leads to interesting synthesis problems. For example, with piezoelectric materials, one often wants to amplify the displacement. This can be done by mechanical displacement amplifiers that need to be synthesized for specific needs. This has received much attention in the literature (Ananthasuresh 2003, Silva and Kikuchi 1999, Silva *et al.* 2000). Since microsystems fabrication techniques make it possible to control the geometry at the microscopic level, it is even possible to design material microstructures such that extreme properties can be effectively achieved. These include negative Poisson ratios and negative thermal expansion coefficients as discussed in Sigmund (1994) and Sigmund and Torquato (1996). In fluids too, interesting problems are posed and solved to design flow paths (Klarbring *et al.* 2003). Attempts have also been made to synthesize microfabrication process flows and lithography mask layouts (Ananthasuresh 2003). Several other efforts are under development (Bendsoe and Sigmund 2003). While these focus on the generality of the synthesis procedures, several problem-specific synthesis methods have also been developed for microsystems. Among these, system-level parametric optimization methods (e.g., Mukherjee *et al.* 1998) are worth mentioning. In this chapter, a bird's-eye view of all these methods is presented by highlighting the underlying mathematical issues.

1.19.1.4 Organization of the Chapter

In Section 1.19.2, we first present the synthesis methods in general in addition to classifying them in a certain way. This is followed by a simple example that considers the parametric optimization. And then, the synthesis methods in different energy domains of microsystems are presented. In the subsequent section, geometric aspects of mask layouts and process synthesis are discussed. Closing remarks summarize the chapter and note opportunities and challenges for further work in this area.

1.19.2 Methods for Synthesis

General methods for synthesis are discussed in brief. They apply not only to microsystems synthesis problems but also to many other problems. We will also discuss how one can look at the synthesis problems in microsystems in a hierarchical way.

1.19.2.1 Direct vs. Indirect Synthesis

Referring back to eqn [1], in a direct synthesis method, when the desired response function is given (i.e., $v(x)$ is known), the differential equation is solved for the unknown function $u(x)$, the design. This direct method is often not possible for most differential equations that govern different physical and chemical phenomena. There are two aspects to it. First, we need to be concerned about the well-posedness of the problem and then the existence and uniqueness of the solution. The question of well-posedness arises because the desired response function might not satisfy the particular features of the solution of the forward (analysis) problem. The existence of a solution is not guaranteed because a given (or desired) response function may be physically impossible to achieve.

In some cases, it may be important to know if the solution is unique. If it is not, additional requirements to choose the best one need to be imposed. These issues are treated extensively in the inverse problems in literature wherein methods are developed to directly address the synthesis problem. On the other hand, in indirect synthesis, optimization methods are often used.

In optimization methods, we try to solve the problem to best meet the needs with respect to the desired response. For this, we need to formulate an optimization problem with an objective function, design variables and parameters, and constraints. The constraints relate to the second aspect of why direct methods of synthesis are not possible (or practically infeasible) for most problems. This is because there usually are limited resources – material, size and space constraints, manufacturability limitations, etc. – to achieve a desired response. So, even if a direct method of synthesis where the inverse differential equation can be solved is used, the constraints make the resulting solution unusable. So, the synthesis methods developed for microsystems rely on optimization theory and methods. These methods are general enough to consider microsystems synthesis at different levels of abstraction as explained in the next section.

1.19.2.2 Synthesis at Different Levels of Abstraction

Microsystems, as their name implies, are integrated systems composed of different subsystems and components as shown in **Figure 3**. A system such as a micromachined diagnostic system on a chip consists of several devices as subsystems including those for plumbing, sensing, signal conditioning and processing, digital output. Each of these devices consists of several components. For example, plumbing requires pumps, valves, fluidic channels, reservoirs, mixers, etc. The behavior of each of these is governed by different physical phenomena depending on the actuation method adopted. To practically realize each of these, there is a need for a fabrication process and a set of masks after the geometry and material are selected for each component through physical level simulations or design. So, synthesis (or for that matter, analysis too) can be viewed at different levels of abstraction.

The highest level is the system level. Here, as explained in Senturia (2001), one considers the whole system with reduced-order models for the individual subsystems. Reduced-order models are necessary to make the system-level representation simple and computationally manageable. Since microsystems consist of movable solids and liquids, they are essentially dynamic systems. So, the governing equations are often first- or second-order ordinary differential equations with time as the independent variable. Each subsystem is then represented as a simple mass-spring-damper model or its equivalent in nonmechanical domains. The parameters of the subsystems' reduced-order model depend on the detailed geometry and the properties of the material that comprise the subsystems. But we do not consider those details at this highest level of abstraction. So, synthesis at this level entails determination of the parameters of the reduced-order models based on the design requirements. The desired responses are also at the highest level of abstraction. For example, in the case of a pressure sensor, one would consider the range, sensitivity, and resolution of the sensor and the effects of changing environmental conditions on the sensor rather than the low-level responses such as the displacement of the diaphragm due to a certain value of the pressure.

The system architecture is also an important component of synthesis at this level. In the case of microsystems, it assumes great significance because many types of subsystems are tightly integrated. There is also the crucial question of integrating the mechanical and electronic elements at the chip level, package level, or not at all. Packaging considerations are also important. It is not easy to treat these issues formally at this point with regard to both analysis and synthesis. So, synthesizing the system architecture is often left to the designer's discretion, prior knowledge, and experience. When formal methods are developed for this, synthesis methods will surely follow. It is important to note, however, that system-level synthesis is certainly possible once the system architecture is decided. This is discussed further in Sections 1.19.2.3 and 1.19.3. The important point to note is that there exist two synthesis problems at the system level as shown in **Figure 4**. The first is to synthesize the architecture of the system, which at this time is largely dependent on designer's preferences, experience, intuition, overall fabrication and packaging considerations, marketing related needs, etc. After the architecture is decided and individual devices are identified, the second synthesis problem comes to the fore. The synthesis at this stage can be addressed by considering a dynamic model of the system with different subsystems (devices) represented as reduced-order models. As explained above, the characteristics of the reduced-order models need to be determined to meet the overall requirements regarding the performance of the system.

If once again the example of the micromachined diagnostic system on a chip is taken, a designer has

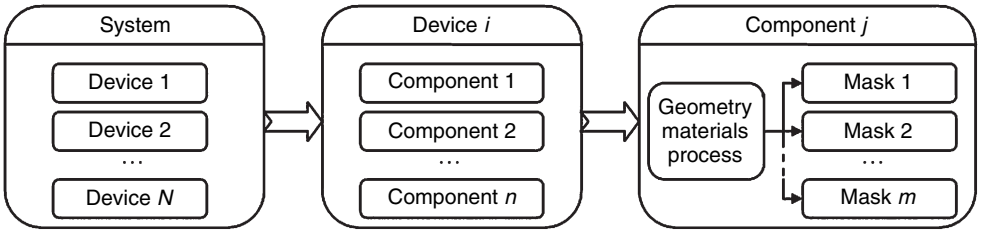

Figure 3 Hierarchical view of a microsystem.

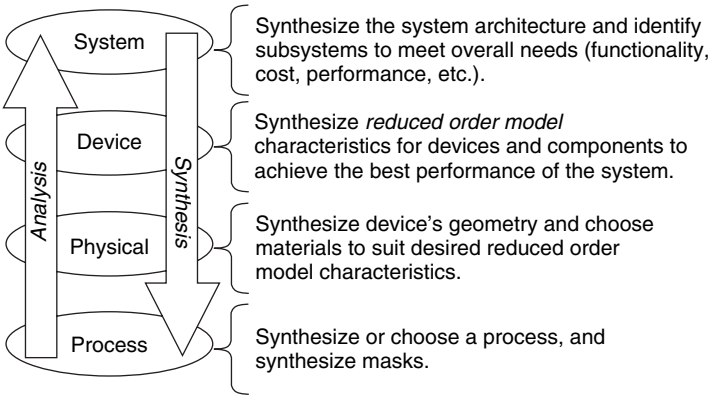

Figure 4 Synthesis problems at different levels of abstraction for a microsystem.

to first decide what devices to use and how each device would need to work. Several questions arise: How is the specimen collected? How is it pumped? How is it mixed with a reagent? What is the sensing mechanism? What are the requirements on the electronics that condition and process the sensor signal and create a quantifiable output, etc? The physical mechanisms of each of the devices that would address such needs require further consideration. Once those questions are answered, reduced-order models should be selected. If the example of a pump is taken, its configuration is to be decided first: should it be a diaphragm-based pump or something else? And then, a model and its parameters need to be identified to quantify flow rate, range and resolution of delivered volume, power consumed, etc. When a model is constructed for all the devices in this manner, synthesis can be done at the system level.

The first two levels of synthesis (see **Figure 4**) are quite difficult; systematic and automated procedures are yet to be developed for any general system. However, much progress has been made at the next two levels of abstraction. Synthesis at the third level (called physical level in **Figure 4**) has received considerable attention. Much of this chapter is concerned with this synthesis (see Sections 1.19.4.1–1.19.4.6). Here, one needs to determine the geometry and materials for each component in view of the requirements decided at the system level and a set of (usually) partial differential equations that govern the phenomena involved. After this, at the fourth level, one needs to synthesize (or choose) a process and lithography mask layouts. This level has received some attention, which is described in Section 1.19.5.

1.19.2.3 Synthesis Aided by Parametric Optimization

Optimization, as mentioned in Section 1.19.2.1, is a useful tool for synthesis. It should be noted, however, that whenever it is possible to solve the synthesis equations directly it should be done. If that is not possible, which is often the case, an optimization problem needs to be formulated. This should try to solve the synthesis equations indirectly in a least-squares sense. That is, the sum of the squares of the differences between desired and designed (or rather to be designed) quantities needs to be minimized. This minimization will be limited by resources and practical considerations. They become the constraints in the optimization problem. Another important aspect of formulating the optimization problem is to identify the design variables. This step is often called design parameterization in multidisciplinary design optimization literature. This can be done in several ways. Three methods are described here. The first is called the parametric optimization.

In parametric optimization, the component that is to be synthesized is almost determined, with the exception of a few parameters. These can be dimensions of certain parts of the components such as widths of beams, thicknesses of the diaphragms, location of supports. While it may appear simple – and it is simple as the variables involved are few – the problems posed in this manner may not always be well posed. That is, the optimization problem may not be smooth and it may not have well-characterized minima. But it is often done because the application of numerical optimization algorithms does give an improved solution. Such an improved design is often interpreted as equivalent to optimized design. For difficult problems,

this often may be the only viable remedy. For example, in an electrostatic comb actuator, if one decides to vary the number of interdigitated comb fingers, the number of beams in the suspension, and the number of fixed electrodes as design variables in the optimization problem, improved solutions are indeed obtained. This aspect has been extensively investigated (Iyer *et al.* 1998, Mukherjee *et al.* 1998, 1999) and summarized in Ananthasuresh (2003, Chap. 10).

A number of optimization algorithms are available for solving parametric optimization problems. Any standard text on optimization (e.g., Papalambros and Wilde 2000, Rao 2000) may be consulted. There are also several software implementations of the optimization algorithms. In parametric optimization, there may be continuous as well as discrete variables. This calls for special optimization techniques that can deal with this. Both deterministic and probabilistic methods may be used. Among the probabilistic methods, the use of genetic algorithms (Goldberg 1989) is on the rise. Computation time for synthesis is often a concern when probabilistic algorithms are used. It is also necessary to ensure that the solution given by an algorithm is indeed a minimum as characterized by Karush–Kuhn–Tucker conditions (Papalambros and Wilde 2000) for a constrained minimum.

1.19.2.4 Shape Optimization

Shape optimization is more general than parametric optimization. Here, the shapes of the components are varied by identifying suitable design variables. The shape of a component does play a significant role in many problems. For example, Ye and Mukherjee (1999) and Ye *et al.* (1998) have shown that by changing the shape of the comb fingers in an electrostatic comb drive actuator, different force–displacement characteristics can be obtained. The shapes of flow channels are of importance in microfluidic systems. The shapes of different elastically deforming parts are also crucial for micromachined grippers and other mechanical devices (e.g., Xu and Ananthasuresh 2003). The shapes of holes within a continuum matter in optimizing the dynamic performance of a component where the elastic and inertial effects compete with each other, as is the case with micromachined resonators.

The design parameterization for shape optimization can be done in many different ways. Splines, Bezier curves, and other smooth interpolant methods for shape optimization in terms of a few continuous variables are often good choices (Xu and Ananthasuresh 2003). Varying the coordinates of nodes in a finite element model is also done (Hetrick and Kota 1999) but it has its drawbacks as explained in Achtziger (2006). It must be noted that shape optimization assumes that the topology of the geometry of a component is already known. There are several methods for the optimization of even the topology. These are explained in the next subsection.

1.19.2.5 Topology Optimization

Microsystems components are multilayered structures made of multiple materials. Choosing the materials and determining the geometry of the components are the main tasks of synthesis at the physical level. As explained above, it can be done by parametric or shape optimization. But there is the fundamental task of choosing the most suitable topology. Consider a simple rectangular domain shown in **Figure 5**. The design domain is the space in which a component has to fit. Let there be three regions of interest at the boundaries of the design domain as indicated by R_1, R_2, and R_3. In structural situations, they will be the points of application of force, sensing ports, or mechanical anchors. In fluidic situations, they will be the entry and exit points for the fluid. In designing photonic band gap material structures, they can be the terminals of wave guides. What is the proper connectivity of these regions of interest? Clearly, as shown in **Figure 5(a)**, there are many possible ways to connect the regions even with a single intermediate point. There can be more than three such regions in different problems. More intermediate points would give a richer variety of

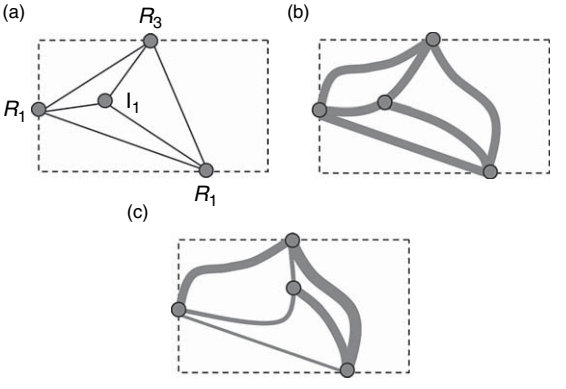

Figure 5 Topology, shape, and parametric optimization problems in schematic form. (a) Topology possibilities with one intermediate point; (b) a possible shape for the full topology; and (c) a final geometric form with different sizes including the shifting of the intermediate point.

topologies than what is shown in Figure 5. Then, the number of connections would increase dramatically and it would be impractical to explore all. This is especially true in view of the possibility that the shapes of these connections need to be explored as well. Furthermore, sizes (or parameters) of different segments of the connections also need to be determined. Thus, there are three levels of optimization. As shown in Figure 5(a)–5(c), there is topology optimization that determines the optimal connectivity, shape optimization that determines the shapes of individual connections, and then the size optimization that determines the sizes or the parameters. As the word topology entails, topology optimization also determines the number of holes in the design domain. It is a way of distributing a given amount of material within a given design domain.

Topology optimization is a powerful technique for determining the optimal distribution of material. It is a rapidly growing field with many applications (Bendsoe and Sigmund 2003). Not only the topologies but also the materials of different connections or parts of connections can be determined using topology optimization. In this method, the key idea is to parameterize the design domain so that general topological variations can be considered within the ambit of continuous optimization. Let us consider a design domain that is discretized into a finite element model – which is often the case as the phenomena governing a microsystem are modeled by partial differential equations for which the finite element analysis is arguably the most efficient numerical solution technique. Then, if we have material everywhere in the design domain, there is nothing to optimize. But then, there will always be a limited amount of material that is to be distributed in a larger domain than the material can fill. So, all elements in the finite element model cannot be filled with material because much material is not available. It then becomes a question of which ones to fill. If we denote the material state of each element by 0 (for empty) and 1 (for full), then we get a binary optimization problem. Because of the combinatorial explosion the binary parameterization gives rise to a large-scale – often computationally intractable – discrete optimization problem. On the other hand, if this material state is smoothly varied between 0 and 1, it gives rise to a continuous optimization problem. Gradient-based methods that solve such a problem are well developed and have been applied to topology optimization problems involving microsystems components. The details of topology optimization are best explained with specific examples in Section 1.19.4. We end this section by giving some general details of an optimal synthesis problem for topology optimization.

1.19.2.6 Optimal Synthesis Problem Statement

The optimal synthesis problem for topology optimization, like any other optimization problem, consists of the following essential features:

$$\begin{aligned} &\underset{d}{\text{Minimize}} \quad f(d, \mathbf{u}, \mathbf{p}) \\ &\text{Subject to} \\ &\qquad \text{Governing equations of static or dynamic equilibrium} \\ &\qquad \text{Resource constraints} \\ &\qquad \text{Performance constraints} \\ &\qquad \text{Practical constraints} \\ &\qquad \text{Bounds on the design variables: } d_l \le d \le d_u \end{aligned} \tag{4}$$

Here f is the objective function that needs to be minimized. When written analytically prior to finite element discretization of the model, it will be a functional for topology optimization problems. For shape and size optimization problems, it is most often simply a function of a finite number of design variables arranged in the form of a column vector $\mathbf{d}$. For topology optimization, the design variable $d(\mathbf{x})$ is a continuous spatial function defined at every point $\mathbf{x}$ in the design domain. This is the reason for the objective function being a functional rather than a function. The functional is most often in the form of an integral in terms of three variables indicated in eqn [4]: design variable d, state variable(s) $\mathbf{u}$, and some parameters $\mathbf{p}$. The number of state variables depends on the number of physical phenomena involved in the problem. In microsystems, as is well known, more than one phenomenon are involved. Thus, there will be more than one state variables. In a mechanical problem of designing structures and compliant (elastic) mechanisms (Ananthasuresh and Kota 1995, Howell 2001), the state variable can be the displacement, the stress, or the strain. These have to obey the static or dynamic equilibrium constraints. If the electrostatics problem is considered, charge and voltage will be the state variables. In a thermal problem, heat flux and temperature are the state variables. For each state variable, there must be a corresponding governing equation. These governing equations are included in the

optimization problem statement because the design variables directly influence the state variables, which in turn influence the objective function and the constraints. The parameters **p** are sometimes what could be the design variables for optimization and sometimes fixed constants that cannot be changed by the designer.

The resource constraints usually refer to the amount of material or space available. Performance constraints include all considerations that are important for a problem, but they are not included in the objective function. For example, in a microactuator design problem, if the objective is to maximize the stroke then one may include performance constraints on delivered force, power consumed, resolution in stroke and force, and so on. Practical constraints include manufacturability concerns and economical considerations. These are more difficult than others. One way to include them is discussed in Section 1.19.5.3. Finally, there will be lower and upper bounds on the design variables, as indicated by d_l and d_u. This problem, once posed properly, can be solved in many ways.

All numerical optimization methods need an initial guess using numerical optimization algorithms which find the optimum iteratively. This process can be loosely compared with the analysis-based iterations that a designer would do. But there is a significant difference that iterations in systematic optimal synthesis are directed by the gradient information at that instant. In trial-and-error-based iteration, it is driven by the designer's understanding of the problem.

The general problem statement shown in eqn [4] will be made specific for a few types of optimal microsystems synthesis problems discussed in Section 1.19.4. Before that, parametric optimization at the system level is described in the next section.

1.19.3 System-Level Synthesis

As noted earlier in the chapter, for most microsystems, there are two synthesis problems at the system level. The first synthesis problem of determining the system architecture is not amenable for systematic synthesis at present. The second synthesis problem of determining the characteristics of the reduced-order models of the subsystems is very possible. Here, it is illustrated with an example.

1.19.3.1 Accelerometer Example

Let us consider one of the most successful microsystems products: an accelerometer. Assume that a designer has decided to use capacitance-based sensing and feedback stabilization technique. With the performance requirements (including resolution and range of the accelerometer) in mind, if the designer wants to see whether to integrate the mechanical and electronics at the chip-level or package-level, it will be beneficial to use a schematic such as the one shown in **Figure 6**. The same schematic is helpful for system-level synthesis too. **Figure 6** shows different subsystems: mechanical subsystem consisting of an inertial mass, a suspension to hold and guide the mass, electrostatic sensing comb array, electrostatic comb array for applying the feedback voltage, damping model, etc.; electronic circuits for capacitance extraction; PID controller; and feedback voltage generation. In order to be realistic, the schematic also includes mechanical and circuit noise sources. In order to quantify the different blocks, we need a reduced-order model or an equivalent electrical circuit for all the subsystems. Once they are formulated, the performance of the system can be simulated. **Figure 7** shows a Simulink (www.mathworks.com) model of this system.

The Simulink model shows the mechanical subsystem using three parameters **K**, **M**, and **D**, which indicate the stiffness, inertia, and damping characteristics. These would be derived from the eigenmode analysis of the mechanical structure including the inertial mass, the suspension, and combs. These appear as gains in the block diagram. Only a few modes in the relevant range of frequencies are included here. This reduced-order model is based on eigenmode shapes (Ananthasuresh *et al.* 1996). The electronic circuits are also represented in **Figure 7** in the Simulink block diagram format. The model characteristics are adjustable in this model. For example, the gains in the PID controller can be tuned until the desired resolution is obtained

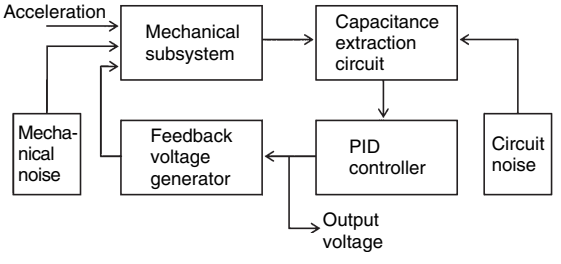

Figure 6 Block diagram of the system-level view of a feedback-stabilized micromachined accelerometer.

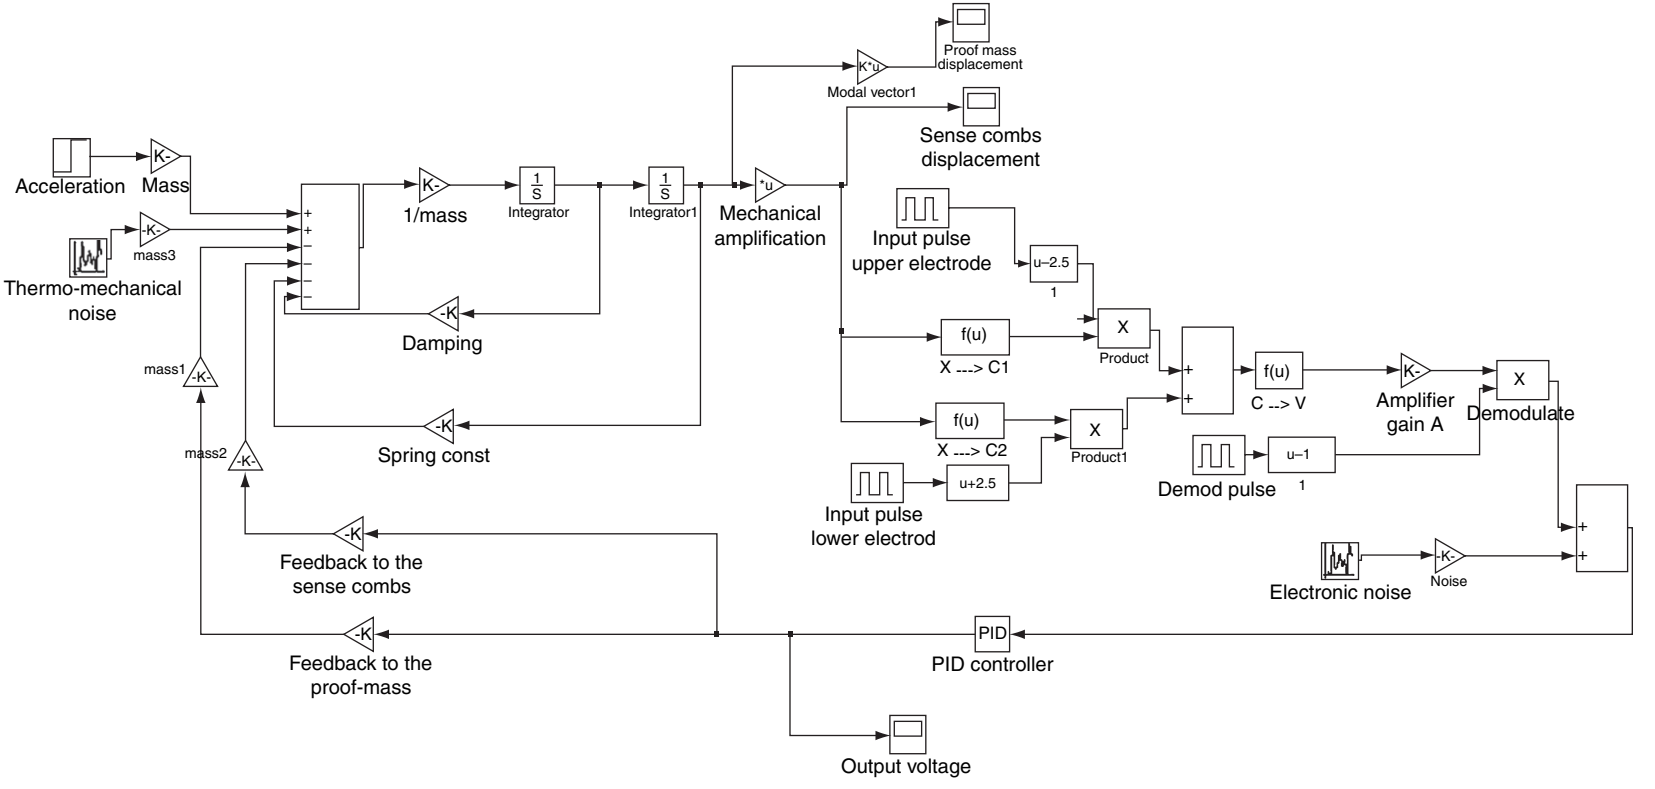

Figure 7 Simulink representation of the block diagram in **Figure 6**.

in the acceleration that is to be sensed. When this process is automated by posing it as a constrained optimization problem, it paves the way for systematic parametric optimal synthesis. The optimization procedure will determine all the parameters in the reduced-order models to meet the desired performance and other constraints.

A slightly different approach is sometimes followed wherein commonly used elements of microsystems are saved in a library. The designer can pick different instances of those elements from the library to create a system such as the one shown in **Figures 6** and **7**. The characteristics of the instantiated elements are adjusted and the system's response is assessed. This is iterated manually to obtain improved design. This approach is described in Ananthasuresh (2003, Chap. 10), Iyer *et al.* (1998), and Mukherjee *et al.* (1999). Some commercial microsystem design software programs follow this approach.

After the subsystems are synthesized (using optimization or not), the next step is to obtain the geometry of individual components that make the subsystems. For example, what physical shape of the inertial mass, suspension, and combs will give the finalized stiffness, inertia, and damping values in the system-level model? This task is described next for a few types of microsystems.

1.19.4 Synthesis of Components of Microsystems

Until now, most of the successful and well-characterized microsystems products consist of simple mechanical structural elements, viz., beams, plates, and membranes often arranged in topologically simple configurations. However, there are instances when simple topologies conceived intuitively are not adequate to meet the specifications. This is especially true when multiple physical phenomena are involved. We shall see how optimal topology synthesis can help in those situations.

1.19.4.1 Mechanical Structures and Transmissions

Movable mechanical structures are the crucial components of microsystems. They help distinguish microsystems chips from purely microelectronic integrated circuit chips. The mechanical components can be broadly classified into two groups based on whether they are intended to be movable or simply bear the loads without significant deformation. The former class, which encompasses most of the microsystems components, can be further grouped in two ways: one in which jointed rigid bodies are constrained to move in a certain way because of joints such as hinges and sliders and the other where elastic deformation of flexible bodies gives the intended motion. Systematic topology synthesis techniques are available for both types. The first type is based purely on kinematic approaches. A recent review of the state of the art in this area can be found in Antonsson and Cagan (2001, Chap. 9). The second type includes elastic mechanics. In this case, one or more of the following characteristics may be of interest:

- Stiffness
- Flexibility
- Strength
- Tracing a path or moving in a certain way
- Energy storage and absorption
- Resonance frequency
- Mode shapes
- Transient response

A microsystem designer may be interested in the overall stiffness of a mechanical component or in the stiffness for a portion of a component. In either case, this requirement can be posed as an objective function. A quantifiable criterion in this case is the strain energy stored in the elastically deformed structure. The lower the strain energy, the stiffer the structure. Hence, for maximizing stiffness, the strain energy should be minimized. The strain energy, SE, of an elastic body is given by the following equation:

$$\mathrm{SE} = \int_{\Omega} \frac{1}{2} \boldsymbol{\varepsilon}^{\mathrm{T}} \mathbf{D} \boldsymbol{\varepsilon} \, \mathrm{d}\Omega \qquad [5]$$

where $\boldsymbol{\varepsilon} = \left\{ \varepsilon_{xx} \, \varepsilon_{yy} \, \varepsilon_{zz} \, \varepsilon_{xy} \, \varepsilon_{yz} \, \varepsilon_{zx} \right\}^{\mathrm{T}}$ is the linear strain with

$$\varepsilon_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial j} + \frac{\partial u_j}{\partial i} \right)$$

wherein the labels i and j take on x, y, and z, and $\mathbf{u} = \left\{ u_x \, u_y \, u_z \right\}^{\mathrm{T}}$ is the displacement vector. The design domain occupied by the elastic body is denoted by Ω. The symbol $\mathbf{D}$ denotes the constitutive material property relationship, which relates stress and strain. As implied in eqn [4], the objective function depends on the state variable $\mathbf{u}$ and the

design variable **D**. In order to see how the design variable appears in **D**, it is necessary to consider how topology optimization techniques continuously parameterize the design space.

In a given problem, any point in the design domain is a potential point to be occupied by the material. Let $\rho(\mathbf{x})$ be the function that decides whether the point located at $\mathbf{x}$ (in some chosen coordinate system) is occupied by the material. Let $\rho(\mathbf{x})$ take one of the two values: 1 or 0. If $\rho(\mathbf{x})$ has a value of 1 at $\mathbf{x}$ then we say that there is material at that point, and if it has a value of 0, then there is no material. The binary function $\rho(\mathbf{x})$ thus becomes the optimization variable. An optimization algorithm decides its value at each point so that an objective is minimized subject to some constraints. But a binary function is not well suited for continuous gradient-based numerical optimization. So, it is relaxed to a continuous function $\rho(\mathbf{x})$, which is bounded by 0 and 1 from below and above, respectively. As an astute reader will immediately realize, in the optimized solution, this leaves scope for some intermediate material state when $\rho(\mathbf{x})$ takes a value between 0 and 1. There are several schemes to prevent this situation of which the power law model (also known as simple isotropic material with penalty – SIMP, Bendsoe and Sigmund 1999) is widely used. In this scheme each material property is multiplied by $\rho(\mathbf{x})^{\eta}$ where η is the penalty parameter, which helps to push $\rho(\mathbf{x})$ to its bounds 0 or 1. Therefore, **D** is given by the following equation

$$\mathbf{D} = \mathbf{D}_0 \rho(\mathbf{x})^{\eta} \qquad [6]$$

where $\mathbf{D}_0$ is the material property with $\rho(\mathbf{x})$ as the design variable.

As per the problem statement in eqn [4], the governing equilibrium equation for the state variable **u** needs to be identified. If the considered problem involves only static loads, the partial differential equation with boundary conditions is given by the following equation:

$$\begin{aligned} &\nabla \cdot (\mathbf{D}\boldsymbol{\varepsilon}) + \mathbf{b} = 0 \quad \text{for}\, \Omega \\ &\sum_j (\mathbf{D}\boldsymbol{\varepsilon})_{ij}\, n_j = t_i \ \text{ on } \partial\Omega_{\mathrm{t}} \ \text{ and } \ \mathbf{u} = \mathbf{u}_0 \ \text{ on } \partial\Omega_{\mathrm{u}} \end{aligned} \qquad [7]$$

where $\mathbf{b} = \left\{ b_x\ b_y\ b_z \right\}^{\mathrm{T}}$ and $\mathbf{t} = \left\{ t_x\ t_y\ t_z \right\}^{\mathrm{T}}$ are body and surface traction forces, respectively, acting in the interior Ω and a portion of the boundary $\partial\Omega_{\mathrm{t}}$, $\mathbf{n} = \left\{ n_x\ n_y\ n_z \right\}^{\mathrm{T}}$ is the unit normal to the boundary, and $\mathbf{u}_0$ is the prescribed displacement over another portion of the boundary $\partial\Omega_{\mathrm{u}}$. The next in the list of constraints in eqn [4] is the resource constraint, which in this case is the upper bound on the volume of material used. This constraint is necessary in this problem because, without it, the entire design domain would be filled with material to give the stiffest topology. In the absence of performance-related and practical constraints, the optimal synthesis problem can be stated as follows:

$$\begin{aligned} &\text{Minimize}_{\ \rho(\mathbf{x})} \quad \mathrm{SE} = \int_{\Omega} \frac{1}{2} \boldsymbol{\varepsilon}^{\mathrm{T}} \mathbf{D} \boldsymbol{\varepsilon}\, \mathrm{d}\Omega \\ &\text{Subject to} \\ &\quad \nabla \cdot (\mathbf{D}\boldsymbol{\varepsilon}) + \mathbf{b} = 0 \,\text{for}\, \Omega \\ &\quad \sum_j (\mathbf{D}\boldsymbol{\varepsilon})_{ij}\, n_j = t_i \,\text{on}\, \partial\Omega_{\mathrm{t}} \,\text{and}\, \mathbf{u} = \mathbf{u}_0 \,\text{on}\, \partial\Omega_{\mathrm{u}} \\ &\quad \int_{\Omega} \rho \mathrm{d}\Omega - V_{\mathrm{u}} \le 0 \\ &\quad 0 \le \rho \le 1 \\ &\text{Given that } \mathbf{D} = \mathbf{D}_0 \rho^{\eta} \end{aligned} \qquad [8]$$

The methods for solving the above calculus of variations problem are discussed in books on structural optimization (Hafka and Gurdal 1989, Weinstock 1974). One popular and computationally attractive method is the optimality criteria method. In this method, the first order necessary condition of the above problem is analytically written in the following form:

$$A + \Lambda B = 0 \qquad [9]$$

where A and B are in terms of the state variable in its equilibrium configuration and is the Lagrange multiplier corresponding to the resource constraint. Then, heuristically (Bendsoe and Kukuchi 1988), iterative update formula for the design variables is set up as follows:

$$\rho^{(k+1)} = \rho^{(k)} + (A + \Lambda B)^{(k)} \qquad [10]$$

where k is the iteration number. As it can be noticed, when the iterative process converges, i.e., $A + \Lambda B = 0$, the necessary condition of eqn [9] is automatically satisfied. In practical implementation, a number of modifications and enhancements need to be made to eqn [10] and some of these are specific to the problem under consideration. Interested readers can refer to the literature (Bendsoe and Kukuchi 1988, Bendsoe and Sigmund 2003, Sigmund 2001c).

Alternatively, mathematical programming methods can be used (Hafka and Gurdal 1989, Papalambros and Wilde 2000, Rao 2000,). For this,

the problem stated in continuous form in eqn [8] can be discretized as follows:

$$\begin{aligned} &\underset{\rho}{\text{Minimize}}\ \frac{1}{2}\mathbf{u}^{\mathrm{T}}\mathbf{K}\mathbf{u}^{\mathrm{T}} \\ &\text{Subject to} \\ &\quad \mathbf{K}\mathbf{u} = \mathbf{f} \\ &\quad \sum_i \rho_i v_i - V_{\mathrm{u}} \le 0 \\ &\quad 0 \le \rho_i \le 1 \end{aligned} \qquad [11]$$

where $\mathbf{u}$ and $\mathbf{f}$ are the displacement and force vectors, respectively, and $\mathbf{K}$ is the stiffness matrix. This problem posed in discrete variables, which are equal in number to the number of elements in the discretized design domain, can be solved using gradient-based numerical optimization algorithms. Details can be found in engineering optimization books (e.g., Papalambros and Wilde 2000, Rao 2000).

Figure 8 shows an example problem and its solution. As can be seen in **Figure 8(a)**, the input required from the designer is minimal: where the structure could be anchored and where the forces are applied. The obtained optimal topology, which shows black for the regions of the domain with $\rho = 1$ and white for regions with $\rho = 0$, is seen in **Figure 8(b)**. Using this, a smooth geometric form shown in **Figure 8(c)** can be obtained. The ability to give the optimal geometry with nominal designer input is the highlight of optimal topology synthesis method.

In compliant mechanisms, which are elastically deformable structures used to transmit force and motion (Ananthasuresh 1994, Ananthasuresh and Kota 1995, Howell 2001), the objective function and constraints are different. For example, if we are interested in maximum displacement at one point in the design domain when force is applied at another point, the objective function becomes the negative of the displacement at the desired point. The volume constraint can be retained as in eqn [8]. A hypothetical example is shown in **Figure 9**. The problem specification is shown in **Figure 9(a)**. This specification is nonintuitive because it is hard for a human designer to imagine what material connectivity would result in the displacement in the desired direction when the force is applied as shown. The optimal topology shown in **Figure 9(b)** provides what is desired but its geometric form is slightly complicated at first sight. However, when it is interpreted as a continuum (filled portion in **Figure 9(c)**), the flexible joint regions and relatively rigid regions can be clearly seen. Then, by imagining rigid bodies joined with hinges at the flexible joint regions, we can see that it is indeed two four-

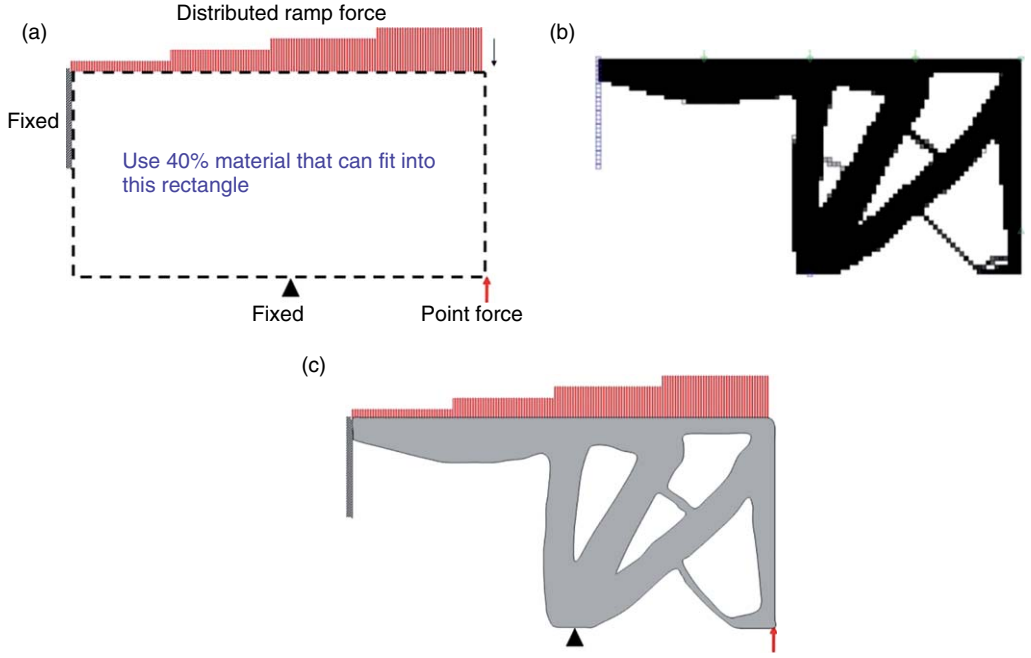

Figure 8 Optimal topology synthesis of the stiffest structure under given static loads for 40% volume constraint. (a) Problem specifications; (b) topology solution; and (c) interpreted final geometric form.

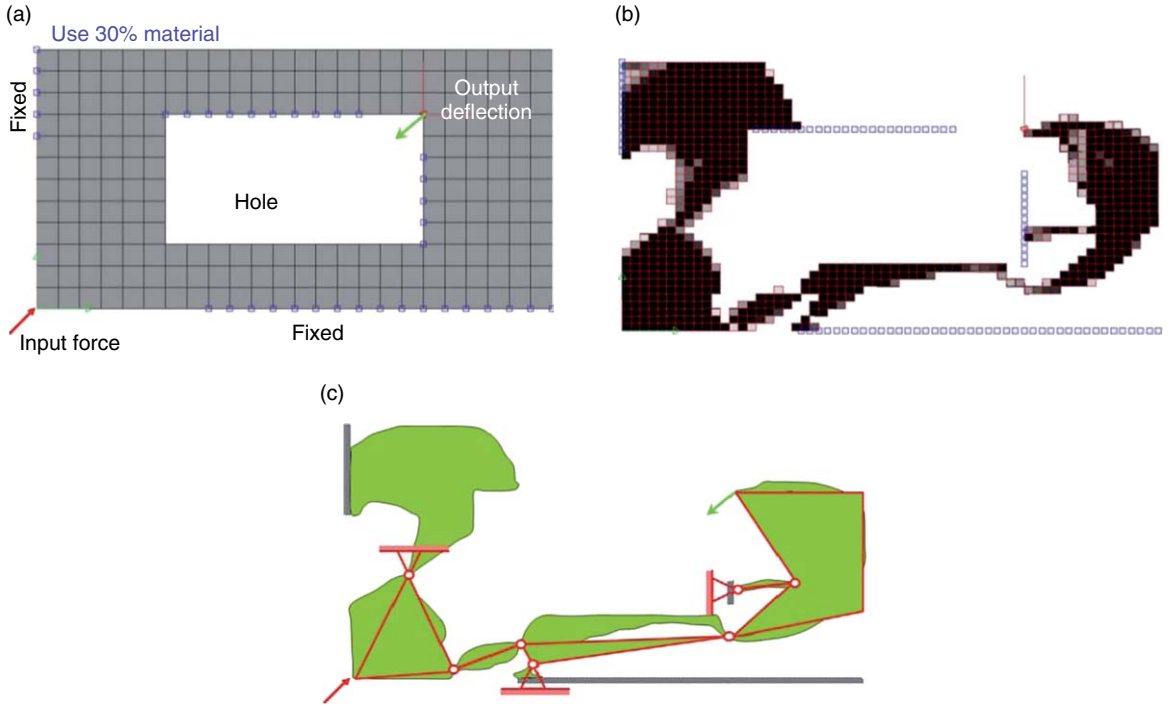

Figure 9 Optimal topology synthesis of a compliant mechanism. (a) Problem specifications; (b) optimal topology; and (c) interpretations of the topology with a smoothened continuum and rigid-body linkage.

bar linkages in tandem. Thus, optimal topology synthesis methodology can aid the designers in suggesting novel topologies that meet the given specifications.

The above two examples were solved using a Fortran program, which includes its own finite element routine and optimization algorithm (PennSyn: www.mecheng.iisc.ernet.in/~suresh/PennSyn). In a similar manner, strength considerations (Duysinx and Bendsoe 1998, Saxena and Ananthasuresh 2001a), prescribed curved paths (Pedersen *et al.* 2001, Saxena and Ananthasuresh 2001b), energy storage to modify the force–deflection characteristic of electrostatic microactuators (Pedersen *et al.* 2006), natural frequencies (Diaz and Kikuchi 1992) and mode shapes (Lai and Ananthasuresh 2002), and transient response (Ma *et al.* 1995) can be optimized. Two microsystem-related examples can be found in Ananthasuresh (2003, Chap. 2).

Arguably, the ability to generate topologies for the mechanical loads has matured much more than the current needs in the microsystems field. As noted earlier, microsystems components are usually very simple beams and diaphragms. But as microdevices get mechanically more complex, we can expect to see the usefulness of the optimal topology synthesis procedures. Next, we consider some coupled domains where similar topology synthesis procedures can be applied.

1.19.4.2 Electrostatically Actuated Structures

Historically, modeling and CAD of microsystems began with the self-consistent solution of coupled electrostatic and elastostatic equations (Senturia *et al.* 1992). In many ways, it is a new problem that arose exclusively in the microscale domain. It is also a practically significant problem as electrostatic actuation is arguably the most popular actuation used in microsystems today. It took significant focused effort to develop computationally efficient numerical techniques and software to solve any general problem of coupled electrostatic and elastostatic simulation problems. The main challenge here was that the two domains are tightly coupled: electrostatic force depends on the geometry of the conductor (or dielectric) parts of the component but the geometry changes under the influence of the electrostatic force. It is best seen with the help of the governing equations of the two domains, as shown in **Figure 10**.

The governing equation for the electrostatics is represented using an integral equation in **Figure 10**.

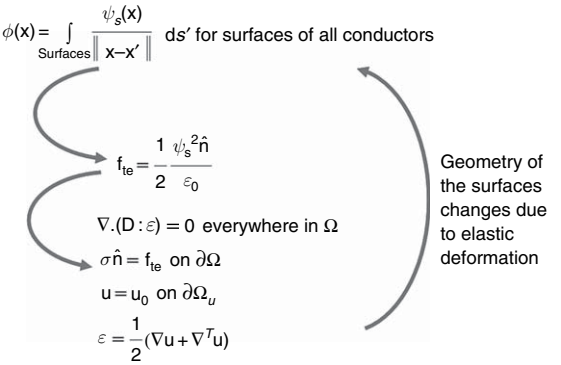

Figure 10 Coupling between electrostatic and elastostatic domains.

Its differential equation form is given by the following equation:

$$\nabla^2 \phi = 0 \qquad [12]$$

where ϕ is the electric potential (i.e., voltage) specified on the surfaces of all the conductors, but it needs to be determined in the intervening medium between the conductors. The surface charge density on all the conductors can then be found using the following expression:

$$\psi_s = \varepsilon_0 \mathbf{n} \cdot \mathbf{E} = -\varepsilon \mathbf{n} \cdot \nabla \phi \qquad [13]$$

where ε_0 is permittivity, $\mathbf{n}$ is the unit surface normal, and $\mathbf{E}$ is the electric field vector. The quantities in the elastostatic equation were explained earlier (see eqn [7]). Since the solution of one governing equation depends on that of the other, the two equations are to be solved simultaneously. Good techniques to do it are now available (e.g., Senturia *et al.* 1997). Now, let us consider the synthesis problem: how is the geometry of the conductors obtained so that they deform as desired when different electric potentials are applied on them?

The notable work in the electrostatic synthesis problem is in Ye *et al.* (1998), and is also described in detail in Ananthasuresh (2003, Chap. 3). This work focused on the shape optimization, in particular, on optimizing the shapes of the interdigitated comb fingers in an electrostatic comb linear actuator. It was shown that the nonlinearity of the stiffness of the suspension of the comb drive can be compensated by curved (rather than the usually straight) comb fingers. Linear, quadratic, and cubic force displacement characteristics were demonstrated.

Interestingly, the topology optimization of this coupled problem had not received attention until recently (Alwan and Ananthasuresh 2006b, Raulli and Maute 2005). An interesting challenge is encountered in doing so because the electrostatic force is a boundary force and the boundaries are not known and will be changing during the process of topology optimization. In Raulli (2006) and Raulli and Maute (2005), a method to track the boundaries was used to impose the forces on the boundaries properly. In Alwan and Ananthasuresh (2006a, b), a novel method that smoothly interpolates the material state from a conduct or to dielectric to void (empty space) was proposed. In this method, a leaky capacitor model and Maxwell's stress tensor were used to represent the surface electrostatic force as a body force (Alwan and Ananthasuresh 2006). This enabled this coupled problem to be cast in the standard form (see eqn [4]) for topology optimization. An example is shown in **Figure 11** for the simplest problem of designing the stiffest structure under electrostatic forces. Here, the bottom electrode was prescribed with a gap above to prevent a short circuit. The mechanical structure's domain along with the location of the mechanical anchor are given. If the structure is too close to the electrode, then there will be a large electrostatic force. On the other hand, if it is too far from the anchoring point, the structure becomes more flexible. So, a trade-off is needed between the two. As shown in **Figure 11**, it takes an arch shape, which is the stiffest for this specification. More work is under way in extending this methodology to other problems including that indicated in **Figure 2**.

1.19.4.3 Electro-thermal-compliant Actuators

The electro-thermal-compliant (ETC) microactuators, as their name implies, are governed by three energy domains: electrical, thermal, and elastic. These actuators, first proposed by Comtois and Bright (1996) and Guckel *et al.* (1992), have been generalized as versatile in-plane actuators in Moulton and Ananthasuresh (2001). The corresponding synthesis problem has been investigated in Mankame and Ananthasuresh (2004), Sigmund (2001a, b), and Yin and Ananthasuresh (2002). Even though it involves three coupled domains, this problem is simpler than the coupled electrostatic–elastostatic synthesis problem. This is because, if the temperature dependence of elastic and thermoelastic properties is neglected, the coupling in this problem is not as strong as it is in the electrostatic case. The coupling involved in this problem is explained below.

Let us consider the statement of topology synthesis problem of ETC actuators as shown in **Figure 12**. The

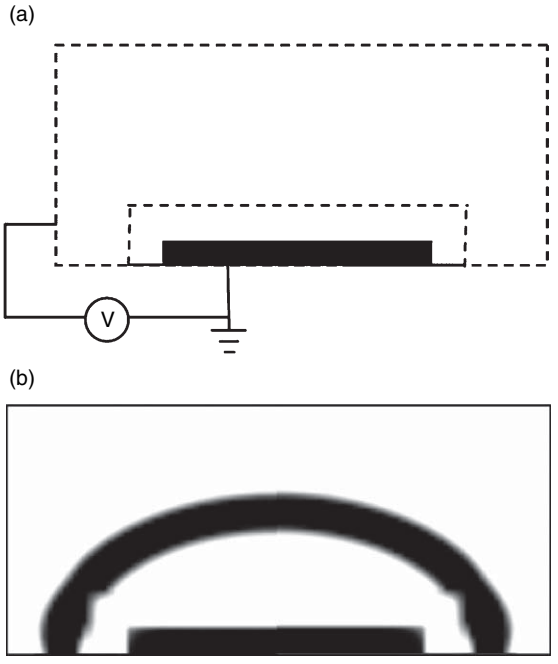

Figure 11 An example of the stiffest structure under electrostatic load. (a) Problem specification; and (b) optimal solution. The objective is to minimize the work done by the electrostatic force because it is equivalent to making the structure the stiffest. The design domain is shown by dashed lines. If the structure is too close to the bottom electrode, the force will be too large. If it is too far from the anchors (and hence from the bottom electrode), it will have a large deformation for a given force. So, the arch is a compromise between the two.

given design domain now has three sets of boundary conditions. First, there is a portion $\partial\Omega_{eg}$, which is electrically grounded, and another $\partial\Omega_{eV}$ where a potential V is applied. Second, there is a portion $\partial\Omega_{tg}$, which is thermally grounded, and a portion $\partial\Omega_{tf}$ where heat flux is specified. The heat flux can be incoming heat or outgoing heat through convection and radiation. Third, mechanical anchoring is done on $\partial\Omega_{mg}$ with external traction force on $\partial\Omega_{mt}$. There is also another portion $\partial\Omega_{md}$ where the displacement is desired in a certain way. The objective of the synthesis problem is to obtain a particular connectivity of the above different regions, perhaps with interior holes, so that upon application of the voltage, the elastic solid deforms to give the desired displacement at $\partial\Omega_{md}$.

For any geometry of the material distribution in Ω of **Figure 12**, first we need to solve the electrical current problem governed by the following equation:

$$\begin{aligned} &\nabla\cdot(k_e\nabla V)=0 \text{ in } \Omega \\ &V=0 \text{ on } \partial\Omega_{eg} \text{ and } V=V_0 \text{ on } \partial\Omega_{eV} \end{aligned} \quad [14]$$

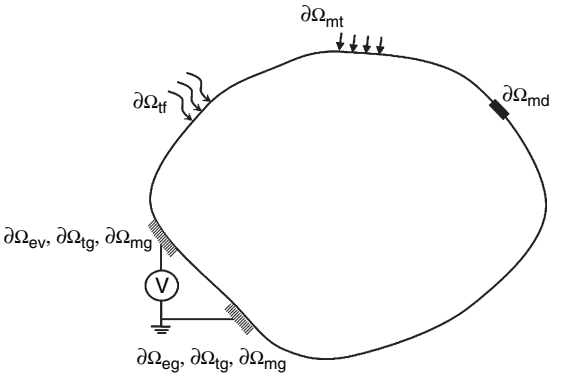

Figure 12 Synthesis problem specification for the electro-thermal-compliant (ETC) microactuator. The synthesis task entails the determination of material connectivity and its geometry within the design domain such that desired output displacement is generated at $\partial\Omega_{md}$ with V applied.

where k_e is the electrical conductivity and voltage V is the state variable. After this equation is solved for V, the Joule heat that is generated goes as a source term in the governing equations of thermal problem as shown below.

$$\begin{aligned} &\nabla\cdot(k_t\nabla T)+\nabla^T k_e\nabla V=0 \text{ in } \Omega \\ &T=T_0 \text{ on } \partial\Omega_{tg} \text{ and } \mathbf{n}\cdot(k_t\nabla T)=f_{nt} \text{ on } \partial\Omega_{tf} \end{aligned} \quad [15]$$

where k_t is the thermal conductivity, $\mathbf{n}$ is the surface normal as usual, f_{nt} is the external heat flux or the temperature-dependent heat flux, which accounts for convection and radiation, and even conduction in some cases, and temperature T is the state variable. Since k_e and k_t can vary significantly with temperature, it is preferable to solve eqns [14] and [15] simultaneously. This is a standard feature in some commercial finite element software programs (e.g., ABAQUS, www.hks.com). Coding this on one's own is also rather straightforward.

After the temperature is known everywhere in the domain, it is included to impose the thermal load as shown below in the governing equations for thermo-elastic static equilibrium

$$\begin{aligned} &\nabla\cdot\boldsymbol{\sigma}=0 \text{ everywhere in } \Omega \\ &\boldsymbol{\sigma}=\mathbf{D}:(\boldsymbol{\varepsilon}-\alpha(T-T_0)\mathbf{I}) \\ &\mathbf{u}=\mathbf{u}_0 \text{ on } \partial\Omega_{md} \\ &\boldsymbol{\varepsilon}=\frac{1}{2}(\nabla\mathbf{u}+\nabla^T\mathbf{u}) \end{aligned} \quad [16]$$

where α is the coefficient of thermal expansion, T_0 is the ambient temperature, and the rest are as defined earlier for the elastostatic equilibrium problem. Eqn

[16] can be solved after eqns [14] and [15] are solved together.

Let the objective of the topology synthesis of ETC microactuators be the maximization of the displacement at a point, which we denote by $u_{\partial\Omega_{md}}$. By using the power law (or SIMP: Solid Isotropic Microstructure with Penalty) design parameterization (see eqn [6]), all material properties can be written in terms of the design variable $\rho(\mathbf{x})$

$$\begin{aligned} k_e &= k_{e0}\rho(\mathbf{x})^\eta \\ k_t &= k_{t0}\rho(\mathbf{x})^\eta \\ \alpha &= \alpha_0\rho(\mathbf{x})^\eta \\ \mathbf{D} &= \mathbf{D}_0\rho(\mathbf{x})^\eta \end{aligned} \quad [17]$$

As before, $\rho(\mathbf{x}) = 1$ indicates the presence of material at $\mathbf{x}$ and $\rho(\mathbf{x}) = 0$ the absence of material at $\mathbf{x}$. The penalty parameter $\rho(\mathbf{x})$ helps to push η to one of its extremes in the optimal solution. Now, following eqn [4], the topology synthesis problem involving the three energy domains can be posed as follows:

$$\begin{aligned} &\underset{\rho(\mathbf{x})}{\text{Minimize}} -u_{\partial\Omega_{md}} \\ &\text{Subject to} \\ &\quad \nabla\cdot(k_e\nabla V) = 0 \text{ in } \Omega \\ &\quad V = 0 \text{ on } \partial\Omega_{eg} \text{ and } V = V_0 \text{ on } \partial\Omega_{eV} \\ &\quad \nabla\cdot(k_t\nabla T) + \nabla^T k_e \nabla V = 0 \text{ in } \Omega \\ &\quad T = T_0 \text{ on } \partial\Omega_{tg} \text{ and } \mathbf{n}\cdot(k_t\nabla T) = f_{nt} \text{ on } \partial\Omega_{tf} \\ &\quad \nabla\cdot\boldsymbol{\sigma} = 0 \text{ everywhere in } \Omega \\ &\quad \boldsymbol{\sigma} = \mathbf{D}:(\boldsymbol{\varepsilon} - \alpha(T - T_0)\mathbf{I}) \\ &\quad \mathbf{u} = \mathbf{u}_0 \text{ on } \partial\Omega_{md} \\ &\quad \boldsymbol{\varepsilon} = \frac{1}{2}\left(\nabla\mathbf{u} + \nabla^T\mathbf{u}\right) \\ &\quad \int_\Omega \rho\, d\Omega - V_u \le 0 \\ &\quad 0 \le \rho \le 1 \\ &\text{Given that } k_e = k_{e0}\rho(\mathbf{x})^\eta;\ k_t = k_{t0}\rho(\mathbf{x})^\eta; \\ &\quad \alpha = \alpha_0\rho(\mathbf{x})^\eta;\ \mathbf{D} = \mathbf{D}_0\rho(\mathbf{x})^\eta \end{aligned} \quad [18]$$

The necessary conditions for the local minimum of this problem can be written and the resulting equations can be analytically simplified to derive an update formula for $\rho(\mathbf{x})$ as in eqn [10]. While this may look intimidating at first sight, the procedure is quite simple if the rules of calculus of variations and ordinary calculus are followed. Interested readers may consult Ananthasuresh (2003), Bendsoe and Sigmund (2003), Hafka and Gurdal (1989), and Weinstock (1974) for details. This procedure can also be performed for more than one material such as silicon and silicon dioxide. An example is shown in **Figure 13** where only thermal heat flux is applied and displacement that is inward into the design domain is desired.

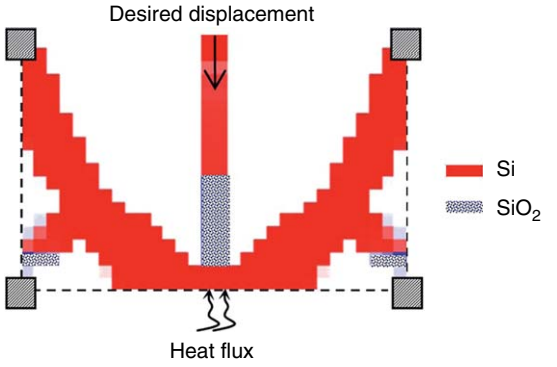

Figure 13 An example of thermoelastic synthesis problem. Here, two materials with different thermal conductivities need to be distributed in a rectangular design domain such that the midpoint of the top edge moves down, which is nonintuitive when heat flux is supplied from the bottom side as shown. The optimal solution achieves this by placing material with low conductivity between the portion that should move down and the portion where heat is supplied. This allows for a small amount of heat to pass and thus decreases the free deflection of the vertical bar in the middle.

ETC microactuators and a three degree-of-freedom planar platform, and a topology-optimized *xy*-microstage can be found in Moulton and Ananthasuresh (2001) and Sigmund (2001a), respectively.

1.19.4.4 Piezoelectric Actuators

Piezoelectric material-based actuators are widely used in micro- and nanopositioners and stages today. Piezoelectric materials provide very small displacements but large forces. So, they need to be combined with mechanical amplification mechanisms. Thus, there is a need for topology synthesis involving piezoactuators. This has been extensively investigated in Ananthasuresh (2003, Chaps. 5 and 6).

In piezoelectric materials, the coupling between the electrical and the elastic fields is inherently present at

the microscopic scale in the material's constitution. When mechanically stressed, these materials generate a net charge through electric polarization; and when an electric field is applied, they develop mechanical strain. Thus, this coupling is different from the ones discussed above in the context of electrostatic and electrothermal with the elastic field. In piezoelectric materials, the stress and strain tensors ($\boldsymbol{\sigma}_{ij}$ and ε_{kl}), and electric field and electric displacement vectors (E_k and D_i) are inherently related as follows:

$$\begin{aligned} \sigma_{ij} &= D_{ijkl}\varepsilon_{kl} - p_{kij}E_k \\ D_i &= p_{ikl}\varepsilon_{kl} + e_{ik}E_k \end{aligned} \qquad [19]$$

where D_{ijkl} is the usual elastic constitutive tensor relating stress and strain, e_{ik} is the dielectric tensor relating electric displacement and the electric field, and p_{kji} is the piezoelectric strain tensor. Based on this, the governing dynamic equilibrium equations in weak variational form under a sinusoidal excitation frequency ω for a body made of a piezoelectric material with a mass density γ can be written as given below (Eer Nisse 1967).

$$\begin{aligned} &\int_{\Omega} \left\{ \left(\varepsilon_{ij} D_{ijkl} \delta\varepsilon_{kl}\right) - \omega^2 \gamma u_i \delta u_i + (\nabla\phi)_i (\delta\varepsilon_{kl} p_{ikl}) \right\} \mathrm{d}\Omega \\ &\quad = \int_{\Omega} b_i \delta u_i \, \mathrm{d}\Omega + \int_{\partial\Omega_t} t_i \delta u_i \, \mathrm{d}\partial\Omega \\ &\int_{\Omega} \left\{ \varepsilon_{ij} p_{kij} (\delta\nabla\phi)_k - (\nabla\phi)_i \, e_{ij} (\delta\nabla\phi)_j \right\} \mathrm{d}\Omega \\ &\quad = \int_{\partial\Omega_d} (D_i n_i) \delta\phi \, \mathrm{d}\partial\Omega \end{aligned} \qquad [20]$$

where $\mathbf{E} = -\nabla\phi$ is used, Einstein's summation index notation is adopted, and state variables and their corresponding virtual quantities (variations) appear. These equations in the weak form can be used in the place of governing differential equations in eqn [4]. Then, by defining an objective function and relevant constraints, an optimization problem is formulated. In the design of the so-called flextensional actuators, a piezoelectric medium is combined with an elastic medium and the maximizing output displacement at a point in the elastic medium for the applied voltage between two points in the piezomedium is sought. The solution to this optimization problem provides a displacement amplifier that is tailored for a given piezoelectric actuator. Details of this can be found in Ananthasuresh (2003), Canfield and Frecker (2000), Silva and Kikuchi (1999), and Silva *et al.* (2000).

There have also been attempts to synthesize piezocomposites, which are made of piezomaterial and a nonpiezomaterial with a regular microstructure. In these problems, the topology of the microstructure is optimized to obtain desired piezoproperties indicated in eqn [19]. This is similar to the topology synthesis of microstructures materials discussed in Section 1.19.4.5. The optimized microstructure of piezocomposites has been manufactured using stereolithography and tested (Silva and Kikuchi 1999, Silva *et al.* 2000). This is indicative of the practical utility of topology synthesis of new piezoelectric materials with improved properties. Since thin piezoelectric films can be deposited and patterned, this provides the scope for novel uses of piezoelectric materials in microsystems.

1.19.4.5 Microstructured Materials

The compliant mechanism shown in **Figure 9** indicates that we can design a constrained elastic body that deforms in a desired manner in response to the mechanical forces applied on it. If this compliant mechanism is interpreted as a building block in the microstructure of a material and if this building block is periodically repeated to create a material, novel and unusual properties can be obtained. These are variously called periodic micromechanisms (Ananthasuresh 2003, Chap. 7), metamaterials, or simply tailor-made materials with an engineered periodic microstructure. Topology synthesis techniques involved in this are similar to the ones described above with the exception of periodic boundary conditions and computing the averaged (or homogenized) effects of a repeating building block. In mircosystems, while this idea of systematically synthesizing and fabricating the microstructure may look rather esoteric, the possibility certainly exists to enhance the performance. The piezocomposites noted in Section 1.19.4 also fall under this class of novel possibilities of combining topology synthesis with modern micromanufacturing methods.

Figure 14 shows a repeating pattern of a rod-and-hinge model. If this pattern is pulled outward in the horizontal direction, one can imagine that it will pull out in the vertical direction also. This means that this arrangement has negative Poisson's ratio (Almgren 1985). This is a consequence of the reentrant type arrangement of the rod and hinges in the building block of this repeating pattern. Now, if the building block with rods and hinges is converted to an elastic continuum – a compliant mechanism – a

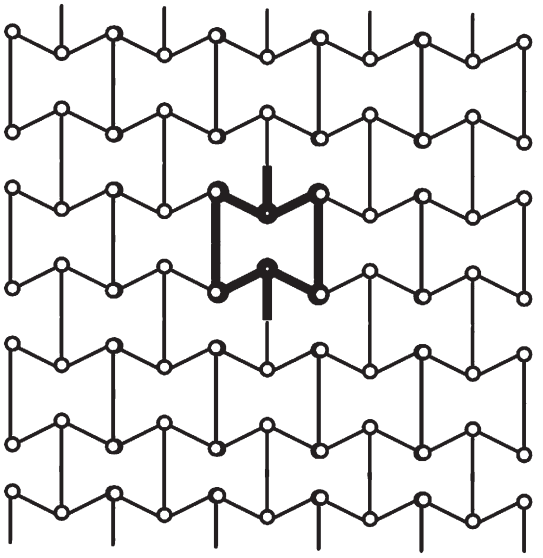

Figure 14 Rod and hinge model of a material with negative Poisson's ratio. (Source: Almgren R F 1985 An isotropic three-dimensional structure with Poisson's ratio = −1. *J. Elast.* **15(4)**, 427–30. Sigmund O 1994 Materials with prescribed constitutive parameters: An inverse homogenization problem. *Int. J. Solids Struct.* **31(17)**, 2313–29.)

microstructured material with negative Poisson's ratio is obtained. An example design, which was fabricated using single-crystal silicon and wafer bonding, is shown in **Figure 15**. This idea was proposed in Sigmund (1995) in which a numerical optimization technique, called inverse homogenization method, was also developed. Subsequently, microstructured materials with other extreme properties such as negative thermal expansion coefficients, tailored band gap characteristics, have been synthesized (Jensen and Sigmund 2006, Sigmund 1994, Sigmund and Torquato 1996). These materials are different from functionally graded materials, which have inhomogeneous material properties in a bulk structure.

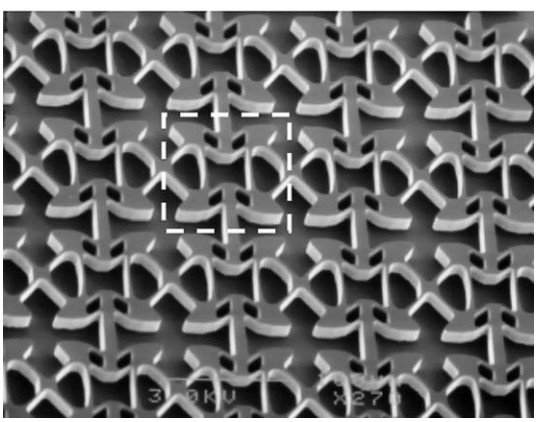

Figure 15 Silicon sheet with a repeating pattern of re-entrant type compliant mechanism building block (shown within a box of dashed lines) to give negative Poisson's ratio.

1.19.4.6 Microfluidic Components and Devices

Microfluidics is one of the most useful and also challenging areas of microsystems. With the advent of bioMEMS (microelectromechanical systems with biology applications), microfluidic devices have already been shown to have immense commercial potential in the healthcare industry. Plumbing fluids at the microscale is one of the main tasks of these devices. The performance of pumps, valves, mixers, reservoirs, etc., must be optimized by suitable geometry optimization to make the microfluidic systems more efficient and cost-effective. While the topology synthesis procedures described so far were concerned only with solids, fluids are not excluded. Methods for optimizing the topology and shape of fluidic systems are also in the offing. Representative works in this area include Evgrafov *et al.* (2006) and Klarbring *et al.* (2003). A simple example is shown in **Figure 16** wherein it is desired to obtain the optimal flow path between the inlet and the outlet to minimize the pressure drop. As one can imagine, exploring this manually involves a lot of trial-and-error attempts before the best is found. Of course, as with solids, experienced fluid mechanicians can do this intuitively. But in complex situations, systematic synthesis methods would help. Referring back to eqn [6] where material state was interpolated

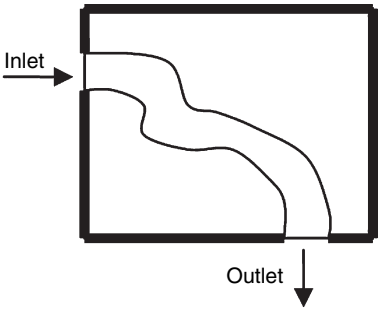

Figure 16 Topology synthesis for flow paths. What is the optimal path between the inlet and the outlet to minimize the pressure drop?

between 0 and 1 to get the absence, presence, and the intermediate state for the problem in **Figure 16**, the state of the material in the design domain varies smoothly between a liquid and a void. Governing equations for this needed special treatment that uses lattice Boltzmann modeling as can be found in Jensen and Sigmund (2006). Similar ideas of smooth transitions between solid and liquid were proposed in fluid–structure interaction topology synthesis problems (Clausen and Sigmund 2006). Significant potential exists in effectively using these techniques in microfluidic components.

1.19.5 Process and Mask Synthesis

The final step in the design of any microsystem component is to obtain the lithography mask layouts that are essential for microfabrication. But interestingly, most often microsystem designers are expected to begin with lithography layouts to initiate their design process. Commercial microsystem design software programs include a module for this and advocate beginning the design task with layout drawings. Lately, this has been changing with the introduction of a system-level abstraction with reduced-order models. In contrast, designers at the macroscale are not overly restricted in creating the geometries while designing parts. At the macroscale, process planning for machining is usually a step that follows the design process. At the microscale, despite the rapid development in microfabrication, several limitations exist, and these constrain the microsystem designers. They also do not yet have tools for the equivalent of process planning. Such tools exist for microelectronics (Hasanuzzaman and Mastrangelo 1996) but not for micromechanical components operating in different energy domains. In this section, some demonstrated works, which are very few, are mentioned, and some possibilities for a paradigm shift in microsystem design at the process level indicated in **Figure 4** are discussed.

1.19.5.1 Process Synthesis

Unlike a macrosystem designer, a microsystem designer ought to choose a fabrication process at the very beginning of the design process. In most cases, the designers use an existing process and tailor the design to fit that process. Those designers who use microsystem foundry processes have no choice in this matter. But for those who can develop and run their own processes, it is sensible to obtain the most suitable process for a given design. This implies that after the geometry of the components and its material composition are decided (preferably without being constrained by how the component is going to be made) a process would be chosen. This is currently done by human designers and microfabrication specialists. Making this systematic and even automating it would be preferable. A few methods have been developed for microelectronic processes along these lines. The investigations and methods described in Hasanuzzaman and Mastrangelo (1996) and Hasanuzzaman *et al.* (1999) are the right steps in this direction. Details can be found in Ananthasuresh (2003, Chap. 8).

1.19.5.2 Mask Synthesis

Choosing a process is not the end of the microsystem design procedure; one needs to create lithography mask layouts that would help realize the desired 3D geometry. Thus, mask synthesis entails systematic means to generate the mask layouts from optimized or finalized 3D geometry of components. There is a limited amount of literature in this regard. Mask synthesis for wet-etched single-crystal silicon is discussed in Lee and Antonsson (2000), with an overview provided in Antonsson and Cagan (2001). In this technique, a genetic algorithm was used to synthesize the desired 3D etch patterns in a single layer of silicon. The mask synthesis for surface micromachining is proposed in Ananthakrishnan *et al.* (2003) wherein a new representation scheme was developed so that the mask synthesis can be reduced to solve a system of linear equations. Details of this can be found in Ananthasuresh (2003, Chap. 9).

1.19.5.3 Synthesis with Manufacturing Constraints

If a component's geometry is determined without considering how it will be fabricated (which is what a designer would like), it might not even be possible to practically realize that geometry with a chosen process. So, it is desirable to include micromanufacturing constraints within the topology synthesis procedures. An attempt in this direction has been made recently for surface micromachining process (Alwan and Ananthasuresh 2006c). Alternatively, a feature-based modeling wherein the designer is automatically restricted from creating features that are

illegal for a chosen process has also been reported (Ananthakrishnan 2000). This enables model creation with human participation as well as automated geometry design.

Given the limited number of investigations in process and mask synthesis and significant opportunities in making the microsystem design efficient, there is a need for further progress in this area.

1.19.6 Closure

Design is an iterative process. Several analysis steps using candidate designs are necessary before a design is finalized. This is a laborious process. The designer's intuition, prior experience, and knowledge about the entity being designed guide this process. Often it is a trial-and-error process even for an experienced designer who encounters a new design task. Synthesis, on the other hand, is a systematic step of arriving at a design in less time than in trial-and-error design. If optimization is used, the systematic synthesis can also give the optimum design. In this chapter, optimal synthesis procedures that are developed for microsystems and their components have been discussed.

Four categories of synthesis problems were noted for different levels of abstraction of microsystems. The first level, where the architecture of the system and its subsystems are identified, is highly subjective and is not easily amenable for systematic synthesis. At present there is no significant literature on this to discuss it. The second level, where a system-level model is constructed with reduced-order models for the subsystems, is suited for parametric optimization. The methods for this are simple as discussed in the chapter. The third level, where the geometry of the components is determined, is the most time-consuming step and is also the most suited for systematic synthesis. The methods for this are described for six different types of problems – many involving multiple coupled energy domains. The fourth level, where the microfabrication process and lithography mask layouts are to be generated, is a practically important synthesis problem. But it has not received as much attention as it deserves. A few methods that are developed for this are presented.

The work noted in this chapter is by no means exhaustive. Several other researchers have also contributed to the synthesis of microsystems. Only selected works that fit within the scope and viewpoint of this chapter are included here.

Synthesis techniques enable designers to design faster and better. Unlike the macroworld where there are many more options for integration and manufacturing, microsystems are conveniently restricted. So, systematic synthesis is possible and beneficial for microsystems. This was the conclusion of a workshop held in 1996 in which several synthesis researchers were working in the field of microsystems (Antonsson 1996). After a decade of further development in synthesis, the microsystems industry and users are yet to significantly benefit by adopting synthesis procedures as part of their design tasks. One hopes that it will change gradually with an anticipation that designers would see synthesis as an integral part of design rather than viewing the design merely as repeated analysis (i.e., simulations) trials until a satisfactory (not necessarily optimum) design is found.

Acknowledgments

Biography

G. K. Ananthasuresh obtained his B.Tech. degree in 1989 from IIT, Madras, and Ph.D. in 1994 from the University of Michigan, Ann Arbor, MI, USA. He was a post-doctoral research associate in the Microsystems Technology Laboratories at MIT, Cambridge, MA, USA, before he joined the University of Pennsylvania's Mechanical Engineering and Applied Mechanics Department in 1996 as an assistant professor and then promoted with tenure to Associate Professor in 2002. He joined the Indian Institute of Science (IISc) in 2004. His research interests include compliant mechanisms, microelectromechanical systems (MEMS), multidisciplinary design optimization, topology optimization, microfabrication, mechanism design and kinematics, protein design, and micromanipulation. He has more than 115 publications out of which more than 45 are journal papers. He is also the author of five book-chapters and an edited book entitled *Optimal Synthesis Methods for MEMS*. He has two patents and three best paper awards at international conferences. He is the recipient of the Swarnajayanthi Fellowship of the Department of Science and Technology of India, National Science Foundations' Early Career (CAREER) award and Society of Automotive Engineers' Ralph Teetor Distinguished Educator award. He has supervised six Ph.D. theses and three MS theses at the University of Pennsylvania. He is currently advising eight students and five research project assistants at IISc.

2.01 Electrostatic Actuation

Hiroshi Toshiyoshi, Institute of Industrial Science, The University of Tokyo, Tokyo, Japan

Glossary

Electrostatic actuation A principle to drive micro actuators using an attractive or a repulsive Coulomb force between electrically charged bodies, which is proportional to the square of applied voltage and inversely proportional to the mutual distance. It is widely used in MEMS actuators thanks to the simplicity of mechanism and its increasing significance in micron scale.

Parallel-plate actuator An ideal analytical model for electrostatic actuators that are composed of a pair of parallel electrode plates (fixed and movable) with an air gap in between.

Comb-drive actuator An electrostatic actuator with an inter-digitized electrodes of a comb-look shape for longer travel distance than that of a parallel-plate actuator.

Vertical comb-drive actuator A derivative of lateral comb-drive actuator, and is usually used to cause out-of-plane motion for tilting mirrors, for instance.

Electrostatic pull-in A characteristic phenomenon found in most electrostatic actuators, at which a movable electrode loses control due to the electrostatic attractive force that has become larger than the restoring force of suspending tethers.

Electrostatic charge-up A cause of displacement drift of electrostatic actuator, where accumulation of electrical charge on the electrodes or nearby bodies causes change in the electrostatic force acting on the movable electrode. In an extreme case of electrostatic charge-up, the movable electrode is trapped on the counter electrode to cause in-use stiction.

Differential voltage drive A method to linearize the displacement-voltage characteristic of electrostatic actuator by using a pair of electrostatic attractive forces pulling a movable body in opposite directions.

Scratch-drive actuator A micro plate with a bushing on the bottom surface of its leading edge, and used to cause long travel range on an electrically insulated surface through the repetition of electrostatic stick-slip motion.

Negative spring constant effect A phenomenon that an electrostatic actuator looks to have reduced its spring constant at an electrically biased state due to the non-linearly increasing electrostatic force over linearly increasing restoring elastic force.

2.01.1 Overview of Electrostatic Actuation

2.01.1.1 Introduction

Electrostatic actuation utilizes an attractive or a repulsive Coulomb force between electrically charged bodies. This mechanism is the most widely used in microelectromechanical systems (MEMS) microactuators today for its mechanical simplicity; a pair of electrodes with a tiny separation can be implemented in various shapes and orientation by the micromachining technique. This mechanism has good compatibility in scale with microfabrication. Electrostatic force acting on the surface drastically increases with decreasing scale, compared with the body force such as gravity and inertia force.

2.01.1.2 Classic Electrostatic Actuation

The history of electrostatic actuators dates back further than that of electromagnetic mechanism, to the early 18th century (Jefimenko 1973). The world's first electrostatic actuator was the electric bell invented by Andrew Gordon in 1742. A tiny metal

hammer was suspended with an electrically insulating thread in between a pair of metal bells that were oppositely charged. When the hammer was attracted to one of the bells, it was charged to the same polarity as the bell and then attracted to the opposite one. The shuttle process of ringing repeated as long as the electricity was supplied to the bells. Gordon also invented another type of electrostatic mechanism called an electric fly. Metal wires were bent in a windmill shape with pointed ends. When the whole windmill was electrically charged, the air molecules around the pointing ends were corona-discharged, resulting in a repulsive force that turned the mill.

Another mechanism, the spark motor, was a rotational version of the Gordon's electric bell, invented by Benjamin Franklin in 1748 (Jefimenko 1973). Glass rods with a metal cap were arranged like the spokes of a wheel and placed in between a pair of Leyden jars that were charged with opposite polarity. The metal cap that passed by the Leyden jar was positively charged by electric breakdown (spark) and was driven out by the repulsive force that turns the wheel. On the other side of the wheel, the cap was negatively charged to keep the wheel rotated. Franklin observed 0.1 W power output by using a wheel 1 m in diameter. Franklin's spark motor was modernized by Karpov *et al.* in 1960 to be a corona motor, where electrical charges were given not by the electrostatic breakdown but by the corona discharge.

Capacitor motor is a precursor of today's electrostatic micromotors. It is also known to be a variable capacitance motor, because the rotor moves in the direction to increase the electrostatic capacitance with increasing drive voltage. The first capacitor motor was developed by Karl Zipernowsky in 1889. Recently, Bollee *et al.* reported a precision-machined version of capacitor motor, as shown in **Figure 1** (Bollee 1969). When voltages were applied to the stator and the rotor, the electrostatic attractive force acted on the rotor in the direction to maximize the overlap of the electrodes. For perpetual rotating motion, pulse voltages were applied to the stators in turn. Bollee demonstrated a capacitor motor of 100 stators that generated 0.6 mW power with an operating voltage of 200 V.

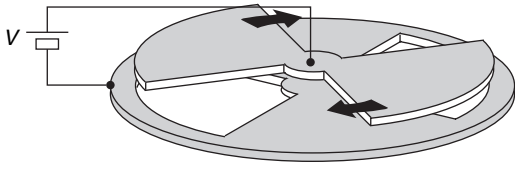

Figure 1 Capacitor motor. (Source: Bollee B 1969 Electrostatic motors. *Philips Tech. Rev*. **30(6/7)**, 178–94.)

2.01.1.3 Electrostatic Actuator in Microscale

Electrostatic motors manufactured by conventional macromachining were reported to be in the same physical scale as today's electromagnetic motors, ranging in the order of a few centimeters to several tens of centimeters, and the electrostatic gaps were made to be on the order of millimeters. In such old and large-scale mechanics, however, the energy density of electrostatic actuator was lower than that of the electromagnetic type, and high voltages (over several hundreds) were needed to produce significant mechanical work. For this reason, the electrostatic force was not a popular principle for macroscale mechanism but was used in limited applications such as dust collectors, electrostatic chuck, and in recent electronics, toner transfer mechanism in laser printers.

A landsliding change in electrostatic actuation came in 1987, when AT&T Bell Labs reported a new use of the semiconductor integrated circuit (IC) processes to develop micromechanical structures (Trimmer and Gabriel 1987). A thin-film polysilicon was used as a structural material to develop a series of free-rotating microgears 125–185 μm in diameter and 4 μm in thickness on a silicon wafer, as shown in **Figure 2**. No actuation mechanism was implemented in their first demonstration, but the scanning electron microscope (SEM) image gave a huge impetus to both electrical and mechanical engineers.

It was only a year later that an electrically driven micromotor was reported by Fan *et al.* with the University of California at Berkeley (Fan *et al.* 1988, Tai *et al.* 1989). The motor material was a thin-film doped polysilicon, the same as that of AT&T microgears. In the Berkeley motor, a cross-shaped rotor

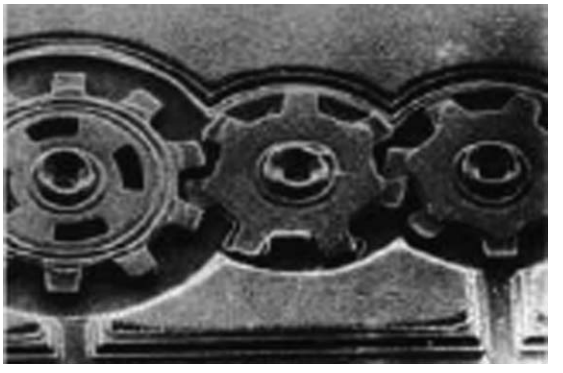

Figure 2 Microgears developed by silicon surface micromachining. (Source: Mehregany M, Gabriel K J, Trimmer W S N 1988 Integrated fabrication of polysilicon mechanisms. *IEEE Trans. ED* **35(6)**, 719–23.)

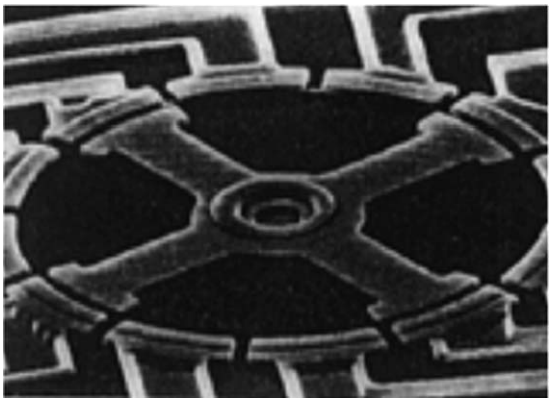

Figure 3 First demonstration of electrostatic micromotor. (Source: Tai Y C, Muller R S 1989 IC-processed electrostatic synchronous microrotors. *Sens. Actuators* **20(1/2)**, 41–8.)

(2 μm in thickness and 120 μm in diameter) was made to freely rotate about the center pivot, as shown in **Figure 3**. A total of 12 stators were placed around the rotor, with a 2 μm gap; a set of triphase voltages (300 V) was applied to the stator pads in turn to generate electrostatic force that worked to align the rotor's end to the stator. The motor was called edge-driven type because the electrostatic force acted on the rotor edges. A silicon nitride film, a solid lubricant material, was deposited on the inner wall of the rotor to reduce the friction with the center pivot (Tai *et al.* 1990). Despite such effort to reduce friction, the maximum rotation speed was limited to only 300 rpm; this speed was quite low compared with the their theoretical prediction, 120 000 rpm. The first prototype motor was also reported to work only for the first 3 min.

A solution to overcome the friction was to eliminate any sliding motion at the mechanical interface. Mehregany *et al.* (1990a, b) with MIT developed a new electrostatic micromotor. A schematic is shown in **Figure 4**. Unlike in the University of California, Berkeley micromotor, there were no projections in the rotor but a round disk. The rotor was designed to have a small looseness in the inner diameter, which allowed the rotor to move toward an electrically biased stator. When the voltage moved to the neighboring stator in turn, the rotor redirected itself to it without sliding on the center shaft, exhibiting a frictionless wobbling motion. The inner circumference of the disk (L_d) was larger than the outer circumference of the center shaft (L_c); hence, the rotation of the disk was reduced with respect to the rotation of voltage by a factor of $(L_d - L_c)/L_d$. Thanks to the frictionless motion and reduction gear mechanism, the disk could rotate at a fast spin rate of 10 000 rpm or higher for more than 1 week in the dry nitrogen environment. Mehregany also discovered that the mechanism of motor failure was associated with the native oxide grown on the surface of the polysilicon rotor; electrical conductance on the surface was degraded by the presence of native oxide, and the rotor became gradually charged up, finally resulting in electrostatic stiction to the substrate or the center post.

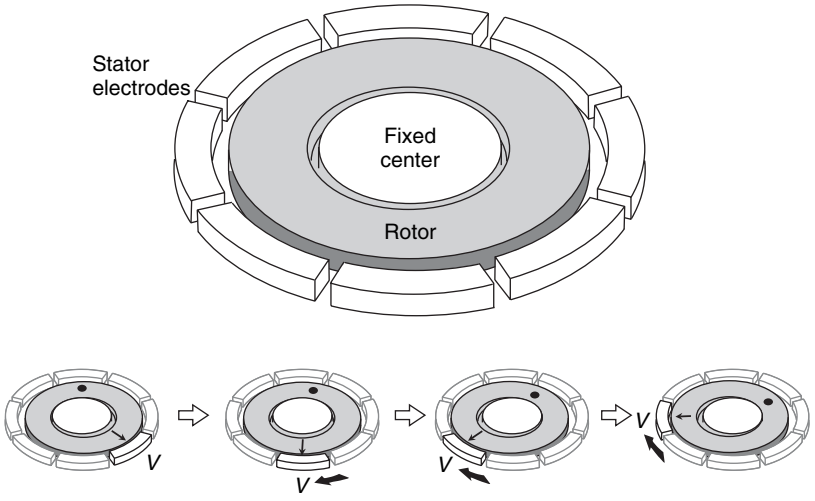

Figure 4 Electrostatic wobble motor. (Sources: Mehregany M, Bart S F, Tavrow L S, Lang J H, Senturia S D, Schlecht M F 1990a A study of three microfabricated variable-capacitance motors. *Sens. Actuators* **A21**, 173–9 and Mehregany M, Nagarkar P, Senturia S D, Lang J H 1990b Operation of microfabricated harmonic and ordinary side-drive motors. *Proc. IEEE Micro Electro Mechanical Systems Workshop*, Napa Valley, CA, USA, February 11–14, 1990, pp. 1–8.)

2.01.1.4 Suspended Micromechanism

Friction due to the sliding motion can be also eliminated by using an elastically tethered structure, but its motion is limited by the elastic restoring force of the suspensions. Mechanically movable suspended microstructures were developed even before micromotors. The earliest micromechanical structure in a cantilever shape was developed by electroplating metal on a metal oxide semiconductor (MOS) transistor substrate, as shown in **Figure 5**, reported by Nathanson and Wickstrom (1965). They used the resonant frequency of the suspended structure for bandpass filtering and obtained the signal component of a particular frequency by using the underlying MOS transistor. Various sorts of bulk silicon micromachined structures were reported in the famous review article by K. E. Petersen (1982). Most of their actuation directions were limited to the out-of-plane with respect to the substrate surface.

The first lateral-motion actuators of long traveling range was developed by Tang *et al.* (1989) with the University of California at Berkeley. **Figure 6(a)** shows a SEM image of the laterally driven electrostatic actuator. The movable structure was suspended with the folded beam structures (100 μm long each)

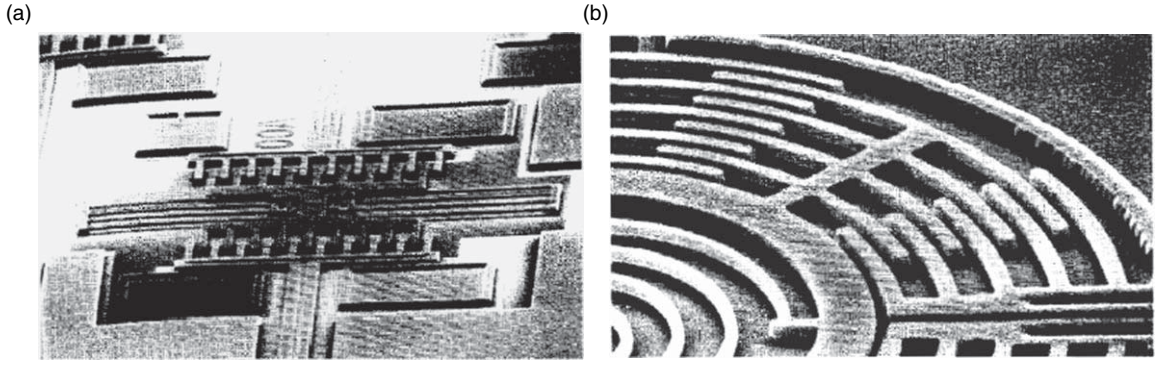

Figure 6 Electrostatic comb-drive resonator: (a) lateral and (b) rotational types. (Source: Tang W C, Nguyen T-C, Howe R T 1989 Laterally driven polysilicon resonant microstructures. *Sens. Actuators* **20**, 25–32.)

and anchored to the substrate at the middle part. The drive electrodes were designed to be interdigitated structures like comb teeth with a 2-μm gap. Mechanical stroke of 5 to 20 μm was reported with typical drive voltage ranging from 10 to 30 V.

Electrostatic force of the comb-drive actuator could be increased by decreasing the intercomb air gap. Hirano *et al.* (1992) reported a postprocess technique to make a comb-drive actuator with very small gap of 0.5 μm, which was further smaller than the resolution of the photolithography steps.

An in-plane rotational version of the comb-drive actuator, as shown in **Figure 6(b)**, was also reported by Tang *et al.* A polysilicon ring 1 mm in diameter was supported in the center part with four sets of meandering suspensions, and coaxial comb electrodes were arranged at the outer rim. The comb-drive mechanism was employed in actuators; they can also be used as physical sensors such as accelerometers, gyroscopes, and electromechanical filters.

2.01.2 Advantages of Electrostatic Actuation

2.01.2.1 Electrostatic Energy

Despite the long history of electrostatic actuation, the mechanism has been used in limited applications where no large force was required. Compared with the magnetic field, electrostatic field has poor energy density; however, it becomes comparable with that of magnetic, because the maximum electrostatic field that a solid insulating material can sustain (electrostatic breakdown field) increases with decreasing thickness of the material. For instance, the breakdown field in silicon dioxide (SiO_2) can be as high as 2 MV cm^{-1}, which corresponds to an energy of a 1.3-T magnetic field. The electrostatic attractive force (pressure) at this field strength is calculated to be almost 0.65 MPa (nearly 6.5 atm). Breakdown voltage (or electric field) further increases in gas. According to Paschen's law, breakdown voltage in gas is known to have a minimum value, no matter how small the electrostatic gap is tuned (Dakin *et al.* 1974, Paschen 1889). For instance, the minimum voltage to start breakdown in air is 330 V; assuming a 1-μm gap, the voltage corresponds to a static field as large as 3 MV cm^{-1}. On the contrary, magnetic field is limited by the saturation field strength of material; typical value is on the order of 1 T.

Besides the large electrostatic energy density in microscale, simplicity of mechanism is an advantage of electrostatic actuation. Compared with electromagnetic actuators that require coils of rather complicated topology, electrostatic actuators can be developed simply by using a pair of electrodes. Consequently, electrostatic actuators can be made light in mass, being more compatible with high-frequency operation.

2.01.2.2 Compatibility with MEMS

From an IC fabrication point of view, metal or semiconductor electrodes sitting on an insulating material (such as silicon dioxide) is a standard combination of materials that could be fabricated by the photolithography and etching processes. Thanks to the fact that electrostatic actuator is driven by voltage (charge) rather than by electrical current, power consumption is expected to be extremely small, and hence, small footprint ICs can be used as a driver. In fact, Digital Mirror Device (DMD) of Texas Instruments is electrostatically controlled by an integrated static random access memory (SRAM) of the complementary metal oxide semiconductor (CMOS) technology (Van Kessel *et al.* 1998). Electrostatic position feedback control is also used in the MEMS accelerometers and optical MEMS mirrors of Analog Devices Inc. (Core *et al.* 1993, Roessig *et al.* 2002).

2.01.3 Analytical Model for Electrostatic Actuation

2.01.3.1 Gap-closing Parallel Plate Mechanism

The actuation principle of an electrostatic actuator is understood by using a simple parallel plate model as shown in **Figure 7**. The drive electrode at the bottom is usually anchored to the substrate and electrically biased. On the contrary, the movable electrode on the top is usually suspended with an elastic hinge, through which it is electrically grounded to the same potential as the substrate. The suspended structures can easily be developed by the surface micromachining with a sacrificially removed material (Bustillo *et al.* 1998). Because of the electrically grounded movable electrode and the nature of the Coulomb force, the applied voltage always works to attract the electrodes regardless of the voltage polarity. Electrostatic repulsive force is available only when permanent electric charges exist on the electrode; the principle is called electret actuation, which will be discussed in Section 2.01.9.

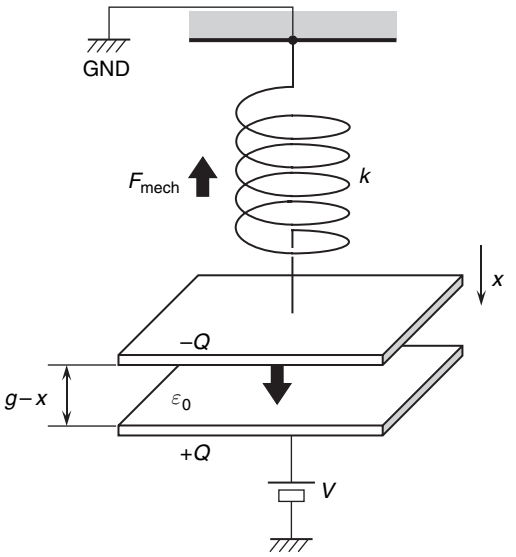

Figure 7 Analytical model for gap-closing parallel plate.

When the voltage is applied to the fixed electrode, the electrostatic attractive force moves the electrode to increase the electric capacitance. The spring suspending the movable electrode deflects until the restoring force reaches equilibrium with the electrostatic force. The electric capacitance C between the plates can be simply modeled as

$$C = \varepsilon_0 \frac{S}{g-x} \qquad [1]$$

where ε_0 is the dielectric constant of vacuum ($8.85 \times 10^{-12}\,\mathrm{F\,m^{-1}}$), S the area of the electrodes, g the initial gap between the electrodes, and x the displacement of the movable electrode toward the fixed one. Note that eqn [1] does not take the field concentration on the plate edge into account, but a contribution from a small fraction area S out from infinitely large plates is assumed. However, when the field concentration is considered, a good approximation for the capacitance is obtained by replacing the area S with a value one would get if the plates were extended artificially by a width equal to three-eighths of the gap (Feynman *et al.* 1964).

In the presence of an applied voltage V, the electrostatic attraction force can be calculated (see Section 2.01.12) as

$$F_{elec} = \frac{1}{2}\frac{dC}{dx}V^2 = \frac{1}{2}\varepsilon_0 \frac{S}{(g-x)^2}V^2 \qquad [2]$$

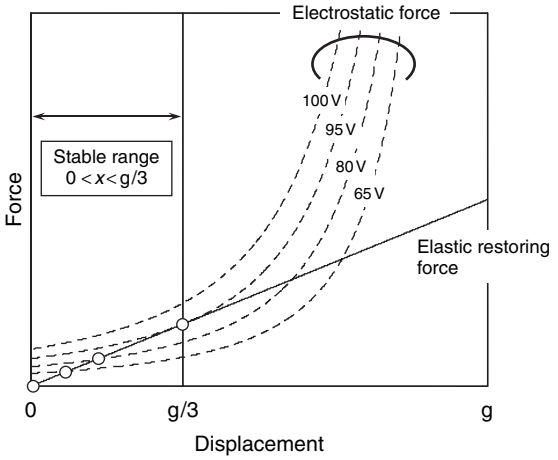

Figure 8 Comparison of electrostatic force and elastic restoring force.

On the contrary, the restoring force by the spring constant k is described simply by Hooke's law as

$$F_{mech} = k\,x \qquad [3]$$

Neglecting the effect of gravity, we equate eqns [2] and [3] to find the actuator displacement at the equilibrium condition for a given voltage as

$$k\,x = \frac{1}{2}\varepsilon_0 \frac{S}{(g-x)^2}V^2 \qquad [4]$$

Figure 8 plots the electrostatic force curve, eqn [2], and mechanical restoring force, eqn [4], as a function of displacement x. The parameters used in the calculation are $100\,\mu m \times 100\,\mu m$ for area S, $3\,\mu m$ for g, and $100\,\mathrm{N\,m^{-1}}$ for k. The intersection of the curves represents the equilibrium displacement at the given voltage. At voltage zero, the curves find a solution at $x = 0$. With increasing voltage, the static force curve moves upward, and the section moves toward greater values of x, implying that the electrostatic gap becomes small with increasing voltage. At some point where the electrostatic voltage exceeds the mechanical restoring force, the movable electrode is brought into contact with the counter-electrode to totally close the gap. This phenomenon is called electrostatic pull-in and is typically found in most electrostatic actuators. In the plot, the pull-in occurs at the point where the electrostatic force curve takes the restoring force line as a tangent.

Figure 9 plots the numerically computed values of x as a function of voltage V, using the same parameter set. Before the pull-in voltage (95 V), the plate displacement increases almost proportionally to

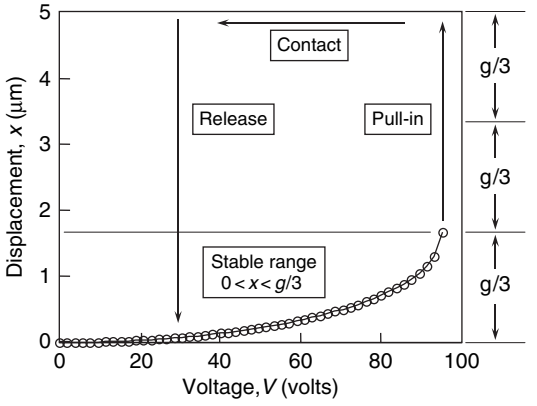

Figure 9 Parallel plate displacement as a function of applied voltage.

the square of voltage, V^2; in this range, the displacement can be stably controlled with negligible hysteresis. When the drive voltage reaches the pull-in voltage, the displacement leaps to close the gap. When the voltage is reduced, on the contrary, the plate remains in contact with the counterelectrode as long as the electrostatic attractive force is greater than the mechanical restoring force. The movable plate is released from the counterelectrode, when the electrostatic force becomes smaller than the restoring force.

2.01.3.2 Electrostatic Pull-in

It should be noted that the electrostatic pull-in occurs when the movable electrode comes to 2/3 of the initial gap. This phenomenon can be understood by rewriting eqn [4] in the following form:

$$\frac{1}{2}\varepsilon_0 \frac{k}{S} V^2 = x(g-x)^2 \qquad [5]$$

The left-hand side of the equation is a constant value determined by the voltage V, whereas the right-hand side varies by the geometrical factors x and g. In **Figure 10**, the pull-in point is shown by the local peak of the curve, where the first-order derivative is null:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left\{x(g-x)^2\right\} = (g-x)(g-3x) = 0 \qquad [6]$$

Therefore, the pull-in displacement is analytically found to be $x_{\text{pull-in}} = 1/3(g)$. In terms of the electrode gap, it corresponds to 2/3 of the initial gap. By substituting this value into eqn [5], we would obtain the pull-in voltage:

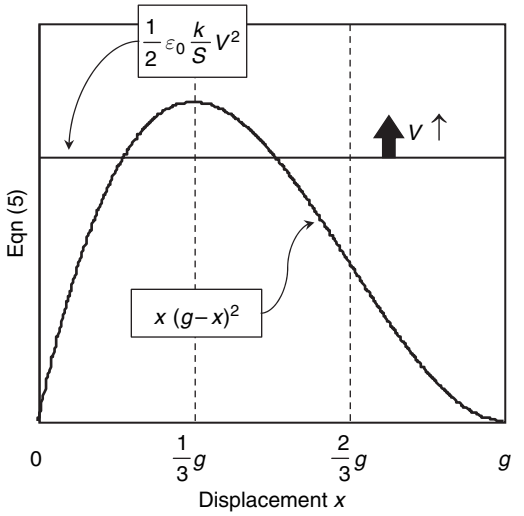

Figure 10 Pull-in instability.

$$V_{\text{pull-in}} = \sqrt{\frac{8\,k\,g^3}{27\,\varepsilon_0\,S}} \qquad [7]$$

The pull-in voltage depends on the geometrical parameters of the actuator, namely, the gap, the electrode area, and the spring shape, whereas the pull-in displacement is determined by the initial gap only.

The displacement after pull-in cannot be calculated by eqn [5], but the arrow in **Figure 9** is inserted by the *a priori* assumption that the displacement is limited by the initial electrostatic gap. Electrostatic actuators are usually designed to have a mechanical stopper somewhere on the way to the counterelectrode to avoid electrical short circuit upon the pull-in contact. In such a case, the maximum displacement should be limited by the position of the stopper. **Figure 11**

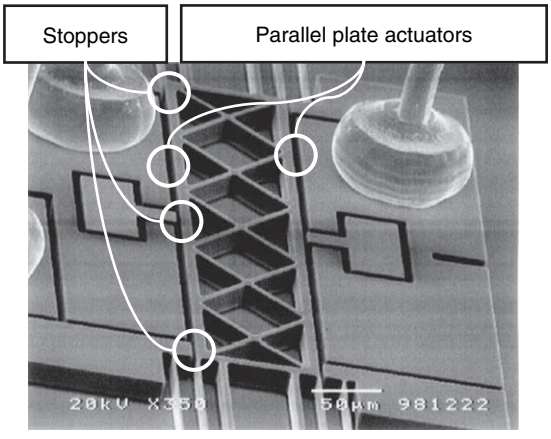

Figure 11 Laterally driven electrostatic actuator with integrated stoppers.

shows an example of parallel plate actuator whose motion is limited by the stoppers located on both the sides. Unlike the theoretical model shown in Figure 7, the structure moves laterally, but it is still well described by the parallel plate model. The SEM image was a part of a microactuator ladder structure made of a 20-μm-thick silicon-on-insulator (SOI) wafer. The movable structure seen in the middle (a meshed structure) was 500 μm long and 20 μm high (in the SOI thickness), and with a 10-μm-wide initial gap. The stoppers were embedded in the drive electrode (anchored to the substrate), and the stopper tips were designed to extend out by 5 μm. In this model, the stoppers are not electrically grounded because of the small area for wire bonding; ideally speaking, they should be grounded to avoid electrostatic charge-up problems.

2.01.3.3 Extending Travel Range

Applications may require long travel distance of the parallel plate actuators. Using a larger value for the initial gap is a solution; however, it comes with a penalty of increased drive voltage. In such a case, one may use the electrostatic comb-drive actuators, which will be discussed in Section 2.01.4. Leverage mechanism is a mechanical solution to extend the travel range. Kwon *et al.* (2006a) converted a rotational motion induced by an electrostatic actuator to produce a relatively large lateral stroke, as also discussed in Section 2.01.4.5. Takeshima *et al.* (1991) adopted a pantograph structure to magnify a small displacement into a large diagonal displacement.

Another solution to extend the travel range is to use a fast feedback control circuit, which enables operation beyond the pull-in displacement without changing the actuator design. J. Chen *et al.* (2004) used a voltage slightly higher than the pull-in voltage to the actuator when the displacement was small and linearly reduced the voltage as the actuator approached the desired displacement. Nadal-Guardia *et al.* (2002) used a current-source feedback control to drive an electrostatic diaphragm actuator and experimentally observed a controlled displacement beyond the pull-in displacement. Using a fixed capacitor in series with the electrostatic actuator is also helpful to delay the pull-in effect (Chan and Dutton 2000, Seeger and Crary 1997). The fixed capacitor and the actuator form a voltage divider. When the actuator plate is about to trip, the actuator capacitance increases, resulting in a reduced voltage across the actuator plates. However, the drawback of this method is that voltage required for operation becomes higher than the pull-in voltage under the open-loop control.

2.01.3.4 Spring Constant of Bending Beam

According to the beam theory (Gere and Timoshenko 1997, Timoshenko and Goodier 1970), beam displacement u under distributed force $q(x)$, as shown in Figure 12, is modeled simply by the following equation:

$$\frac{d^4u}{dx^4} = \frac{q(x)}{EI} \quad [8]$$

where E is the Young's modulus (160 GPa for single-crystal silicon along the <110> direction and 130 G for <100>) and I the second moment of area. When the beam section is rectangular with width w (lateral) and height h (vertical) and is forced to bend in the direction of the thickness (out of plane), the moment of inertia is written as

$$I = \frac{w h^3}{12} \quad [9]$$

When the beam is bent laterally in the direction of the width, the moment of inertia is

$$I = \frac{w^3 h}{12}$$

We use the bending beam model to derive a spring constant of a cantilever with a fixed end and a free tip. When a concentrated force P is applied downward on the cantilever tip at $x = l$, as shown in Figure 13, the beam also experiences a repulsive force in the upward direction from the supporting wall at $x = 0$. Eqn [8] is rewritten as

$$EI\frac{d^4u}{dx^4} = P\delta(x) + P\delta(x-l) \quad [10]$$

where $\delta(x-a)$ is the delta function that is defined as follows:

$$\delta(x-a) = \begin{cases} 1\,(x=a) \\ 0\,(x\neq a) \end{cases} \text{ and } \int_{-\infty}^{+\infty} \delta(x-a) = 1 \quad [11]$$

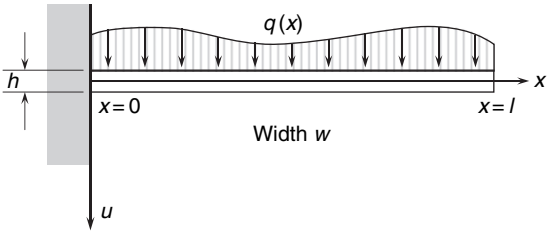

Figure 12 Bending beam under distributed force.

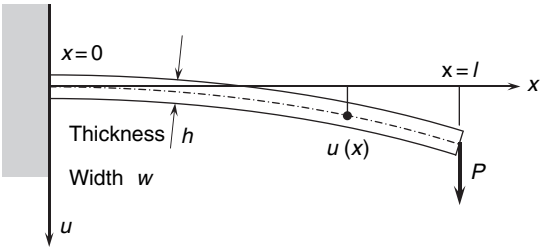

Figure 13 Fixed-end cantilever.

Note that the force and the displacement are defined to be positive in the downward direction. By integrating eqn [10] with respect to x, one would obtain the series of differential equations as follows:

$$EI\frac{d^3u}{dx^3} = -P + C_1 = -V_x \,(\text{shearing force}) \qquad [12]$$

$$EI\frac{d^2u}{dx^2} = (-P + C_1)x + C_2 = -M_x \,(\text{bending moment}) \qquad [13]$$

$$EI\frac{du}{dx} = \frac{1}{2}(-P + C_1)x^2 + C_2x + C_3 \qquad [14]$$

and

$$EI\,u(x) = \frac{1}{6}(-P + C_1)x^3 + \frac{C_2}{2}x^2 + C_3x + C_4 \qquad [15]$$

By using the boundary conditions that $u = 0$ and $du/dx = 0$ at $x = 0$ in eqns [14] and [15], respectively, we find $C_3 = C_4 = 0$. Because the shearing force $EI\left(d^3u/dx^3\right)$ is equal to $-P$ everywhere in the beam, $C_1 = 0$. In addition, no moment is given to the beam's free end, $EI\frac{d^2u}{dx^2}\big|_{x=l}$ and thus $C_2 = P/l$. Therefore, the equation for the cantilever's deflection is written as

$$u(x) = \frac{P}{6EI}\left(3lx^2 - x^3\right) \qquad [16]$$

At the cantilever tip, the displacement is calculated to be $u(l) = Pl^3/3EI$. By substituting this in Hooke's law, one would obtain the spring constant k to be $3EI/l^3$.

A similar procedure can be used to derive the spring constant for various kinds of boundary conditions. Some representative beams that are frequently used in MEMS actuators are listed in **Figure 14**.

2.01.3.5 Electrostatic Actuation of Distributed Gap System

The analytical model presented in the previous section was good for a suspended mass model, where electrostatic force acts only on a limited place such as the cantilever tip. When voltage is applied to the

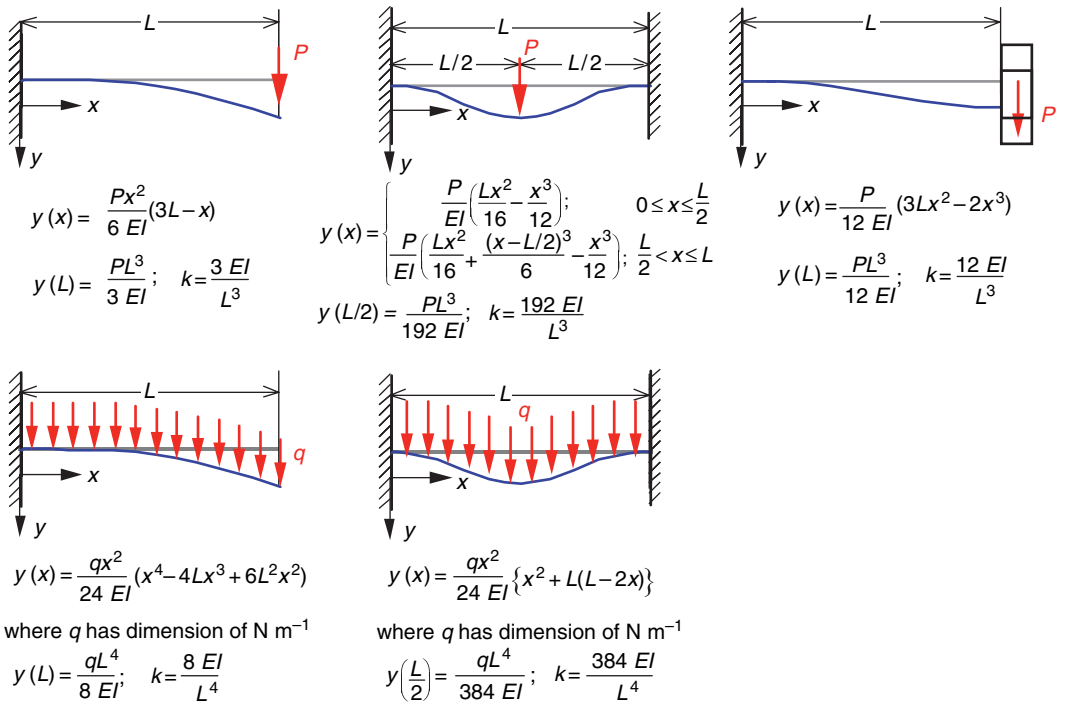

Figure 14 Spring constant of suspending beams of various boundary conditions.

entire cantilever or bridge, on the contrary, one should take the distributed force into account. Fortunately, the analytical model for such systems is not at all complicated in form, but it has already been presented by eqn [8]. Assuming a cantilever or bridge of width w suspended at the initial height g from the substrate surface and that it is biased to a voltage V with respect to the substrate, we only replace the distributed pressure $q(x)$ with the electrostatic pressure, and hence, eqn [8] is written as

$$EI\frac{d^4u}{dx^4} = \frac{1}{2}\varepsilon_0\frac{w}{g-u(x)}V^2 \qquad [17]$$

Despite the simplicity of the form, analytical solution is difficult to present. Readers are advised to use a numerical simulation module (such as the Runge–Kutta method) from commercially available mathematical software.

Figure 15 shows the results of numerical simulation using Mathcad™ (www.mathsoft.com); a simulation program is also shown in **Figure 16**. The simulation was performed with a small voltage and repeated by raising the voltage by small increments until the computation failed to converge, where pull-in instability was defined. The profile shown in **Figure 15** is of the last one before such pull-in.

The distributed gap system can also be applied to an actuator with a tapered electrostatic gap, as shown in **Figure 17** (Saruta *et al.* 2002). The maximum displacement can be made large by designing an electrode that has a wider gap near the end of an electrostatic cantilever or in the center part of a bridge.

While most finite element method (FEM)-type MEMS simulators on electrostatic force take a long time (more than an hour, depending on the complexity of structure) to finish calculation at one voltage, the analytical model presented was finished instantly. However, the analytical model discussed here holds good only for an actuator before electrostatic pull-in. The boundary condition changes after a cantilever or a bridge is brought into contact. Post pull-in simulation was studied by Gorthi *et al.* (2006).

2.01.4 Comb-drive Actuators

2.01.4.1 Sliding Plate Model

The electrostatic attractive force acting on the parallel plate actuator rapidly increases as the gap is closed, leading to quite a large nonlinear displacement–voltage characteristic. It also suffers from the pull-in instability that limits the maximum stable displacement within one-third of the initial gap. On the contrary, the comb-drive mechanism, invented by W. Tang (Tang *et al.* 1989), linearly increases the overlap between the comb fingers, resulting in an extended stable range of displacement as well as margin to the pull-in instability.

Figure 18 shows an example of the comb-drive mechanism made by the bulk silicon micromachining on an SOI wafer; the device was developed to control the submicron gap between the silicon tips, where a tunneling current flowed (Toshiyoshi *et al.* 1999). The square frame with many release holes was suspended with four pairs of folded beam suspensions. On the inner right-hand side of the frame, a comb-drive mechanism was integrated to move the frame in the direction to close the tip-to-tip distance. The bar connecting the folding points of the suspensions was used to suppress the in-plane rotation of the frame, by which the comb-to-comb short circuit was avoided. For designing the suspension rigidity, one may refer to **Figure 14** to find $k = 12EI/l^3$ for one cantilever with its tip rotation restricted. Because the folded suspension shown in **Figure 18** consists of four parallel pairs of two suspensions in series, the total spring constant is $k_{\text{total}} = 4 \times (1/2) \times k = 24EI/l^3$.

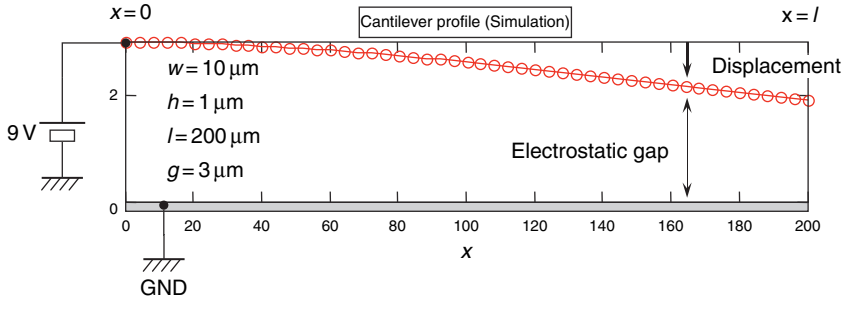

Figure 15 Simulation result of electrostatic cantilever.

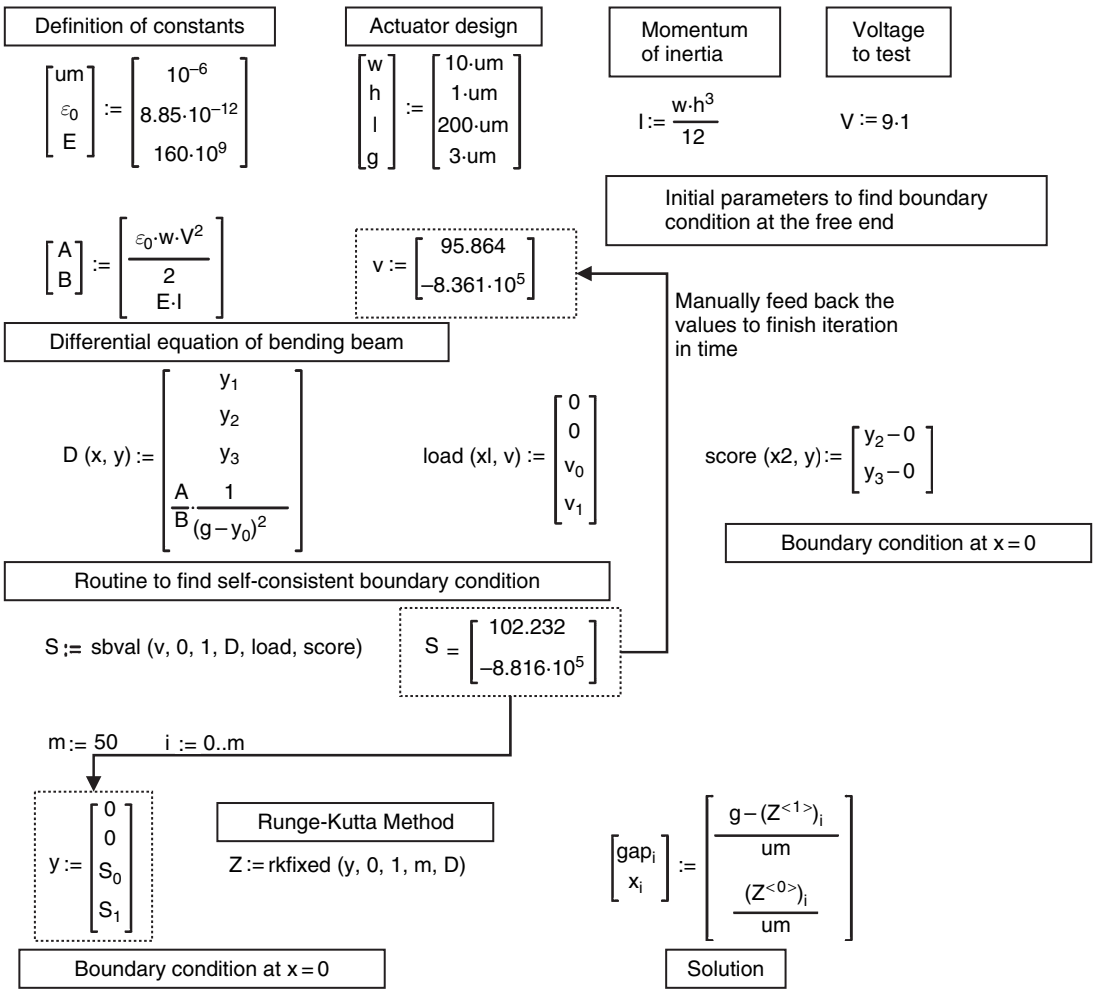

Figure 16 MATHCAD™ program for electrostatic cantilever.

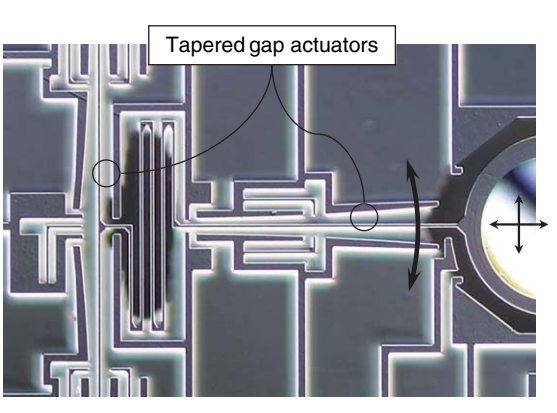

Figure 17 Electrostatic actuator with tapered gap.

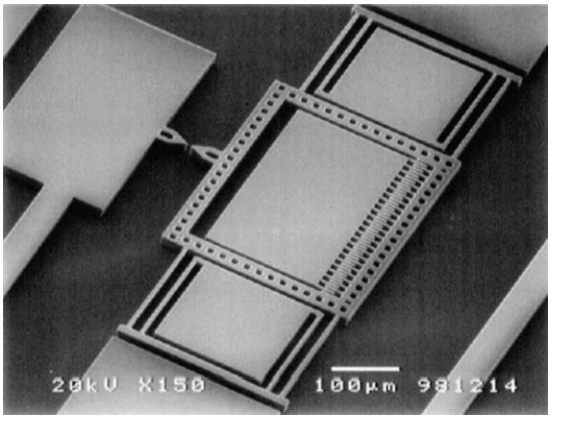

Figure 18 Electrostatic comb-drive actuator.

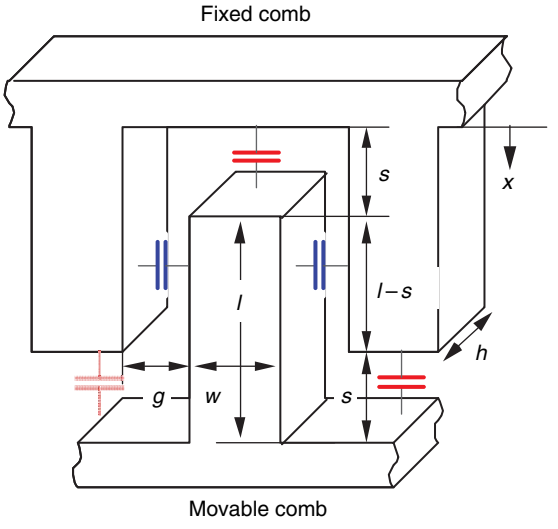

Figure 19 Analytical model (unit cell) for electrostatic comb-drive mechasnism.

Figure 19 illustrates a unit cell of the comb-drive electrodes of comb length l, width w, gap on the side g, gap on the comb tip s, and comb height h. The initial overlap of the opposing tips is written as $l = s$ in this model. The tips are usually made without having overlap ($l = s$), such that the effective gap g, after the comb is engaged in operation, can be made smaller than the photolithography resolution, enabling electrostatic actuation at lower voltages. Having no overlap is also beneficial for extending the travel distance of the movable comb.

When the upper comb in Figure 19 is displaced downward by travel distance x, the capacitor made at the comb tip is written by using the gap-closing parallel plate model:

$$C_{\text{tip}} = \varepsilon_0 \frac{w \times h}{s - x} \qquad [18]$$

On the contrary, the capacitor on the comb side can also be represented in a similar manner but with a sliding motion:

$$C_{\text{side}} = \varepsilon_0 \frac{h(l - s + x)}{g} \qquad [19]$$

The capacitor in the unit cell contains contribution from two side walls and two tips; thus,

$$C_{\text{unit}} = 2\left(C_{\text{tip}} + C_{\text{side}}\right) = 2\varepsilon_0 \left(\frac{w \times h}{s - x} + \frac{h(l - s + x)}{g}\right) \qquad [20]$$

Assuming that the comb fingers are arranged in the span of W, the number of fingers is calculated to be $N = W/2(w + g)$. Therefore, the total capacitor of an actuator is given as

$$C_{\text{unit}} = \varepsilon_0 \left(\frac{w \times h}{s - x} + \frac{h(l - s + x)}{g}\right) \frac{W}{w + g} \qquad [21]$$

For calculating the electrostatic force of the comb-drive mechanism, one may substitute eqn [21] into eqn [2]; hence,

$$F_{\text{unit}} = \frac{1}{2}\varepsilon_0 \left(\frac{w \times h}{(s - x)^2} + \frac{h}{g}\right) \frac{W}{w + g} V^2 \qquad [22]$$

It should be noted that the fringing effect (field concentration) has been neglected in this first-order approximation model. The effect of the substrate (ground plane) is also not taken into account.

Figure 20 shows the capacitance C_{unit} as a function of comb position x, calculated by using the following parameters: $h = 3\,\mu\text{m}$, $g = 1\,\mu\text{m}$, $w = 2\,\mu\text{m}$, $s = l = 6\,\mu\text{m}$, and $W = 100\,\mu\text{m}$. In a small displacement range of up to $4\,\mu\text{m}$, the capacitance increases almost linearly with the displacement, thanks to the sliding component C_{side}. When the comb tip comes to close the gap, the capacitance rapidly increases by the contribution from the gap-closing effect of C_{tip}.

Recalling the fact that the electrostatic force is proportional to the first-order derivative of the capacitance with respect to the position x, the linear range in the plot implies that the comb-drive mechanism is rather free from the pull-in effect. In an extreme case with a deep trench, $s >> l$, it is also possible to eliminate the effect of the capacitor at the tip, C_{tip}, and the electrostatic force becomes

$$F_{\text{unit}} = \frac{1}{2}\varepsilon_0 \frac{h}{g} \frac{W}{w + g} V^2 \qquad [23]$$

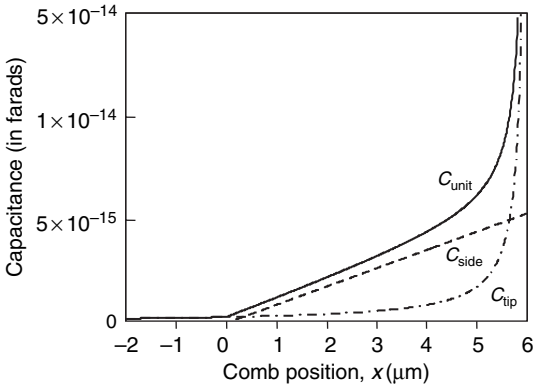

Figure 20 Capacitance of comb-drive as a function of electrode position.

Eqn [23] implies that the electrostatic force is independent of the comb's geometry, namely, the overlap of the comb electrodes, but it is proportional to the square of voltage. It should also be mentioned that using a small gap g does not lead to the limited travel distance but allows us to operate with lower voltages.

2.01.4.2 Electrical Ground Potential

A voltage may directly be applied to a suspended structure that is intended to move in the direction normal to the substrate surface, provided that the substrate is electrically grounded. A diaphragm structure for the electrically tunable Fabry–Perot interferometer is one such application (Ford *et al.* 1998). However, suspended structures designed to move in the lateral direction should be electrically grounded to avoid the vertical motion. In such a case, drive voltages are applied to the fixed electrodes.

2.01.4.3 Linearization by Differential Voltage Drive

An interesting feature of the comb-drive mechanism is that the displacement can be linearized in part with respect to the drive voltage. **Figure 21** illustrates the comb resonator developed by Tang *et al.* (1989) (shown in **Figure 6**). The movable structure is electrically grounded, and the electrodes on the left- and the right-hand side are biased to V_L and V_R, respectively. When a common DC bias voltage V_{bias} is superposed with a differential voltage v, one would write

$$V_L = V_{bias} - v \quad [24]$$

$$V_R = V_{bias} + v \quad [25]$$

where the differential voltage v is controlled to be smaller than the bias voltage ($|v| < |V_{bias}|$).

Neglecting the contribution from the comb tips, we write the force acting on each side of the actuator by using eqn [23]:

$$F_L = A(V_{bias} - v)^2 \quad [26]$$

$$F_R = A(V_{bias} + v)^2 \quad [27]$$

where $A = \varepsilon_0(bW/2g(w+g))$ is a geometrical factor commonly applied to both sides. Therefore, the net force acting on the movable plate is

$$\begin{aligned} F_{net} &= F_R - F_L \\ &= A(V_{bias} + v)^2 - A(V_{bias} - v)^2 \\ &= 4A \cdot V_{bias} \cdot v \end{aligned} \quad [28]$$

Thus, the force is found to have been linearized in terms of the differential voltage v. Using the same parameter set used to plot **Figure 20**, we examined the effect at different bias voltages as shown in **Figure 22**. It is clearly seen that the displacement is proportional to the differential voltage under the condition $|v| < |V_{bias}|$. Eqn [28] also implies that the bias voltage V_{bias} is used as a gain to tune the sensitivity to the differential voltage v. **Figure 22** also shows the validity of the gain control without degrading the linearity. Parallel plate actuators can also be linearized in the same manner, but the linear range is small due to the asymmetry of the geometrical factor A.

The differential voltage scheme shown in **Figure 21** requires complicated driver circuits with two AC voltage sources superposed on a DC bias voltage by using, for instance, analog operational amplifiers. In fact, an equivalent function can be made simply by using only one AC voltage source as

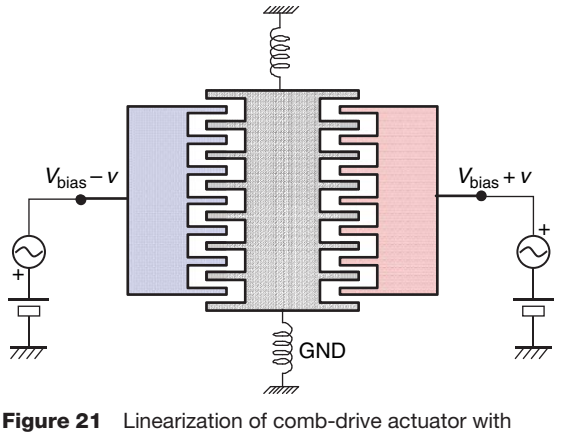

Figure 21 Linearization of comb-drive actuator with differential voltages.

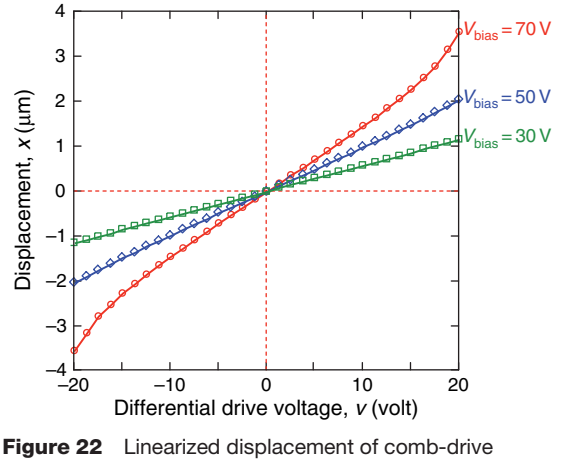

Figure 22 Linearized displacement of comb-drive mechanism.

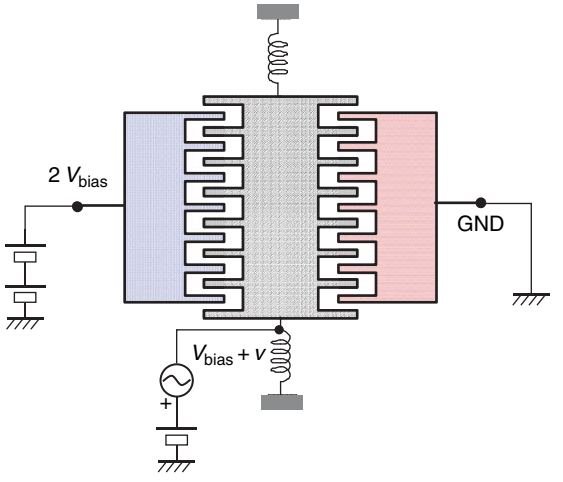

Figure 23 Differential voltage drive with only one AC voltage source.

shown in **Figure 23**, where voltages of $2V_{bias}$, $V_{bias} + v$, and 0 are applied to the left-hand-side, the movable, and the right-hand-side electrode, respectively. Thanks to the fact that electrostatic attractive force is independent of the voltage polarity, the net drive voltage on each side of the movable electrode is

$$\text{Left: } |(V_{bias} + v) - 2V_{bias}| = V_{bias} - v \text{ and} \quad [29]$$

$$\text{Right: } |0 - (V_{bias} + v)| = V_{bias} + v \quad [30]$$

Hence, the new method is found to be equivalent to **Figure 21** in terms of electrostatic force. When the suspended structure is in a close vicinity to the substrate surface, it would also be attracted toward the substrate because of the applied bias voltage. To avoid the problem, an equipotential $V_{bias} + v$ should be given to the substrate surface or a shield layer inserted in between the substrate and the suspended structure. The latter solution can be made by using a polysilicon surface micromachining technique with more than two polysilicon layers.

2.01.4.4 Bistable Digital Actuation Model

The comb-drive mechanism was originally developed to improve the linearity in displacement. As discussed in the analytical study, straight comb fingers in the deep trench would be helpful for that purpose. On the contrary, the nonlinearity can also be intentionally designed by altering the shape of the comb finger into a hammer-head style as shown in **Figure 24(a)** (Kwon *et al.* 2005). Kwon *et al.* with GIST reported the hammer-head comb drive to realize a bistable motion that could be mechanically latched with the aid of the buckling of suspension. A schematic of the actuator is shown in **Figure 24(b)**. The movable comb electrode was designed to have no overlap with the counterelectrode at the rest position. Once a pulse voltage was applied, the movable comb was pulled inside the counter-comb, and it remained engaged without voltage, thanks to the pressing force induced by the buckled suspension. To disengage, a pulse voltage is applied again to the counterelectrode to pull out the comb. Unlike the standard comb design shown in the previous sections, the hammer-head comb uses the electrostatic force acting on the corners.

2.01.4.5 Rotational Comb-drive Actuators

Combination of the comb-drive mechanism with a lever can be used to generate a relatively large stroke in microactuators. Kwon *et al.* reported a rotational comb-drive mechanism with coaxial comb fingers developed by the bulk silicon micromachining on

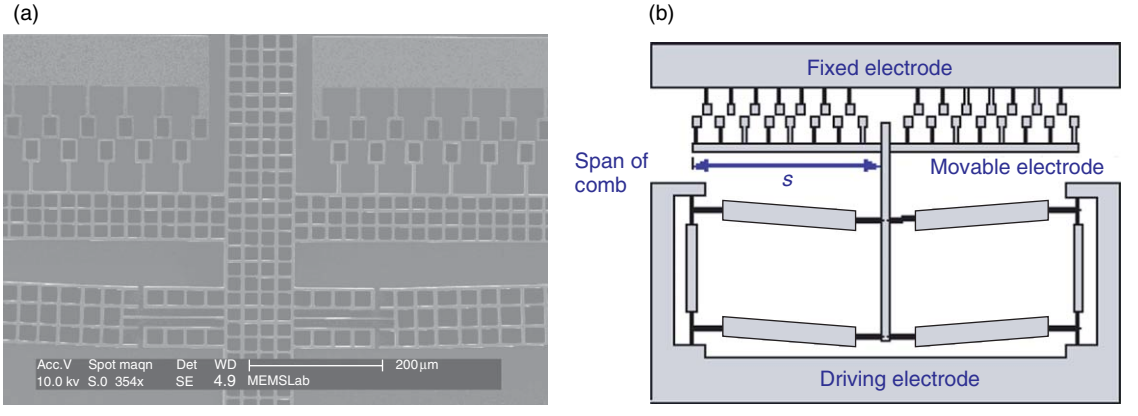

Figure 24 Bistable comb-drive mechanism with hammer-head electrode. (Source: Kwon H N, Hwang I-H, Lee J-H 2005 A pulse-operating electrostatic microactuator for bi-stable latching. *J. Micromech. Microeng.* **15**, 1511–16.)

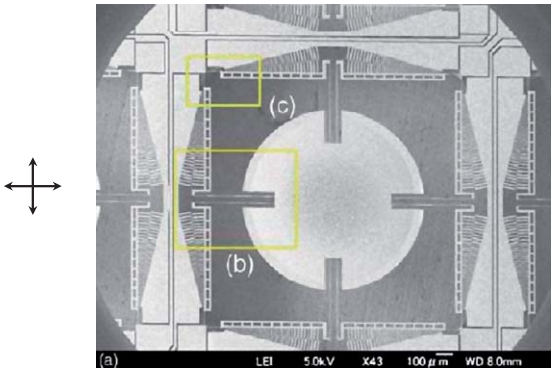

Figure 25 Coaxial comb-drive mechanism to convert angular motion into lateral stroke. (Source: Kwon H N, Lee J-H, Takahashi K, Toshiyoshi H 2006a Micro XY stages with spider-leg actuator for two-dimensional optical scanning. *Sens. Actuators* **A130-131**, 468–77.)

an SOI wafer, as shown in **Figure 25** (Kwon *et al.* 2006a). They used a pair of opposing coaxial comb drive and converted the rotational motion into a lateral motion by using the flexures. Maximum displacement of 55 μm was obtained by a DC voltage of 40 V. They used a rigid bar for holding the comb fingers and a thin flexure (1 μm wide and 90 μm long) for the rotation support; thanks to the rigidity contrast, the comb electrodes were operated stably despite the small electrostatic gap of 2.5 μm. Kwon used an orthogonal set of such unit to develop a micro *XY* stage (Kwon *et al.* 2006a) with an integrated silicon lens. They demonstrated a spatial light modulation of infrared by using the $f-\theta$ lens scanner mechanism.

2.01.4.6 Micro *XY* Stage with Comb-drive Mechanism

An *XY* stage with a nested comb-drive mechanism, as shown in **Figure 26** was reported by Takahashi *et al.* (2007, 2006a). They used a double-gimbal structure of an SOI wafer to accommodate two orthogonal sets of comb-drive mechanisms to realize a cross-talk-free *XY* motion. Thanks to their new device layout technique that split the electrostatic elements (electrodes) and elastic elements (suspensions) into the SOI and the recessed substrate, respectively, the device was relatively made in a small footprint compared with the previously reported devices (Kim *et al.* 2003, Kwon and Lee 2002, Kwon *et al.* 2006b, Sarajlic *et al.* 2005). For electrical interconnection to the inner stage, they used the elastic suspension as well as an additional small tether of negligible added rigidity, as

shown in **Figure 27**. With a 2 mm × 2 mm device footprint, they observed maximum 19 μm in the *X*-direction and 23 μm in the *Y*-direction with a voltage of 110 V_{DC}.

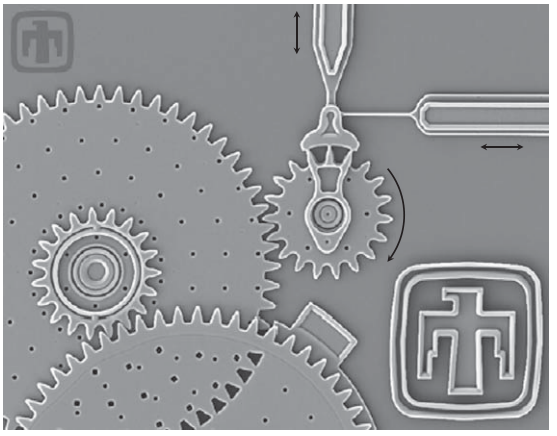

Figure 28 Micromechanism to convert lateral stroke into rotational motion. (Courtesy: Sandia National Laboratories, SUMMiT™ Technologies, www.mems.sandia.gov.)

2.01.4.7 Conversion Mechanism

Sandia National Laboratories reported a micromechanism to convert the stroke of comb-drive actuators into a perpetual rotational motion, as shown in **Figure 28**. A pair of comb-drive actuators was arranged in the orthogonal direction. Their stroke was intentionally preset to be out of phase by 90°, such that they worked as a two-cylinder engine to rotate a tiny gear that functioned as a crankshaft. The rotation of the gear was transferred to a larger gear that worked as a rotation stage. The mechanism can also be used in the linear racks of long stroke and in the 3D self-assembly. They developed a surface micromachining technique of five polysilicon layers called SUMMiT V (Sandia Ultra-planar, Multi-Level MEMS Technology V) to produce the complex mechanisms (Sniegowski and Garcia 1996, http://mems.sandia.gov/).

2.01.5 Torsion Mirror Actuators

2.01.5.1 Gap-closing Rotational Motion

Rotational motion is used for, for instance, torsion mirrors that spatially modulate light beams in free space. An electrostatic version of the torsion mirror was reported in the review article by Petersen (1982). The mirror was operated at the resonant frequency for large scan angle as a galvano mirror. In the 1990s or later, the torsion mirror mechanism was commonly used to statically scan the light beams in free space for an optical switching application (Aksyuk *et al.* 2003, Brosnihan *et al.* 2003, Dadap *et al.* 2003, Toshiyoshi and Fujita 1996, Toshiyoshi *et al.* 2001) and for image projection display (Van Kessel *et al.* 1998).

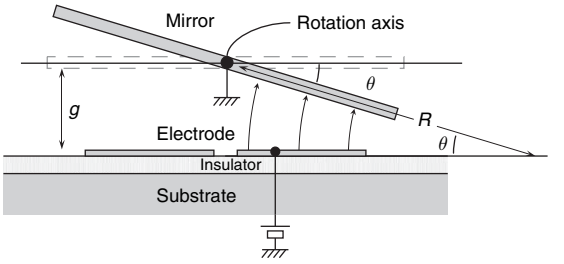

Figure 29 Analytical model for electrostatic torsion mirror actuator.

An analytical model for the torsion mirror actuator is illustrated in **Figure 29**. Usually, the mirror plate is suspended at the center axis with a pair of torsion bars, and drive electrodes are located underneath, on the counter-substrate. The drive electrodes are made shorter in width than the mirror to avoid short circuit upon the mirror's pull-in contact. A simple analytical model for the electrostatic torsion mirror was presented by Toshiyoshi *et al.* (Toshiyoshi and Fujita 1996, Toshiyoshi *et al.* 2001), by representing the electric field with the coaxial arcs, neglecting the field concentration on the mirror edges. For more detailed analysis, one should use the numerical simulation software with an electromechanical co-solver module (www.conventor.com/, http://intellisense-software.com/). When the mirror of width W and length L (taken normal to the page) is rotated to the counterelectrode by angle θ, the distance between the arc center and the mirror axis is

$$R = \frac{g}{\sin\theta} \qquad [31]$$

where g is the elevation height of the mirror axis measured from the substrate surface. Assuming that the electrostatic field in between the mirror plate and the counterelectrode is represented by an arc, the length of the arc located at position x on the mirror is $(R-x)\theta$. Therefore, the electrostatic field strength is

$$E(x) = \frac{V}{(R-x)\theta} = \frac{V}{\left(\frac{g}{\sin\theta} - x\right)\theta} \qquad [32]$$

where V is the applied voltage. The equation is also valid when $\theta < 0$ (mirror angle of elevation). At an extreme case of $\theta \to 0$, the field is equivalent to that of a parallel plate actuator.

The electrostatic pressure acting on the mirror plate, $\varepsilon_0 E^2/2$, is integrated in the mirror width to produce an electrostatic torque.

$$T_{\text{elec}}(V) = \int_0^W \frac{1}{2}\varepsilon_0 \frac{V^2}{\left[\left(\frac{g}{\sin\theta} - x\right)\theta\right]^2} L\, x\, \mathrm{d}x$$
$$= \frac{\varepsilon_0 L V^2}{2\theta^2}\left\{\frac{W\sin\theta}{g - W\sin\theta} + \log\left(1 - \frac{W}{g}\sin\theta\right)\right\} \quad [33]$$

For $|\theta| << 1$, we take an expanded form

$$T_{\text{elec}}(V) = \frac{\varepsilon_0 L V^2}{2\theta^2}\left\{\frac{1}{2}\left(\frac{W\sin\theta}{g}\right)^2 + \frac{2}{3}\left(\frac{W\sin\theta}{g}\right)^3\right\} + O(\theta^2) \quad [34]$$

to avoid the divergence in numerical calculation.

On the contrary, the restoring torque of the torsion beams of a rectangular cross section is given as:

$$T_{\text{mech}} = 2 \times \frac{G\, a\, b^3}{3\, l}\theta\left\{1 - \frac{192}{\pi^5}\frac{b}{a}\tanh\left(\frac{\pi a}{2b}\right)\right\} \quad [35]$$

where $a \times b$ is the section area of the beam, taking $a > b$, and G is the shear stress of rigidity (62.1 GPa for silicon). By numerically computing the equation $T_{\text{elec}}(V) = T_{\text{mech}}$, one will obtain the mirror angle as a function of drive voltage. As torsion mirror is a variation of parallel plate mechanism, the motion is restricted by the electrostatic pull-in effect. For a small angle design, the maximum mirror angle is limited by the pull-in contact at θ/g. Like a parallel plate mechanism, coincidentally, the pull-in contact is nearly 1/3 of the contact angle, which has been experimentally observed (Isamoto *et al.* 2004).

A large torsion angle upward of 90° can also be possible by using flexible torsion bars. Takahashi *et al.* reported a thin single-crystal silicon beam only 0.5 μm thick, 2 μm wide, and 500 μm long to support a 500 μm × 1000 μm plate that tilted to almost 90°, as shown in **Figure 30**. They used the sidewall of the through-hole underneath the torsion mirror plate and manufactured an electrically addressable microshutter array for an infrared spectroscope (Takahashi *et al.* 2006b).

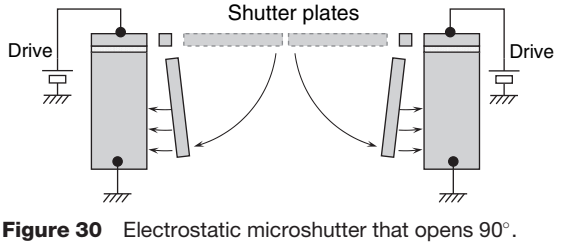

Figure 30 Electrostatic microshutter that opens 90°.

2.01.5.2 Torsional Motion Combined with Vertical Motion

When the suspensions have small rigidity in the up/down motion of the plate, the torsional motion is accompanied by the vertical piston motion of the plate. By taking advantage of the mechanical linearity in a small displacement range, we simply use simultaneous equations that take the vertical and the rotational motion into account. For the torsional motion, eqns [33] and [35] are modified to be

$$\begin{cases} T_{\text{elec}}(\theta, z, V) = \displaystyle\int_0^W \frac{1}{2}\varepsilon_0 \frac{V^2}{\left[\left(\frac{g-z}{\sin\theta} - x\right)\theta\right]^2} L\, x\, \mathrm{d}x \\ T_{\text{mech}}(\theta) = 2 \times \dfrac{G\, a\, b^3}{3\, l}\theta\left\{1 - \dfrac{192}{\pi^5}\dfrac{b}{a}\tanh\left(\dfrac{\pi a}{2b}\right)\right\} \end{cases} \quad [36]$$

The plate height has been changed from g to $g - z$, where z is the mean downward displacement of the plate. The force balance in the vertical direction should be simultaneously considered. The electrostatic force can be obtained by integrating the cosine component of the electrostatic pressure acting normal onto the plate.

$$\begin{cases} F_{\text{elec}}(\theta, z, V) = \displaystyle\int_0^W \frac{1}{2}\varepsilon_0 \frac{V^2}{\left[\left(\frac{g-z}{\sin\theta} - x\right)\theta\right]^2} L\cos\theta\, \mathrm{d}x, \\ F_z(z) = k_z\, z \end{cases} \quad [37]$$

where k_z is the rigidity of the suspension in the vertical direction.

By simultaneously solving eqns [36] and [37], one would obtain the angle θ and the downward displacement z at an equilibrium point under a given voltage. In a small angle operation (~1°), the analytical model agreed fairly well with the experimental results, as reported by Isamoto *et al.* (2004).

2.01.5.3 Double-gimbal Torsion Mirror

An analytical model that was extended to a 2D torsion mirror was reported by Toshiyoshi *et al.* (Toshiyoshi and Fujita 1996). **Figure 31** shows the SEM image of the 2D scanner made by the silicon surface micromachining technique MUMPs (www.memscap.com/). The mirror plate (400 μm × 400 μm in area and 1.5 μm in thickness) was suspended by the double-gimbal structure that consisted of two pairs of torsion bars of 2 μm wide, 1.5 μm thick, and 200 μm long. The micromirror and the frame were suspended above the

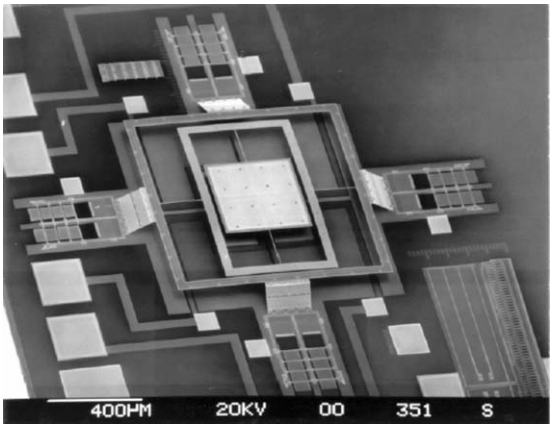

Figure 31 Double-gimbal electrostatic torsion mirror. (Source: Toshiyoshi H, Piyawattanametha W, Chan C-T, Wu M C 2001 Linearization of electrostatically actuated surface micromachined 2-D optical scanner. *J. Miroelectromech. Syst.* **10(2)**, 205–14.)

substrate by an air gap of 72 µm, using the microelevator self-assembly (MESA) technique developed by Li *et al.* (Fan *et al.* 1997). All the suspended structures were electrically grounded, and the scan angles were electrically controlled by using four voltages applied to the quadrant electrodes underneath the mirror. In recent study, Tsai and Wu (2005) reported a gimballess 2D scanner by using the Sandia National Laboratories' SUMMiT V Process.

For analyzing the 2D tilting motion, the coordinate conversion is used to find a position on the mirror after 2D rotation. The origin of the coordinate XYZ is set at the center of the mirror, and it is rotated with the mirror around the Y-axis by angle ϕ, leaving a new coordinate frame $X'Y'Z'$ at the initial place. After the ϕ rotation, A point (x, y, z) on the mirror is transferred to a new coordinate (x', y', z') in the frame $X'Y'Z'$. The new coordinate is written by using a transfer matrix of rotation as

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \mathbf{M}_\phi \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} \cos\phi & 0 & \sin\phi \\ 0 & 1 & 0 \\ -\sin\phi & & \cos\phi \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} \quad [38]$$

For the θ scan around the X axis, we use

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \mathbf{M}_\theta \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & -\sin\theta \\ 0 & \sin\theta & \cos\theta \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} \quad [39]$$

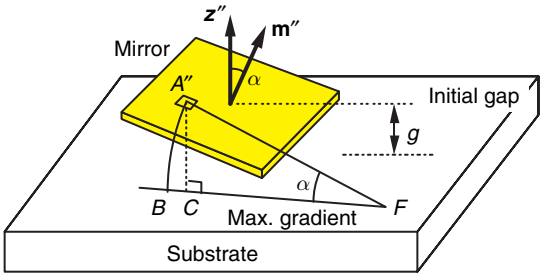

Figure 32 2D torsion mirror after rotation.

Due to the rotation mechanism shown in Figure 32, we first use the ϕ rotation and then θ rotation, i.e., the transfer matrix would be

$$\mathbf{M} = \mathbf{M}_\theta \mathbf{M}_\phi = \begin{pmatrix} \cos\phi & 0 & \sin\phi \\ \sin\theta\sin\phi & \cos\theta & -\sin\theta\cos\phi \\ -\cos\theta\sin\phi & \sin\theta & \cos\theta\cos\phi \end{pmatrix} \quad [40]$$

By using the transfer matrix [40], we calculate an element of small area (dS) on the mirror at point $A = (x, y, 0)$ and its normal vector $\mathbf{m} = (0, 0, 1)$ to be transferred to

$$A'' = (x\cos\phi, x\sin\theta\sin\phi + y\cos\theta, -x\cos\theta\sin\phi + y\sin\theta) \quad [41]$$

and

$$\mathrm{m}'' = (\sin\phi, -\sin\theta\cos\phi, \cos\theta\cos\phi) \quad [42]$$

respectively. The maximum slope angle α of the mirror measured with respect to the substrate surface is calculated by the inner product of $\mathbf{m}''$ and the substrate normal $\mathbf{z}'' = (0, 0, 1)$, and thus,

$$\cos\alpha = \mathbf{m}'' \cdot \mathbf{z}'' = \cos\theta\cos\phi \quad [43]$$

Therefore, angle α is calculated to be

$$\alpha = \cos^{-1}(\cos\theta\cos\phi) \quad [44]$$

We assume an electric field in the shape of arc, as discussed in the previous section for the 1D torsion mirror. As shown in Figure 32, the arc length at point A on the mirror is calculated to be

$$\widehat{A} = \frac{g + A''_z - z}{\sin\alpha}\alpha \quad [45]$$

where g is the initial height of the mirror, z the downward displacement caused by the mean electrostatic force, and A''_z the Z-component of point A on the mirror.

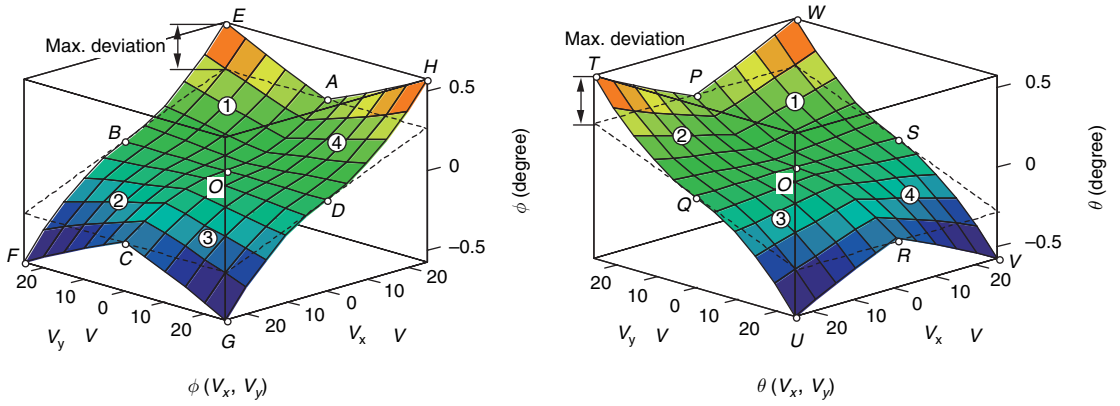

Figure 33 Simulated results of angle–voltage characteristics of the 2D torsion mirror.

Therefore, the electric field is

$$E = \frac{V}{\widehat{A}} = \frac{V}{\dfrac{g + A''_z - z}{\sin\alpha}\cdot\alpha} = \frac{\sin\alpha}{\alpha}\cdot\frac{V}{g - x - x\cos\theta\sin\phi + y\sin\theta} \quad [46]$$

The electrostatic force action on the element is written as

$$dF = \frac{1}{2}\varepsilon_0 E^2\, dS = \frac{1}{2}\varepsilon_0\left(\frac{\sin\alpha}{\alpha}\cdot\frac{V}{g - x - x\cos\theta\sin\phi + y\sin\theta}\right)^2 dS \quad [47]$$

Hence, the electrostatic torques for ϕ- and θ-scan are

$$T_\phi(\phi,\theta,V) = \iint_S \frac{1}{2}\varepsilon_0 x \times\left(\frac{\sin\alpha}{\alpha}\cdot\frac{V}{g - x - x\cos\theta\sin\phi + y\sin\theta}\right)^2 dS \quad [48]$$

and

$$T_\theta(\phi,\theta,V) = \iint_S \frac{1}{2}\varepsilon_0(-y) \times\left(\frac{\sin\alpha}{\alpha}\cdot\frac{V}{g - x - x\cos\theta\sin\phi + y\sin\theta}\right)^2 dS \quad [49]$$

respectively. The negative sign of $(-y)$ in the second equation is due to the definition of angle θ. Contribution from the four electrodes should be summed to calculate the net electrostatic torque. The range of integration for each voltage contribution is taken to be equal to the corresponding electrode area, based on the assumption of the arc-shaped electric field. The electrostatic torques are compared with elastic restoring torque to find equilibrium angles (ϕ, θ) at a given voltage, as shown in **Figure 33**. Toshiyoshi *et al.* (2001) also deal with the vertical motion $-Z$ of the mirror plate. They also demonstrated that the differential voltage scheme worked with the 2D torsion mirror to linearize the angles with respect to the voltage sets.

2.01.6 Vertical Comb-drive Actuators

2.01.6.1 Out-of-plane Motion

Careful measurement of a comb-drive actuator reveals a small out-of-plane (up-and-down) motion along with a large lateral stroke. The parasitic out-of-plane motion is actually due to the presence of the substrate plane that is set at the same potential as the suspended structure, resulting in an asymmetric electric field distribution across the substrate plane. As **Figure 34** illustrates, the bottom side of the suspended structure does not have electric field but there is an electric field on the top surfaces, which causes a small pull-up motion.

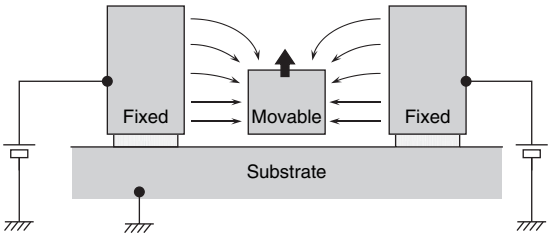

Figure 34 Cross-sectional view of comb-drive mechanism with ground plane.

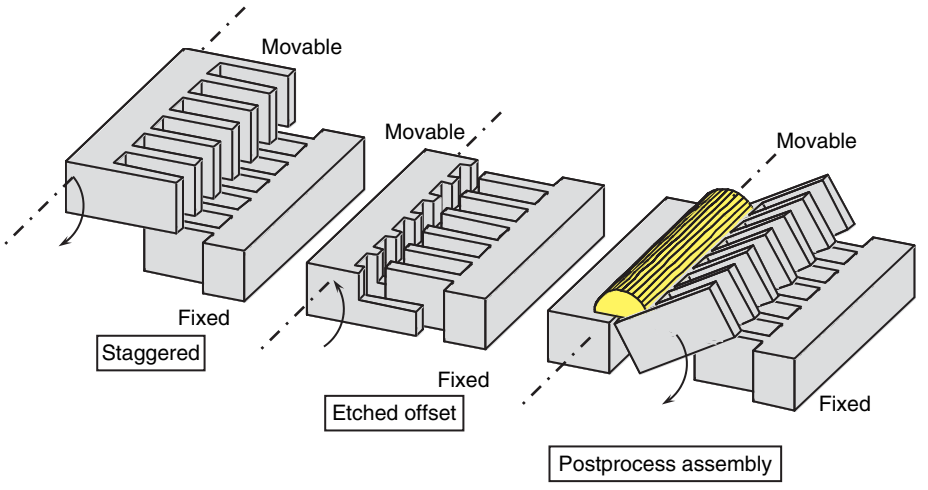

Figure 35 Vertical comb-drive actuation electrodes.

The lateral comb drive was later modified to a vertical comb-drive mechanism that effectively produces large out-of-plane rotational motion with a given device footprint. Several designs of vertical comb-drive actuators were reported, as listed in **Figure 35**. A staggered comb layout is an early version of vertical comb-drive actuators, using the top and the bottom silicon layers of an SOI wafer, for instance, to develop the comb electrodes (Conant 2003). The structure is made by the double-side photolithography and deep reactive ion etching (DRIE) process of silicon, and therefore, the electrostatic operation results are sensitive to the misalignment between the top and the bottom electrode patterns. Optical scanners with staggered combs, as shown in **Figure 36**, were developed by Fujitsu Co. for a free space optical crossconnect application (Yano *et al.* 2005). They thinned down the carrier wafer (the bottom part) of an SOI wafer to 100 μm thickness so that the actuators can be produced by using the silicon DRIE technique. Double-step etching of silicon can also be used to make vertical comb electrodes with height offset. Zicker *et al.* used a combination of the aluminum and photoresist masks to make a height offset (Zicker *et al.* 2002). Patterson *et al.* (2002) and Piyawattanametha *et al.* (2005) reported a postprocess assembly technique for comb-drive offset. They used the surface tension force of thermally reflow photoresist to lift one of the comb pair. Kim *et al.* with the University of California at Berkeley used an accelerated silicon creep at an elevated temperature (900°C) to make a comb offset (Kim *et al.* 2005). Process-stiction of an SOI microstructure onto the substrate can also be used (Isamoto *et al.* 2005), which is easy and reproducible compared with other methods, thanks to the precisely controlled BOX (buried oxide) thickness of a bonded SOI wafer.

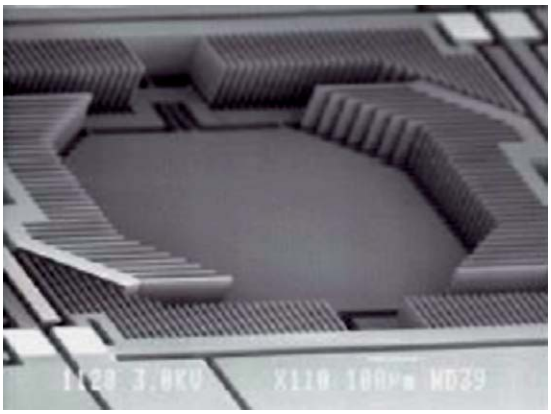

Figure 36 An example of microelectromechanical systems (MEMS) devices equipped with vertical comb-drive mechanism. (Source: Yano M, Yamagishi F, Tsuda T 2005 Optical MEMS for photonic switching – compact, stable optical crossconnect switches for simple, fast, flexible wavelength applications in recent photonic networks. *IEEE J. Sel. Top. Quantum Electron.* **11(2)**, 383–94.)

2.01.6.2 Analytical Model for Vertical-comb Drive

The electromechanical structure of a vertical-comb-driven torsion mirror is complicated compared with that of a simple parallel plate mechanism, and it is suggested that readers use a FEM software that is adapted to the MEMS technology for accuracy. Nevertheless, analytical model presented is useful to obtain a first-order picture of the actuator's

electromechanical behavior. In this section, we study the staggered comb of a uniform comb height by using a simplified model shown in **Figure 37**.

The upper electrodes are fixed, while the lower electrode is suspended to move in the vertical direction Y. The comb displacement y is measured by the position of the movable comb's top surface, taking the origin $y = 0$ aligned at the bottom position of the fixed combs. Assuming that the electrical capacitance C is represented by the overlap area between the electrodes, i.e., by neglecting the field concentration on the comb corners, one would write the capacitance (on both the sides of the comb) as

$$C(y) = \begin{cases} 0 \ (y < 0) \\ 2\varepsilon_0 \dfrac{y}{g} \ (0 < y < h) \\ 2\,\varepsilon_0 \dfrac{2h - y}{g} \ (0 < y < 2h) \\ 0 \ (y < 2h) \end{cases} \qquad [50]$$

where g is the lateral gap between the combs and h the height of the comb finger. Note that we have taken the unit length of the comb (normal to the page surface) to calculate the capacitance. **Figure 37** plots the capacitance of the comb as a function of the movable comb position (solid curve). In the same plot, a numerically calculated capacitance is shown (dashed curve), which has a finite value of capacitance even when the movable comb is not engaged between the fixed ones and has smooth connection in this range. However, the capacitance slope is found to be in parallel with that of the analytical model in the range of $0 < y < 2h$. Remembering that the electrostatic force is proportional to the derivative of capacitance, the analytical model is expected to be in good agreement with the actual device.

The torque contributed by a small fraction of such comb electrodes located at a distance x measured from the rotation axis is represented by

$$\frac{1}{2}\frac{\mathrm{d}C(y)}{\mathrm{d}y} V^2 x \, \mathrm{d}x$$

where $\mathrm{d}x$ is the comb length measured in the direction normal to the page surface. We integrate the contribution along the comb finger and multiply it with the comb number N to obtain the electrostatic torque:

$$T_{\mathrm{elec}}(\theta, V) = N \int_{x_0}^{x_0 + t} \frac{1}{2}\frac{\mathrm{d}C(x\theta)}{\mathrm{d}y} V^2 x \, \mathrm{d}x \qquad [51]$$

where the local comb position y has been replaced with the product of the comb angle θ and the position of the section x, i.e., $y = x\theta$.

The torque is compared with the mechanical restoring torque, eqn [35], to obtain the angle as a function of applied voltage.

Figure 38 shows a typical simulation result of a torsion mirror with vertical comb-drive actuators. The angle is saturated at high voltage, because the mean electrostatic capacitance takes its maximum value when the movable comb electrode is fully engaged in the fixed electrodes, and therefore, a thicker layer should be used to make taller electrodes to tilt the comb electrodes more. For achieving a large scan angle at resonance, Yoda *et al.* (2005) reported a two-mass-two-spring system to magnify the small amplitude a vertical-comb plate to make a large oscillation of the scanning mirror.

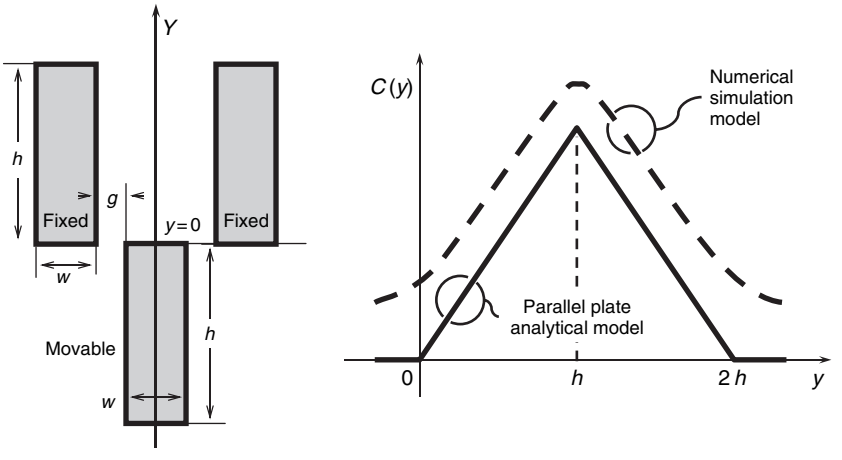

Figure 37 Simplified analytical model for staggered comb drive.

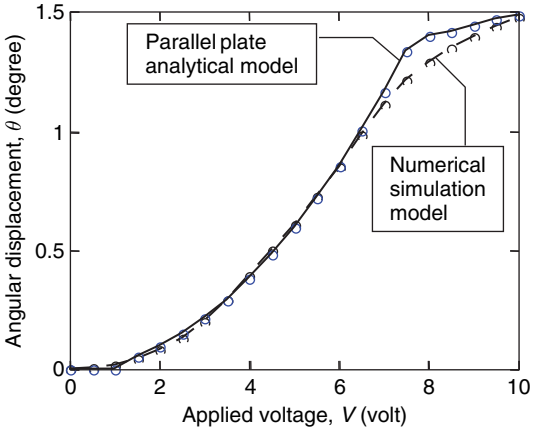

Figure 38 Simulation result of vertical-comb mirror angle as a function of drive voltage.

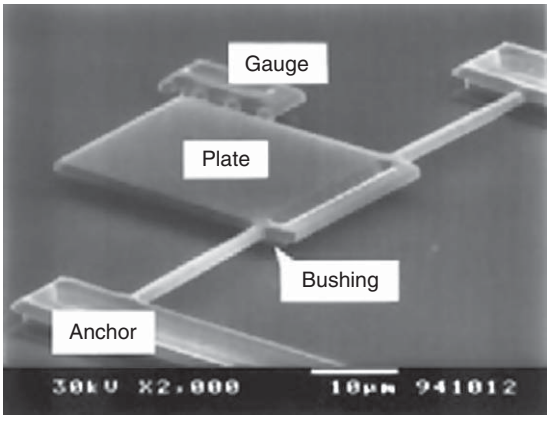

Figure 39 Scratch-drive actuator (SDA). (Source: Akiyama T, Shono K 1993 Controlled stepwise motion in polysilicon microstructures. *J. Microelectromech. Syst.* **2(3)**, 106–10.)

Eqn [51] suggests that the electrostatic torque can be made large by using many comb fingers in a given area, i.e., by increasing the comb finger density. Designing a thin comb finger and a small air gap will increase the density. Small air gaps also help increase the electrostatic force. However, one should be warned that the small-gap comb electrodes are likely to fall into the lateral pull-in instability. A suspended structure experiences an in-plane electrostatic torque rather than an out-of-plane torque and makes the comb fingers trip to the other, resulting in mechanical stop and electrical short circuit. To overcome this problem, Fujitsu Co. used V-shaped suspensions by combining two straight beams with a relatively large opening on the mirror side and a small pointing root on the fixed anchor (Yano *et al.* 2005). The V-shaped suspensions were found to have large lateral rigidity and small rotational rigidity. They used such optical scanner array to manufacture a fiber-optic crossconnect of 128 input ports and 128 output ports(Yano *et al.* 2005).

2.01.7 Scratch-drive Actuators

2.01.7.1 Tethered Linear Actuation

Most MEMS actuators are made to be tethered to the substrate via elastic suspensions, which is useful to minimize the friction force associated with the mechanical motion. However, friction was also found to be a useful tool to make a powerful microactuation mechanism. Akiyama and Shono (1993) invented a novel electrostatic linear actuator called a scratch-drive actuator (SDA) that stepped forward with a pulse voltage like an inchworm.

The actuator is made with a polysilicon plate of typical 100 μm × 100 μm in area and 1–2 μm in thickness, as shown in **Figure 39**. The leading edge of the plate has a bushing on the bottom, placed on a silicon substrate with a thin layer of silicon nitride (insulator) in between. Drive principle is a repetition of the following steps: (1) When a voltage (typical 20–100 V) was applied to the plate through the polysilicon tether, the actuator plate deflected downward to the substrate by the electrostatic attractive force. Due to the strong friction between the actuator plate and the substrate, the tail of the plate was pinned down to the substrate, while the point-contact bushing on the leading edge was forced to slide forward with a small increment in a 10- to 30-nm range. (2) When the voltage dropped to zero, the actuator plate was released from the substrate and it bounced upward. At this moment, the plate was dragged forward to the bushing because the rotation pivot was at the bushing contact. (3) The actuator plate was immediately pulled down again by the next voltage peak to keep the position. The repetition of Steps (1) to (3) enables the actuator plate to move forward. The SDA in **Figure 39** showed a travel distance of 50 μm. Traveling speed was controlled by tuning the frequency of the pulse voltage in the range of 1 Hz to 100 kHz.

Higher output force is possible by making an array of SDAs in one sheet. Minotti *et al.* integrated more than 1000 pieces of SDA plates in a polysilicon sheet of 2 mm × 3 mm, as shown in **Figure 40**. Assuming a 100-μN output from a single SDA plate, the total

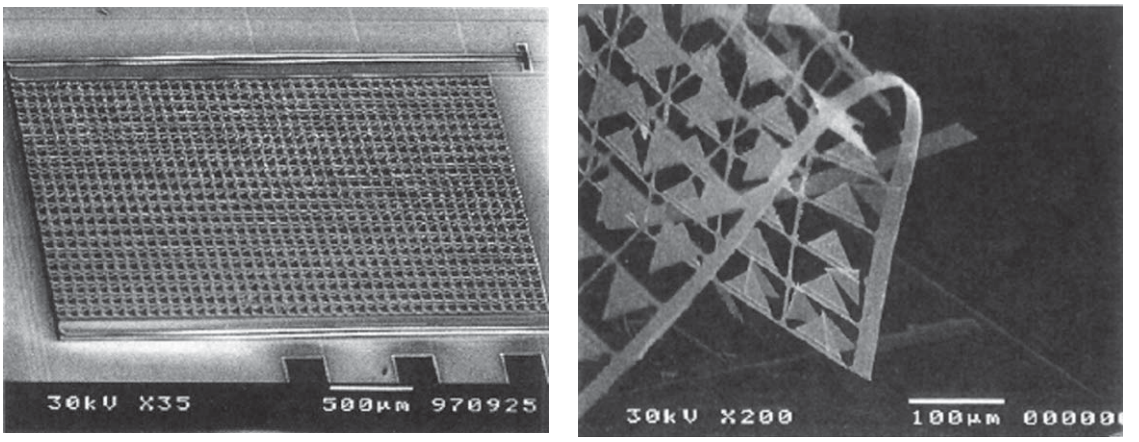

Figure 40 Sheet of arrayed scratch-drive actuators (SDAs). (Source: Minotti P, Langlet P, Bourbon G, and Masuzawa T 1998 Towards new cylindrical electrostatic micromotors using tubular combinations of arrayed direct drive actuators. *Jpn. J. Appl. Phys.* 37 part 2: L622–5.)

output force was estimated to be 0.1 N or 10 g; this implies that the SDA can hold a load mass of 10^6 times its own weight.

2.01.7.2 Self-assembly Using SDA

The output force of the SDA was found to be stronger than other electrostatic microactuators. Akiyama also demonstrated a lift-up motion of a micropiece of quartz (~1 mm) by using a single SDA of 60 µm × 75 µm operated at 110 V (Akiyama and Shono 1993). From this experiment, he estimated the actuator force output to be more than 50 µN. SDA was found to be a useful built-in actuator to self-assemble 3D microstructures after sacrificial release. **Figure 41** shows an example of such 3D microstructure of polysilicon that was elastically deformed by the SDA array (Akiyama *et al.* 1997).

In Akiyama's first demonstration, the SDA plate was elastically tethered by the polysilicon hinges, which were also used as an electrical interconnection to the SDA plate. However, the travel distance of the SDA plate was limited by the elastic restoring force of the springs. A nontethered version of SDAs was reported by Li *et al.* with the University of California at Los Angeles (UCLA) in 1997 (Fan *et al.* 1997). They used the polysilicon surface micromachining of multiuser MEMS processes (MUMPs) to develop the chain of SDA plates that were mechanically guided by the stapled rails (Fan *et al.* 1997), also integrated with a 3D hinged structure (Pister *et al.* 1992). They put a microball lens of 300 µm in diameter in the socket plate and jacked it upward by more than 100 µm using the force of SDA modules, as shown in **Figure 42**. Both vertical *Z*-direction and lateral *X*- and *Y*-directions were controlled by the SDA arrays. Thanks to the multilayered structure of the MUMPs, the drive voltage was applied through

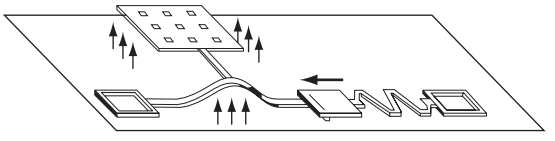

Figure 41 Self-assembled 3D microstructure using scratch-drive actuator (SDA). (Source: Akiyama T, Collard D, Fujita H 1997 Scratch drive actuator with mechanical links for self-assembly of three-dimensional MEMS. *J. Microelectromech. Syst.* **6**, 10–17.)

(Source: Fan L, Wu M C, Choquette K, Crawford M 1997 Self-assembled microfabricated XYZ stages for optical scanning, alignment. *Proc. Int. Conf. Solid-State Sensors and Actuators (Transducers 97)*, Chicago, IL, USA, June 16–19, 1997, pp. 166–22.)

the underlying thin polysilicon layer (called poly-0), keeping the SDA plate and the rest of the structure at the electrical ground. Li *et al.* also developed a bidirectional SDA module by connecting a pair of oppositely directed SDAs; micropatterns of photoresist were used to mechanically bind the SDAs and also to electrically decouple them.

2.01.8 Electrostatic Impact-drive Actuators

2.01.8.1 Inchworm Actuation

The prototype model of micromechanical impact-drive actuator, presented by Higuchi *et al.* with the University of Tokyo in 1987, also used the friction to keep the position and to generate thrust force (Higuchi *et al.* 1988). They used a pair of metal blocks (several centimeters large) combined with a piezoelectric PbZrTi (lead zirconium titanate, PZT) actuator and demonstrated step motion by using pulse and ramp voltages. The step motion was found to be in nanometric range, and thus, they could use the mechanism to position the probe tip of, for instance, atomic force or tunneling microscope.

2.01.8.2 MEMS Inchworm

A MEMS version of impact-drive actuator, an electrostatic impact-drive mechanism (EIM), was reported by Mita *et al.* (2003) with the University of Tokyo in 2003. **Figure 43** illustrates the actuation principle of the EIM, where a silicon hammer is suspended with an elastic spring in a square shell made by the silicon micromachining. The mass was designed to be a movable electrode in an electrostatic actuator, and the wall on the opposing side was used as a counterelectrode. The pulse voltage applied to the counterelectrode attracted the mass by the electrostatic pull-in mechanism. The kinetic energy gained by the electrostatically accelerated mass was transferred to the shell by collision. When the impact force exceeded the friction force, the entire shell box moved forward until all the kinetic energy was consumed. The cycle was repeated by modestly retracting the mass by releasing the voltage.

Figure 44 shows a SEM image of the microfabricated EIM actuator. The silicon hammer in the middle had two masses on both sides, and the elastic suspensions were accommodated in the notched part in the middle. The drive electrodes were located on

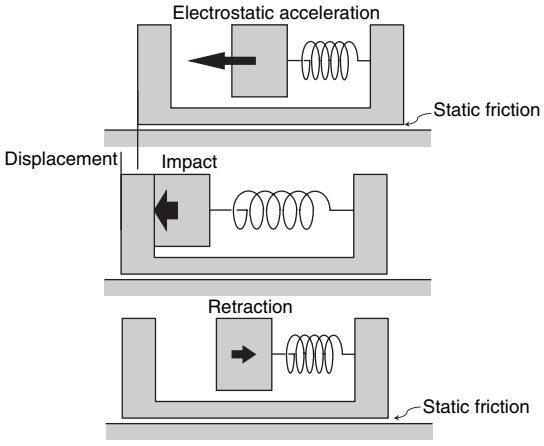

Figure 43 Operation steps of an electrostatic impact-drive mechanism (EIM). (Source: Mita M, Arai M, Tensaka S, Kobayashi D, Fujita H 2003 A micromachined impact microactuator driven by electrostatic force. *J. Microelectromech. Syst.* **12**, 37–41.)

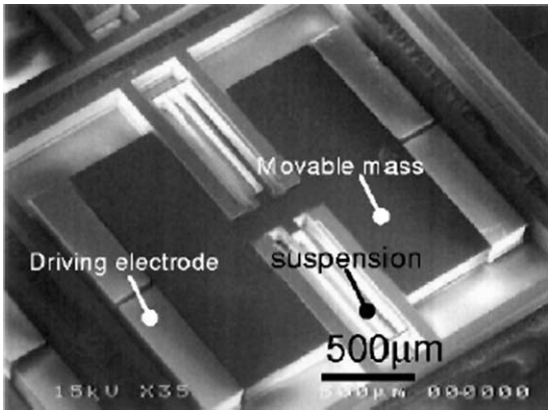

Figure 44 Scanning electron microscopic (SEM) image of microelectromechanical systems (MEMS) impact-drive actuator. (Source: Mita M, Arai M, Tensaka S, Kobayashi D, Fujita H 2003 A micromachined impact microactuator driven by electrostatic force. *J. Microelectromech. Syst.* **12**, 37–41.)

both sides of the hammer, by which bidirectional motion could be achieved. The stopper for the hammer was located in the middle part, rather than the hammer edge, in order to have a large electrode area for higher driving force. The device was made by bulk micromachining a silicon wafer with DRIE. The entire mechanism was hermetically sealed by the wafer bonding technique, and the electrical interconnection was made by using thin gold thread of wire bonding. The impact actuation was found to be powerful that gives unlimited travel distance regardless of the tethering wires. With a sinusoidal voltage of 100 V_p at 200 Hz, the module traveled at 2.7 $\mu m\, s^{-1}$,

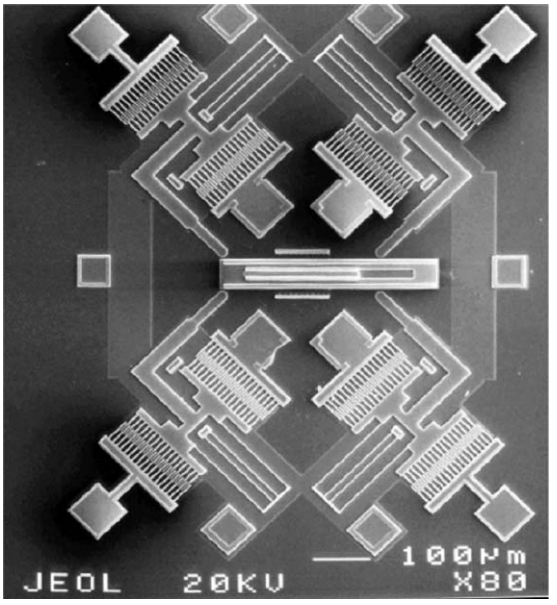

Figure 45 Micromechanical sliders using impact drivers. (Source: Daneman M J, Tien N C, Solgaard O, Pisano A P, Lau K Y, Muller R S 1996 Linear microvibromotor for positioning optical components. *J. Microelectromech. Syst.* **5(3)**, 159–65.)

with minimum step of 13 nm. The authors expected wireless control of the EIM by integrating a power transmitting module in the package.

The impact-drive mechanism was also used to develop a micromechanism of a slider. Pisano *et al.* with the University of California at Berkeley developed a bidirectional linear slider by using four sets of comb-drive impact actuators with a hammer head, as shown in **Figure 45** (Daneman *et al.* 1996). They demonstrated a slider speed of $1\,\mathrm{mm\,s^{-1}}$ with a 0.27-μm step by applying pulse voltages of 12.5 V at 7 kHz. Pai *et al.* used a similar mechanism but with electrothermal actuators to compose an optical fiber switch (Pai and Tien 1997). They used the microhinge technology to integrate a vertical reflector sitting on the slider. The mirror was driven in and out to change the optical path in a small free space between four optical fiber facets.

2.01.9 Electret Actuators

2.01.9.1 Use of Repulsive Coulomb Force

All the electric actuators discussed in the previous sections utilize the attractive Coulomb force between oppositely charged bodies. Electrostatic repulsive force can also be seen in, for instance, an electroscope, which is a simple device consisting of a metal piece sticking out of a glass jar with thin leaves of metal hanging inside. When the external metal piece is touched by a charged body, the leaves spread apart by the Coulomb force. However, the charge on the metal body cannot be fixed permanently, and a relatively large voltage is needed for charging.

2.01.9.2 Electret by Corona Discharge

True charge can be permanently trapped in dielectric material by the corona discharge or by the poling process at temperature higher than glass transition point. The first electret motor was developed in a macroscale by Gubkin in 1961 (Jefimenko 1973). The rotor consisted of a pair of electrets that had been polarized in the opposite directions, and the rotating position was electrostatically controlled by using the metal stator electrodes. Later, Jefimenko *et al.* reported another type of electret motor by using the electret material on the stators and by biasing the rotor (Jefimenko 1973). In the micromechanical scale, Wood *et al.* (1987) used a negatively charged plastic film on an optical fiber to control the position by the electrostatic force.

2.01.10 Film Actuators

2.01.10.1 Electrostatic Induction

Electrostatic induction has been known for a long time. Riccardo Arno invented a macroscale induction motor in 1892, by using the polarization in a dielectric material. A dielectric rotor (an ebonite rod of 8 cm in diameter and 18 cm in length) placed in a rotating electric field built up the polarization by electrostatic induction. Due to the rotation of the electric field and the dielectric response delay of the material, the polarization direction had a small angular offset with respect to the turning electric field, causing a torque on the rotor. Arno used a high voltage of 3.8 kV to demonstrate a rotation speed of 250 rpm and output torque on the order of 10^{-4} Nm.

2.01.10.2 Flexible Film Actuators

The charge trapped in a dielectric material disappears by discharge, and hence, the electromechanical performance of an electret actuator may drift with aging. Egawa *et al.* reported a highly reproducible electrostatic repulsive force by using an instantaneously induced charge on a highly resistive film (Egawa and Higuchi 1990).

Figure 46 illustrates the side view and the step motion of the film actuator. The stator was made of a flexible printed circuit board (PCB) with triphase

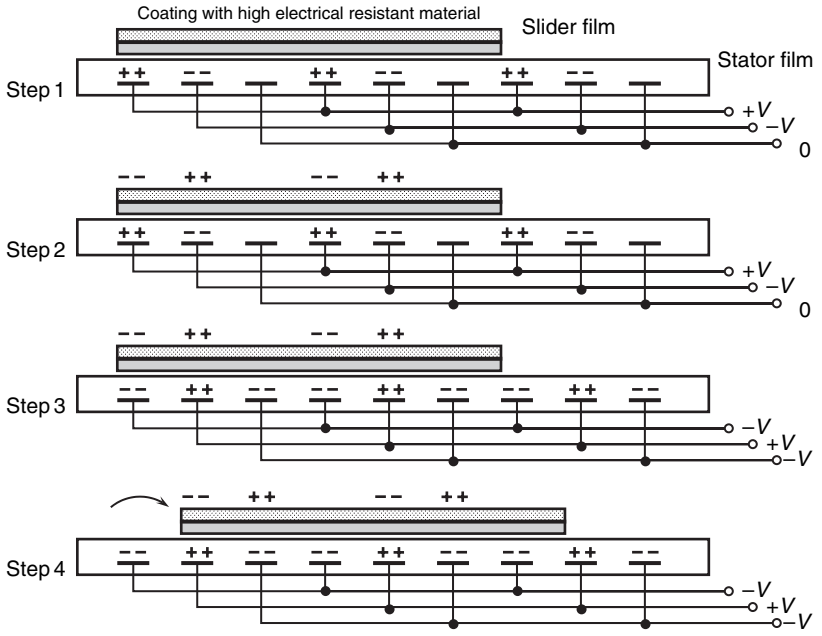

Figure 46 Operation steps of film actuator using electrostatically induction. (Source: Egawa S, Higuchi T 1990 Multi-layered electrostatic film actuator. *Proc. IEEE Micro Electro Mechanical Systems Workshop*, Napa Valley, CA, USA, February 11–14, 1990, pp. 166–71.)

electrodes embedded inside. The slider is a piece of plastic film coated with a material of high electric resistance. In the operation Step 1, the electrodes in the stator were biased with voltage. The distributed voltages induced charge on the slider film in Step 2, causing electrostatic attractive force. Due to the high resistance in the coated film, the charge was immobilized for a short time even when the driving voltages were partially flipped as shown in Step 3. At this step, the slider film experienced repulsive force in the vertical direction. At the same time, the film was pulled to the right by the electrostatic attractive force of the distributed charge. As a result, the slider film levitated for a short time to make a gliding inchworm step in the lateral direction. No accurate alignment or positioning was needed to set the slider film, because all the electrode patterns were made in the stator film.

The same authors also reported another type of electrostatic film actuator; different from the previous one, both the films (stator and slider) were made of patterned flexible PCB. Similar sliding motion was observed by using a set of sinusoidal voltage waves of different phases. The advantage of the second film actuator was that it could be made large in area to increase the output force. Furthermore, the films were stacked up to multiply the force in a given area. Egawa developed a stacked film actuator of 50 pairs of sheets and demonstrated 300 N output with a drive voltage of 2 kV. Thanks to the mechanical flexibility of the film, the actuator could be used on a curved surface such as a pillar. They also demonstrated rotational types of electrostatic film actuator.

2.01.11 Pitfalls in Electrostatic Actuation and Hints

2.01.11.1 Displacement–Response Trade-off

Displacement is not a sole parameter to describe the performance of an electrostatic actuator, but the fundamental resonant frequency plays an important role when the actuator is used for high-speed applications such as optical switches and radio frequency waveguide switches. Representing an electromechanical actuator by using a quadratic oscillating system with a mass m and a spring constant k, one would write the fundamental resonant frequency f_0 as

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \qquad [52]$$

Substituting another form of the equation, $k = 4\pi^2 m f_0^2$, into eqn [4], which gives the

equilibrium point of electrostatic force and elastic restoring force, one will obtain a governing equation of a parallel plate actuator:

$$x(g-x)^2 f_0^2 = \frac{\varepsilon_0}{8\pi^2}\frac{S}{m}V^2 \qquad [53]$$

The equation reveals that the electrostatic parallel plate has a built-in trade-off relation between the resonant frequency (speed) and the displacement (Toshiyoshi *et al.* 2002). For a larger displacement, one may need to use a soft spring, but the resonant frequency is lowered. For a fast response of actuator, on the contrary, one would use a hard spring, sacrificing the displacement. We sometimes encounter a difficulty in designing actuators when both speed and displacement are sought for.

MEMS designers are usually given a limited device footprint, material combination, and maximum allowable voltage for operation when they design actuators to meet the device requirements. Prototype devices would be developed in a trial-and-error manner by using a couple of different dimensions for, for instance, the suspension width on a photomask, because the width is a parameter that could easily be altered without causing significant layout change in the device master plan. But changing the suspension width alone may not be enough to improve the performance. **Figure 47** plots a displacement–frequency curve calculated by using the governing eqn [53], taking the suspension width as a plotting parameter. Given a voltage and a gap, one may not be able to escape from the governing curve or to approach the target performance region.

Eqn [53] suggests three parameters to improve the performance, namely, m, g, and V (Toshiyoshi *et al.* 2002). The mass m of the movable part should be designed to be light to improve the response. From a density point of view, silicon is a light material ($\rho = 2.33 \times 10^3\,\mathrm{kg\,m^{-3}}$), compared with metals such as plated nickel ($\rho = 7.2 \times 10^3\,\mathrm{kg\,m^{-3}}$) or even aluminum ($\rho = 2.7 \times 10^3\,\mathrm{kg\,m^{-3}}$). Weight saving by using a honeycomb structure would also be effective (Patterson *et al.* 2000). Using a small electrostatic gap g is helpful to increase the output force of the actuator. For this reason, narrow trench etching by silicon DRIE is highly appreciated for comb-drive mechanisms. High voltage should also be permitted to drive the actuator, because the electrostatic force is proportional to the square of voltage. As an advanced MEMS approach, several works on high-voltage driver circuits integrated with microactuators have been reported (Brosnihan *et al.* 2003, Takahashi *et al.* 2005).

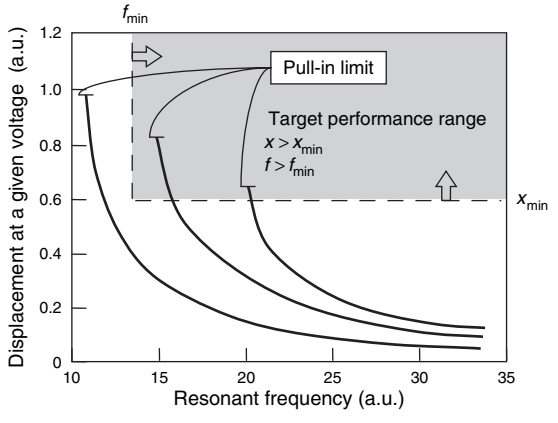

Figure 47 Trade-off relation between resonant frequency and displacement at a given voltage.

2.01.11.2 Doubled-frequency Response

Due to the nature of attractive Coulomb force, electrostatic actuators exhibit static displacement in the gap-closing direction regardless of the polarity of applied voltage, which is usually seen in the frequency range fairly lower than the actuator's resonant frequency, as shown in **Figure 48(a)**. When the input voltage does not have a DC component, the actuator responds to both positive and negative peak voltages, and it seems to have doubled the frequency with respect to that of the input voltage. One should be aware of this nonlinearity when measuring the frequency response of electrostatic actuators. For a better understanding of the actuator's response by suppressing the higher modes, the drive voltage should be accompanied with a DC offset, as shown in **Figure 48(b)**. Note that the AC component of the drive voltage should be small compared with the DC component.

Figure 49 shows the results of numerical simulation of a quadratic oscillation system with an electrostatic force by using the Runge–Kutta method. At a frequency lower than the resonant frequency, the actuator's displacement was limited in the $+X$ range. When the frequency was set to the resonance, the displacement oscillated in both $+X$ and $-X$ directions at the input frequency; also a small offset toward $+X$ was observed in the response. At a frequency higher than the resonance, the amplitude becomes small but a small offset displacement remains in the level.

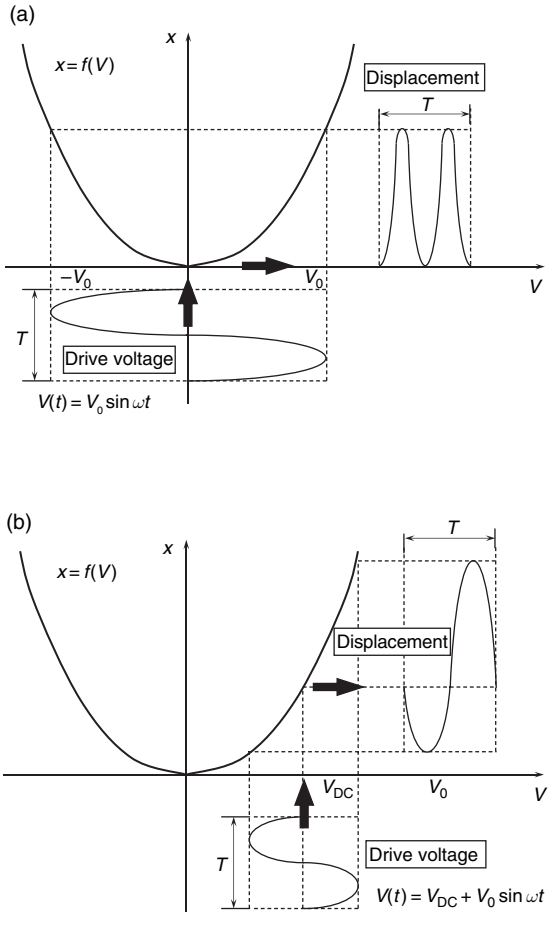

Figure 48 Plot of the transfer function of electrostatic actuator.

2.01.11.3 Pseudostatic Operation at Frequency Higher than Resonance

Thanks to the offset displacement seen in the high-frequency range, electrostatic actuators can be operated by the amplitude-modulated (AM) voltage, as if it were driven by a DC voltage of the same peak value. **Figure 50(a)** and **50(b)** compares the numerically calculated responses to a step-function voltage and an AM voltage, respectively. The AM voltage was designed to have an envelope curve identical to the step function, and its carrier frequency was set to a frequency 100 times higher than the actuator's resonance. The simulation results clearly show that the responses were almost equal to each other, reflecting the envelope shape. The AM voltage drive requires a complicated driver circuit and more power to transmit. Nevertheless, it promises a benefit that no electric charge builds up on the electrodes, and therefore, the actuator's displacement is less likely to drift with time.

2.01.11.4 Negative Spring Constant Effect

Another characteristic of electrostatic actuator is the bias-voltage dependence of its resonant frequency, which tends to shift toward lower frequencies with increase of the bias voltage. **Figure 51** is the experimental result of frequency response of an electrostatic torsion mirror that had a gap-closing electrostatic mechanism between the SOI microstructure and the silicon substrate. The mirror was originally developed for a variable optical attenuator (VOA) of relatively low drive voltages (~5 V) (Isamoto *et al.* 2004). When the mirror was operated at a 1 V AC with increasing bias voltages from 2 to 5 V, the resonant peak was found to shift toward the lower frequency from 750 to 650 Hz (13% down). In a practical scene of the optical fiber system, the lower shift of the resonance results in degraded temporal response in the switching operation of the VOA, in particular at the rising edge of drive voltage.

The phenomenon is known to be a negative spring constant effect or electrostatic soft spring effect (described by the Duffing's equation), which associates with the nonlinear characteristic of the electrostatic actuation. In addition to the elastic restoring force, $k\,x$, the actuator plate is pulled in the opposite direction by the electrostatic attractive force

$$\frac{1}{2}\varepsilon_0 \frac{S}{(g-x)^2} V^2$$

Even though the bias voltage is fixed at a constant value, the static force increases its strength as the displacement x approaches the pull-in displacement. Therefore, the actuator plate at a biased position looks as if it is suspended with a spring of reduced rigidity, resulting in the shift of resonance toward the lower frequency.

The negative spring constant effect becomes a problem when a fast response of the actuator is sought for at relatively large displacement, or when one measures the resonant frequency in a physical sensor. The benefit of the negative spring constant effect is that it could be used to electrically tune the mechanical resonance of a MEMS oscillator.

Hysteresis is also observed in the frequency response of electrostatic actuator, when it oscillates at a large amplitude. **Figure 52** shows the frequency response curve. Due to the negative spring constant

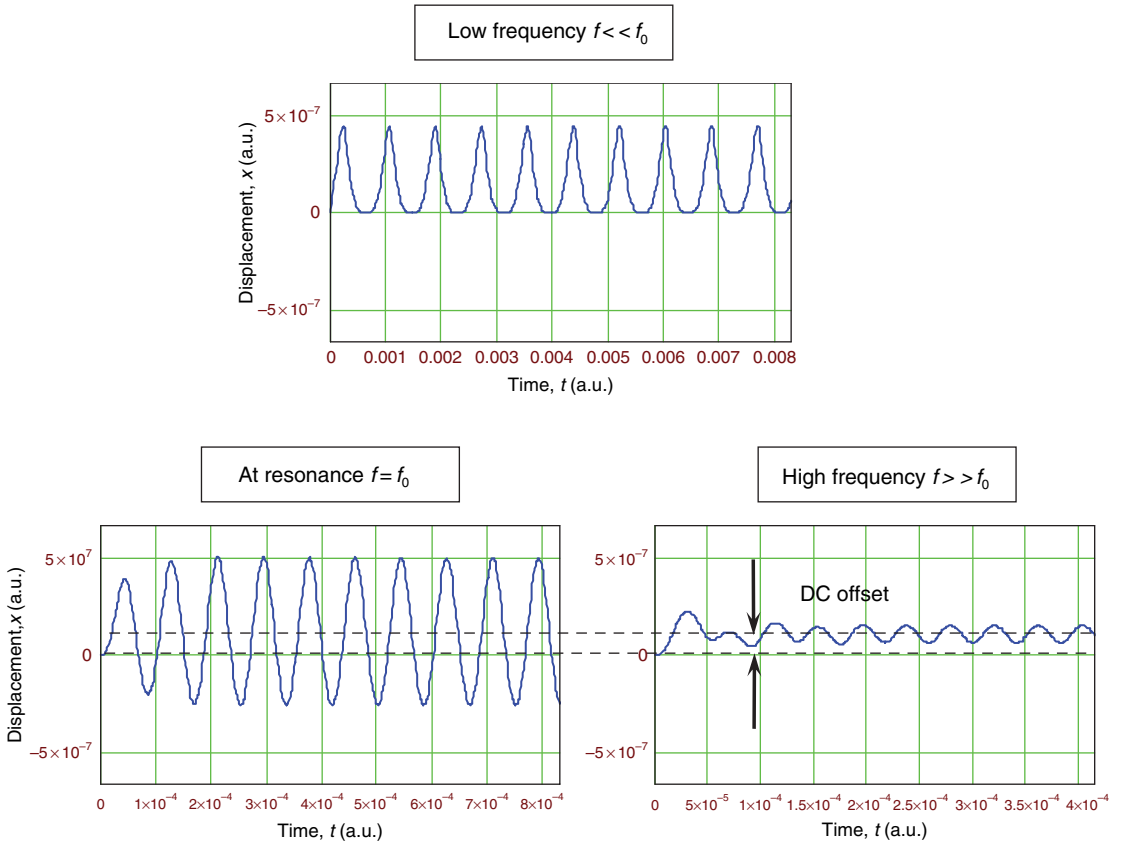

Figure 49 Response of electrostatic actuators in different frequency ranges.

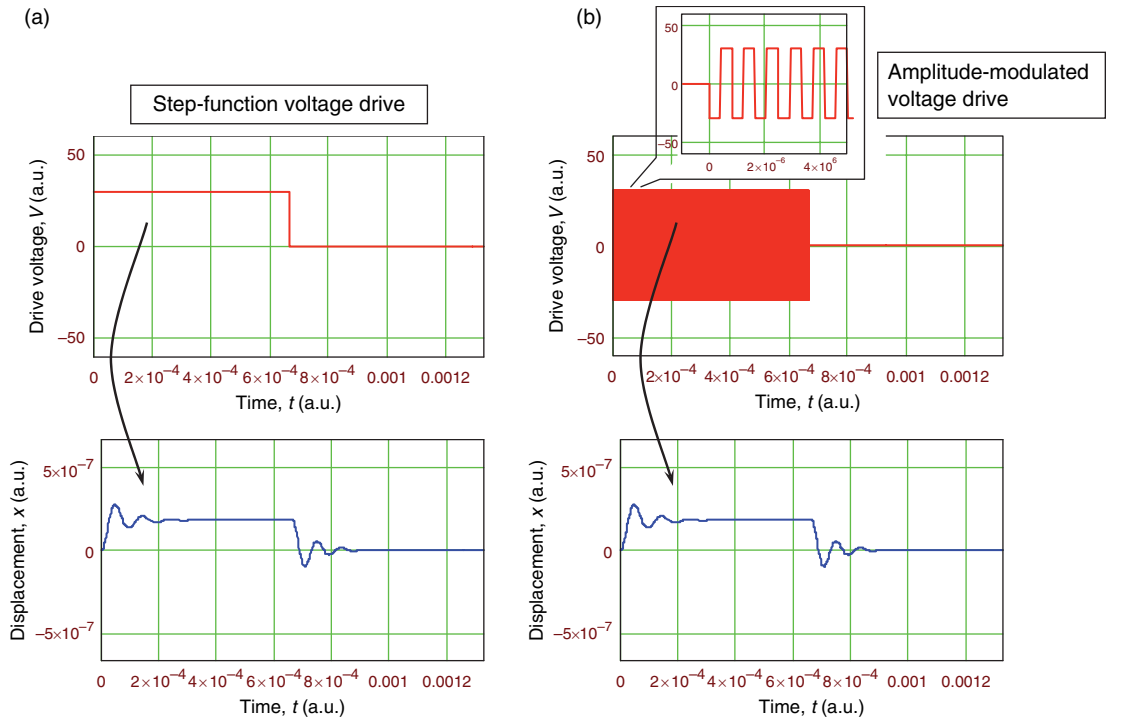

Figure 50 DC voltage operation and amplitude-modulated voltage operation.

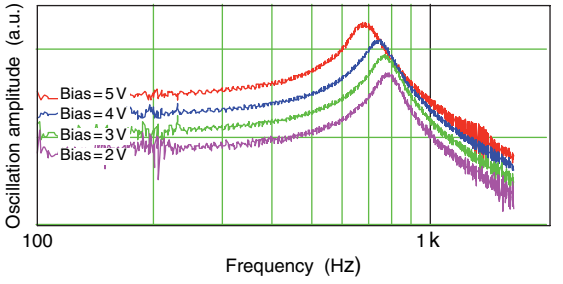

Figure 51 Shift of resonant frequency due to the negative spring constant effect of electrostatic actuation.

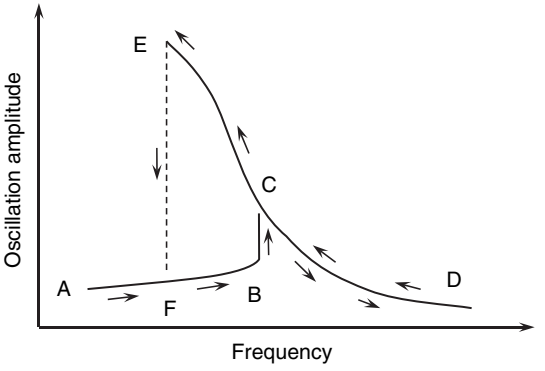

Figure 52 Hysteresis in frequency response of electrostatic actuator.

effect, the response peak inclines toward the lower frequency side. Oscillation amplitude becomes large when the excitation frequency is changed from point A to point B, and the amplitude is observed to jump to point C, after which it becomes small again, with the increase in the frequency to point D. When the frequency is decreased from point D, on the contrary, the amplitude keeps growing large until it collapses at point E. Therefore, when measuring the frequency response by manually tuning the frequency of a function generator, readers are advised to sweep up and down the frequency to see whether the actuator has a large difference in the amplitude.

2.01.11.5 Shortening Settling Time of Step Response

Damped oscillation as shown in Figure 53 is usually observed in an electrostatic actuator when it is driven with a step-function voltage. The duration of oscillation is long when the actuator has high quality factor (high Q), i.e., low loss. High-Q oscillation system is suitable for, for instance, a galvano scanner that spatially modulates a light beam with a large angle and

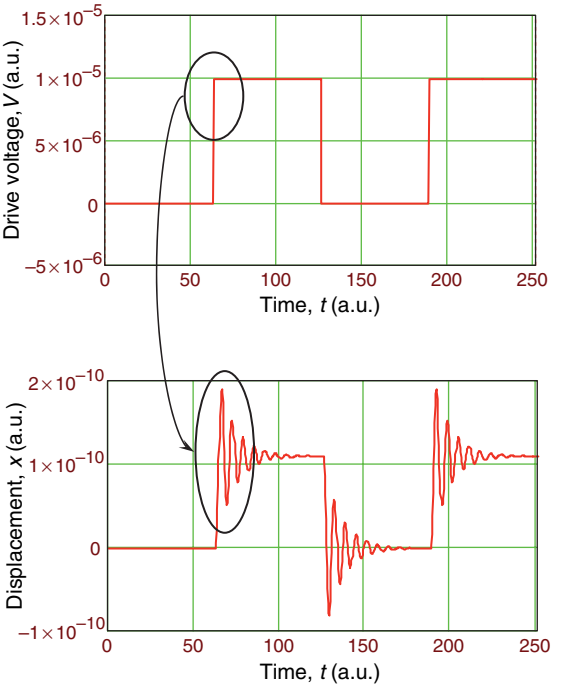

Figure 53 Damped oscillation observed in step response.

with a low voltage. However, relatively long settling time of a high-Q system becomes a problem when the actuator is used for optical switches, for instance. Long-term drift of actuator displacement can be controlled by using a feedback system that monitors the displacement, but the feedback system is not always fast enough to give correction to the transient response in time.

If the resonant frequency of the system (ω_0) is known, a simple feed-forward control can be used to suppress the damped oscillation. Figure 54 is a close-up view of the leading edge of the step response in Figure 53. Thanks to the fact that the damped oscillation is well described by $A + B\exp(-t/\tau)\sin\omega_0 t$, the oscillation would nearly diminish when it is superposed with another step response with a phase delay of π/ω_0, as shown by the dashed curve. This gives an insight that the damped oscillation can be eliminated by driving the actuator with superposed step-function voltage with a phase delay. Figure 54 is an example of feed-forward voltage for minimum settling time that was found in a trial-and-error manner by using a numerical simulation. Thanks to the superposed step voltages, the leading edge became almost free from damped oscillation (the falling edge required another preshaped voltage, which is not shown here). Note that the oscillation frequency depends on the electric

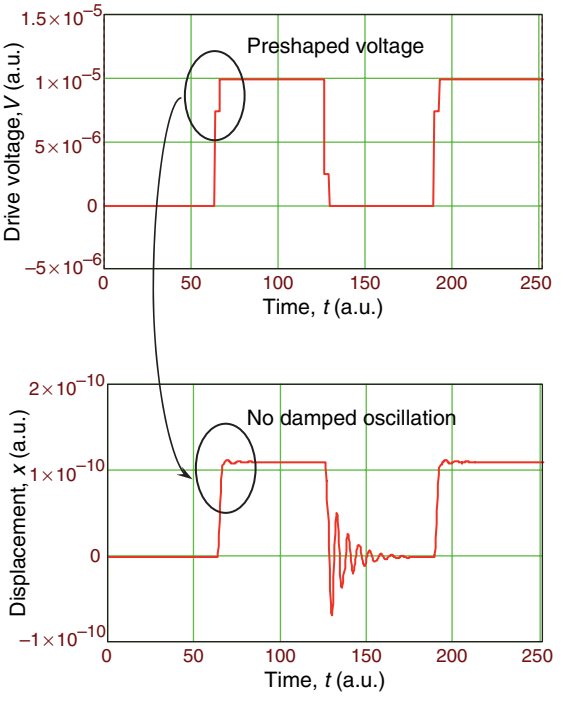

Figure 54 Response to a preshaped step-function voltage.

bias voltage due to the negative spring constant effect, and therefore, the feed-forward control system may require a look-up table of parameters.

2.01.11.6 Polarity-dependent Displacement

Electrostatic actuators made of semiconductor silicon sometimes exhibit peculiar behavior such as asymmetric displacement even when they are driven with an AC voltage without any offset. Figure 55 is an

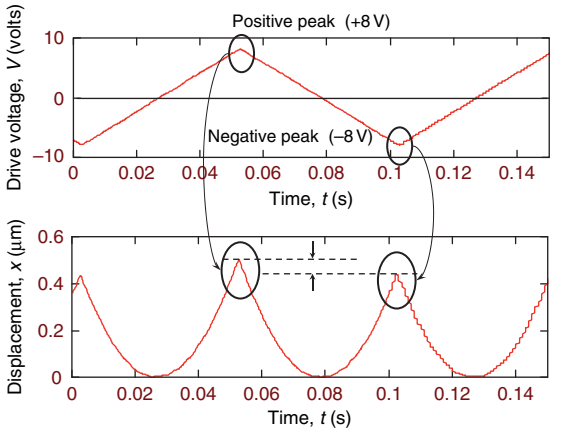

Figure 55 Asymmetric electrostatic displacement.

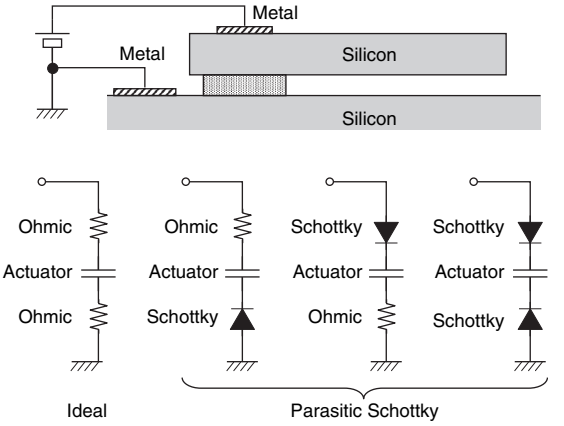

Figure 56 Schottky contact to cause asymmetry in electrostatic displacement.

example of such asymmetric displacement, which becomes notable when the drive voltage is as small as a few volts. This phenomenon is observed randomly on chips sampled out from a large number of devices made on a single piece of wafer at a time. In this figure, the peak at the positive input voltage is shown larger, but the polarity may switch on a different chip.

The asymmetry is most plausibly explained by using the Schottky diode made at the interface of the silicon and the metal, as illustrated in Figure 56. Actuators made of silicon usually require metallization for better electrical conductivity, and aluminum or a combination of chromium and gold is usually used for good adhesion to silicon and gold bonding wires. However, it is sometimes observed that the metal is not well processed to make an ohmic contact with silicon but makes an electric potential barrier. In such a case, the actual voltage drop across the actuator electrodes becomes smaller than the applied voltage by the potential barrier, and the electrostatic displacement is produced to be small. The randomness in the polarity is explained by the chance that one of the electrodes (the SOI structure or the substrate, for instance) is not made in ohmic but in Schottky.

2.01.11.7 Electrostatic Drift

Electrostatic actuators made by the surface micromachining may be found to have a drift in their displacement, as shown in Figure 57, even though they are operated at a constant drive voltage from a controlled voltage source. The drift is a serious problem for an application such as analog

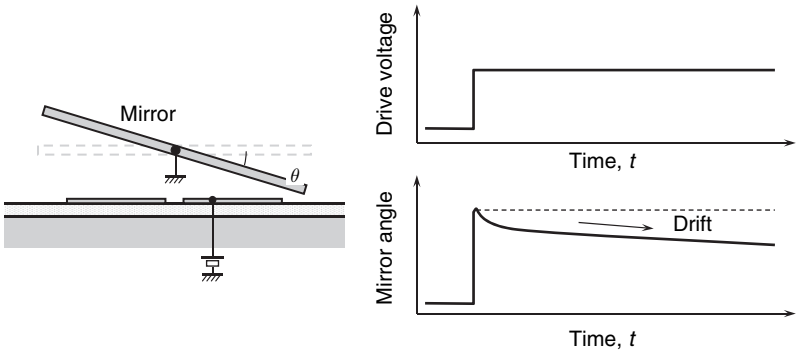

Figure 57 Example of electrostatic drift in displacement.

controlled optical switch, where the mirror position should be maintained at a fixed angle for a long time with an analog controlled voltage. The drift is usually observed in the tendency that the displacement (mirror angle) becomes smaller with aging on the order of minutes to days.

Most electrostatic drift can be suppressed by reducing the risk of charge buildup around the movable structure by, for instance, removing all the electrically floating patterns. It is also helpful to minimize the area of electrical insulator that is exposed to the movable element, as illustrated in **Figure 58**. In the silicon surface micromachining technology, thin-film silicon nitride is used as an insulator on the substrate, thanks to its chemical tolerance to hydrofluoric acid. However, silicon nitride is also known to be a material that easily captures charge (Wibbeler *et al.* 1998), possibly resulting in the drift of electrostatic performance. For a torsion mirror application, for instance, the gap between the electrodes sitting on the nitride layer should be made as small as possible.

Electrostatic drift is also seen in a device that is free from a nitride insulator. One of the curves shown in **Figure 59** is a drift observed in a silicon bulk micromachined actuator; it was originally developed as an electrostatic torsion mirror for a fiber optic attenuator (Isamoto *et al.* 2004). The electrostatic mirror was made of the active layer of an SOI wafer, and it was suspended on the substrate with an air gap in between. Operating voltage was applied to the suspended mirror with respect to the substrate at the ground level. The aforementioned plot was observed in the mirror chip, whose substrate ground was taken by the gold wire bonded on the top surface, leaving the bottom surface at an electrical floating level. **Figure 59** also shows another curve of less fluctuation; it was observed in the mirror chip of the identical design but with an evaporated metal layer on the backside of the chip. Thanks to the conductivity of the deposited metal, the electrical potential in the silicon substrate was flattened, and the voltage across the air gap was explained to have been stabilized.

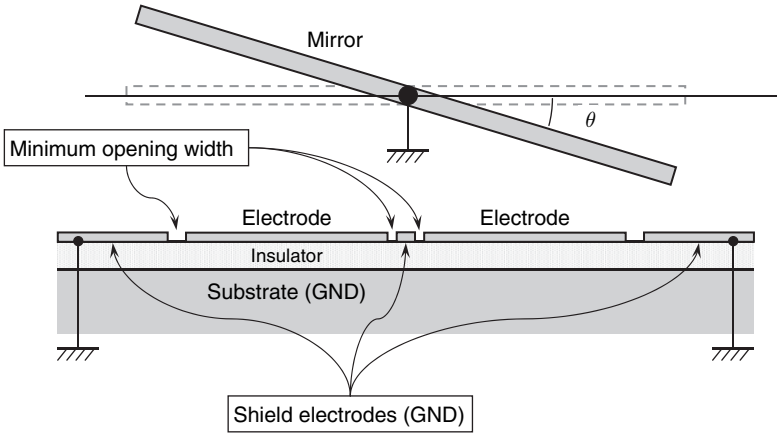

Figure 58 Minimum area of insulator for less risk of electrostatic drift.

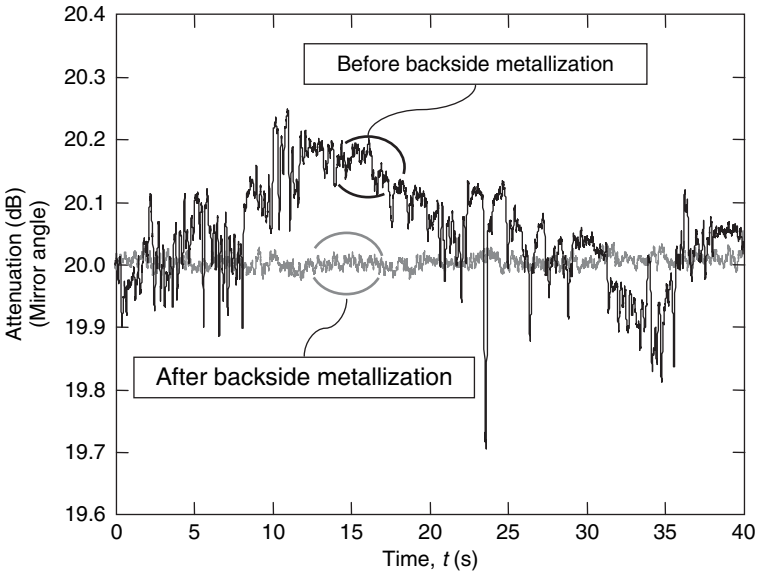

Figure 59 Short-term electrostatic drift.

2.01.11.8 MEMS Digital-to-analog Conversion Mechanism of Displacement

Toshiyoshi *et al.* (2000) reported a micromechanism to produce a displacement that was free from electrostatic fluctuation or drift. The mechanism is an *N*-stage network of ladder-connected suspensions, where an array of electrostatic microactuators was attached, as shown in **Figure 60**. The relative rigidities of the suspensions were designed to be either C or 2C such that it copied the function of digital-to-analog

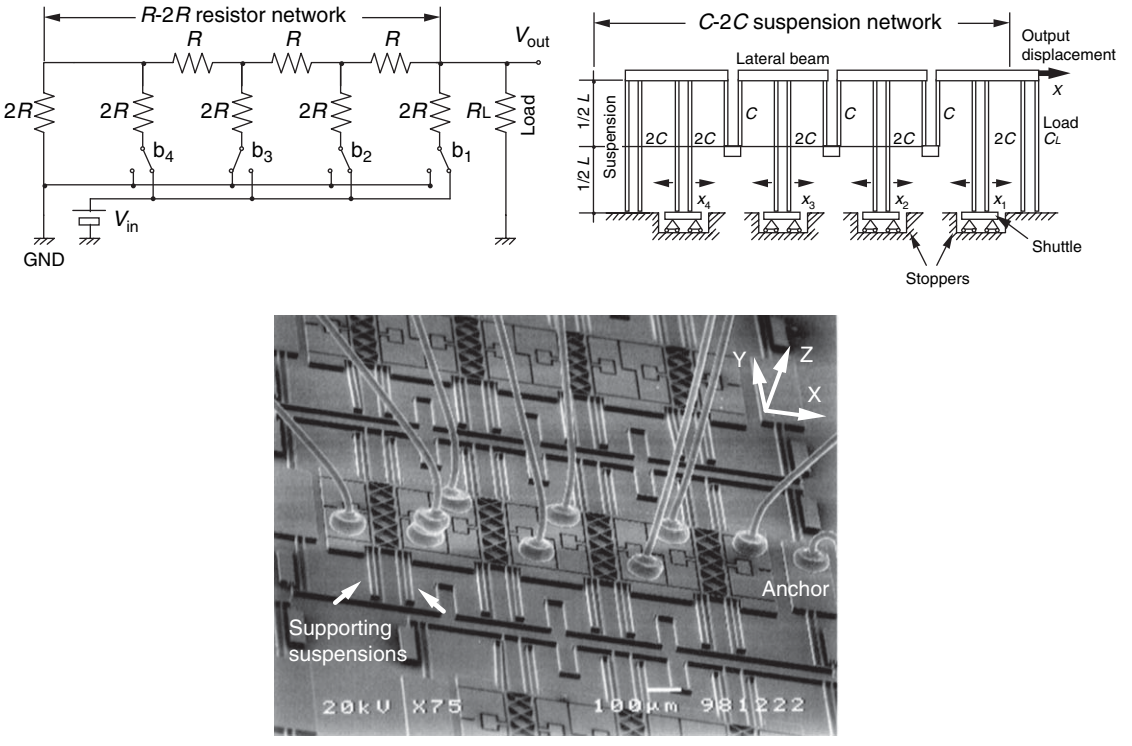

Figure 60 Microelectromechanical digital-to-analog converter of displacement (MEMDAC).

conversion of voltage using the R-2R resistor network. Each actuator in the network was an electrostatic shuttle moving back and forth between the drive electrodes and was operated by the corresponding digit (0 or 1) of input code. The N-bits of local displacement accumulate in the suspension network to synthesize an analog output displacement, which was proportional to the analog value coded with the N-bit input. Due to the analogy of electrical digital-to-analog converter, the mechanism was called microelectromechanical digital-to-analog converter (MEMDAC). The output displacement was free from the electrostatic drift or voltage fluctuation because the stroke of every shuttle was clipped by mechanical stoppers. They demonstrated a total stroke of 5.8 μm with an incremental step of 0.38 μm with a 4-bit MEMDAC. An electrothermal version of MEMDAC was also reported by Yie *et al.* (1999).

2.01.12 Electrostatic

2.01.12.1 Electrostatic Energy

Electric capacitance C between oppositely charged material bodies is defined by the amount of charge $\pm Q$ in Coulombs and the potential difference V in volts as follows:

$$Q = CV \qquad [54]$$

The electrostatic energy stored in the capacitor increased by the work that is done to pump up a small charge $\mathrm{d}Q$ against a potential difference $V = Q/C$. Integrating the work $(Q/C)\mathrm{d}Q$ until the bodies are charged to Q, the total work $((Q/C)\mathrm{d}Q$ until the bodies are charged to Q, the total work (energy) is written as

$$W = \int_0^Q \frac{Q}{C}\mathrm{d}Q = \frac{1}{2}\frac{Q^2}{C} \qquad [55]$$

Rewriting this equation in terms of voltage, we will obtain the stored energy as

$$U = \frac{1}{2}CV^2 \qquad [56]$$

2.01.12.2 Electrostatic Capacitance of Parallel Plates

Assuming a pair of conductive plates of infinite area placed in parallel with a gap g, we artificially cut out a small fraction of area S, where the electrostatic flux is uniformly distributed with its direction normal to the surface. Applying Gauss's law

$$\int_S \mathrm{div}\,\mathbf{E}\,\mathrm{d}S = \frac{1}{\varepsilon_0}\int_V \rho\,\mathrm{d}V$$

to the closed surface containing the small upper plate, we obtain the field strength E_{upper} to be $Q/(2S\varepsilon_0)$. In the same manner, the field strength originated from the lower plate is written to be $E_{\mathrm{lower}} = Q/(2S\varepsilon_0)$ in the same direction, and therefore, the net field strength is $E_{\mathrm{upper}} + E_{\mathrm{lower}} = Q/(S\varepsilon_0)$. The potential difference V can be obtained by multiplying the field strength by the plate distance g, and thus, $V = Qg/(S\varepsilon_0)$. Substituting this form in eqn [54], the capacitance of the parallel plates is written as

$$C = \varepsilon_0\frac{S}{g} \qquad [57]$$

2.01.12.3 Electrostatic Force

The principle of virtual work is used to derive the electrostatic force of electrostatic actuator. We assume a suspended electrostatic actuator that has come to a displacement x, counterbalancing with the electrostatic force F under a constant drive voltage V. When an imaginary small displacement Δx occurs on the movable electrode toward the direction to increase the capacitance by ΔC, the electrostatic energy stored in the capacitor increases by $1/2(\ \Delta CV^2)$. At the same time, the movable electrode gives a work $F\Delta x$ to external. The energy for these two components is contributed by the voltage source, which has given the capacitor the additional amount of charge ΔQ against the potential difference V. Hence, the energy balance is written as

$$\frac{1}{2}\Delta CV^2 + F\Delta x = \Delta QV \qquad [58]$$

Using $\Delta Q = \Delta CV$ for this equation, one obtains

$$\begin{aligned}\frac{1}{2}\Delta CV^2 + F\Delta x &= \Delta CV^2 \\ F\Delta x &= \frac{1}{2}\Delta CV^2\end{aligned} \qquad [59]$$

By taking the limit of $\Delta x \to 0$, the output force of an electrostatic actuator driven by a constant voltage is written as

$$F = \lim_{\Delta x \to 0}\frac{1}{2}\frac{\Delta C}{\Delta x}V^2 = \frac{1}{2}\frac{\mathrm{d}C}{\mathrm{d}x}V^2 \qquad [60]$$

Biography

Hiroshi Toshiyoshi received his M.Eng. and Ph.D. degrees in Electrical Engineering from the University of Tokyo, Tokyo, Japan, in 1993 and 1996, respectively. Since April 2002, he has been an Assistant Professor with the Institute of Industrial Science (IIS), the University of Tokyo, Tokyo, Japan. From April 1999 to March 2001, he had been a Visiting Assistant Professor at University of California, Los Angeles for his sabbatical years. He is currently a Co-Director of the first Japan–France international research collaboration LIMMS (Laboratories for Integrated Micro Mechatronic Systems) established between IIS and Centre National de la Recherche Scientifique (CNRS), France. He also conducts a three-year project on Optomechatronics at Kanagawa Academy of Science & Technology (KAST), Kanagawa, Japan since April 2005. His main research interest is optical and RF MEMS.

2.02.1 Introduction

We have all played with magnets. A pair of magnets by itself makes a wonderful toy. The most familiar magnets may be the small decorative magnets used to fasten notes to the refrigerator door. As you fasten the notes to the refrigerator door with the magnet, you become aware with your fingertips that the space around the magnet has attractive forces. In another familiar type of magnet, a coil is wound around an iron core, the strength

of the external magnetic field being determined by the current in the coil. These two types of magnets, permanent magnets and electromagnets, play a much larger part in our daily lives as well as in microsystems.

At the microscale, magnetic actuation is one of the more promising actuation mechanisms compared to other such mechanisms. Most microactuators actuate mechanical moving parts using electrostatic, piezoelectric, thermal, magnetic, or other actuation mechanisms, as shown in **Figure 1** (Oh and Ahn 2006). For miniaturized structures, electrostatic actuation becomes more attractive due to their fast response time and reliability. However, it is difficult to achieve large forces and deflections because of the extremely high voltages required. Piezoelectric actuation can yield very large forces, but very small deflections even with very high voltages. The drawback of small strokes has been overcome by the hydraulic amplification of the piezoelectric, stacked piezoelectric disks or piezo bimorphs. Thermal actuation can provide large forces via large strokes, but is relatively slow and may not be suitable for many fluids due to heat dissipation. Thermal actuators require a large amount of thermal energy for their operation, and therefore consume substantial electrical energy. High temperature and complicated thermal management are further drawbacks of thermal actuation.

On the other hand, many microactuators employ magnetic actuation, which often involves permanent magnets and electromagnetic coils. Magnetic actuation enables large forces and deflections with low power consumption. The relative advantages and disadvantages of electrostatic actuation, piezoelectric actuation, thermal actuation, and magnetic actuation are well summarized by Liu (2006) in **Table 1**.

Today we can see magnetic actuation being combined with microsystems in an amazing variety of ways. Magnetic actuation can be utilized to miniaturize pumps, valves, mixers, mirrors, and switches. Applications include valving, pumping, and mixing of fluids, as well as the incorporation of mirrors and switches into microsystems. In addition, magnetic forces are used to transport, position, separate, and sort magnetic and nonmagnetic objects such as magnetic particles, magnetically labeled cells, or plugs of ferrofluids. Magnetic actuation is also closely related to magnetic sensing, as magnetic fields are used to produce and sense motion. In particular, magnetic sensors are used to generate an electrical signal to sense motion (Ripka 2001). Indeed, many materials, components, and fabrication methods for magnetic actuation originated in the field of magnetic sensing.

In this chapter, we begin our study of magnetic actuation by discussing the basic theories and

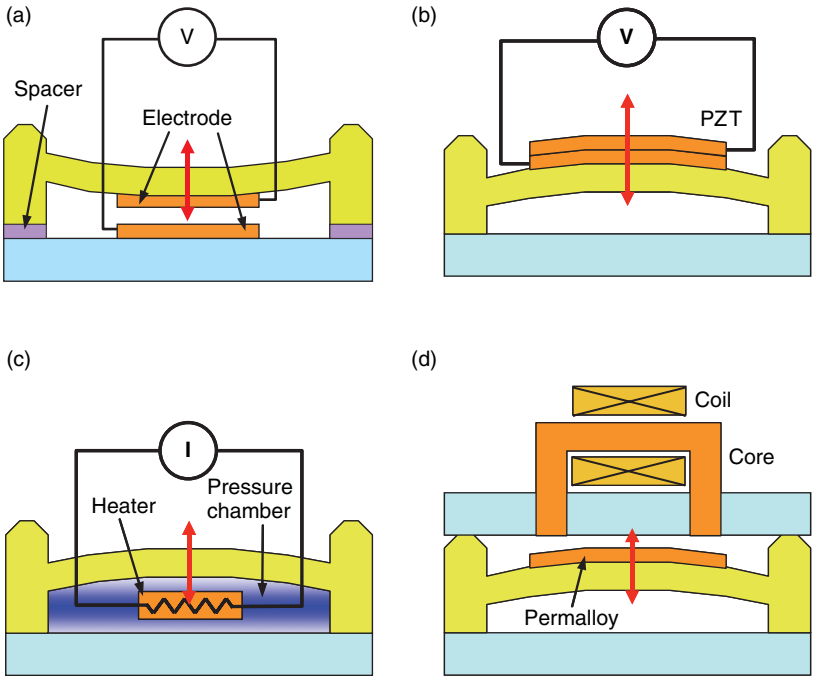

Figure 1 Illustrations of actuation principles of microactuators with mechanical moving parts: (a) electrostatic (b) piezoelectric; (c) thermal; and (d) electromagnetic actuation. The spacer in the electrostatic actuation is working as an insulating layer.

Table 1 Comparison of various actuation methods

	Advantages	*Disadvantages*
Electrostatic actuation	Simplicity of materials; fast actuation response	Trade-off between magnitude of force and displacement; susceptible to pull-in limitation
Piezoelectric actuation	Fast response possible; capable of achieving moderately large displacement	Requires complex material preparation; degraded performance at low frequencies
Thermal actuation	Capable of achieving large displacement (angular or linear); moderately fast actuation response	Relatively large power consumption; sensitivity to environmental temperature changes
Magnetic actuation	Capable of generating large angular displacement; possibility of using very strong magnetic force as bias	Moderately complex processes; difficult to form on-chip, high-efficiency solenoids

Source: Liu (2006).

actuation mechanisms pertaining to microscale magnetic actuation. Then, representative magnetic materials and fabrication processes that are key building blocks in magnetic microsystems are reviewed. Finally, selected examples of magnetic microactuators in the areas of microfluidics, microoptics, microelectronics, and lab-on-a-chip (LOC) devices are discussed.

2.02.2 Principles

2.02.2.1 Scaling Effect

As discussed by Judy (2001), the scaling of any device or system from the macroscale to the microscale dramatically affects the overall design, materials, and fabrication processes. The author reviewed the influences of scaling on material properties, mechanical systems, fluidic systems, chemical and biological systems, thermal systems, electrical and magnetic systems, and optical systems. Especially when scaling down electrical and magnetic systems, there are preferable dimensions suitable for electrostatic or magnetic actuation, yet the dimensions are in the micrometer range.

As summarized in **Table 2**, it is possible to estimate the dimensions where magnetic forces are still dominant. In the case of an electrostatic actuator, the maximum energy density is limited by the maximum electric field that can be applied before electrical breakdown occurs. This maximum electric field is approximately $3\,\mathrm{M\,V\,m^{-1}}$, giving an energy density in vacuum on the order of $4 \times 10^{1}\,\mathrm{J\,m^{-3}}$. In the case of an equivalent magnetostatic actuator, the maximum energy that can be produced is determined essentially by the maximum value of the flux density of the existing materials. Typically, the flux density is on the order of 1 T or $1\,\mathrm{V\,s\,m^{-2}}$, giving a magnetostatic energy of $4 \times 10^{5}\,\mathrm{J\,m^{-3}}$. The ratio of the magnetostatic to the electrostatic energy density at the macroscale is then

$$\frac{U_{\text{magnetostatic\_macro\_max}}}{U_{\text{electrostatic\_macro\_max}}} \approx 10^{4} \qquad [1]$$

which shows why electromagnetic forces dominate in the macroworld and electrostatic forces appear only in very few cases.

Scaling down of the dimension in electrostatic actuation leads to new phenomena. For example, the breakdown voltage is a function of the electrode gap, and a plot of this is known as the Paschen curve

Table 2 Comparison of scaling electrical and magnetic systems

	Electrostatic	*Magnetostatic*
Energy density	$U_{\text{electrostatic}} = \frac{1}{2}\varepsilon E^2$	$U_{\text{magnetostatic}} = \frac{1}{2}\mu^{-1}B^2$
Macroscale	$E_{\max} = \sim 3\,\mathrm{M\,V\,m^{-1}}$ $U_{\max} = \sim 40\,\mathrm{J\,m^{-3}}$	$B_{\max} = \sim 1\,\mathrm{T}$ (or $1\,\mathrm{V\,s\,m^{-2}}$) $U_{\max} = \sim 4\,00\,000\,\mathrm{J\,m^{-3}}$
Microscale	$E_{\max} = F(x)$ (function of electrode gap) $U_{\text{micro\_max}} >> U_{\text{macro\_max}}$ (function of electrode gap)	$B_{\max} =$ const. (dependence on materials) $U_{\text{micro\_max}} = U_{\text{macro\_max}}$ ($10^{6}\,\mathrm{J\,m^{-3}}$ for saturated Fe, $10^{5}\,\mathrm{J\,m^{-3}}$ for saturated Ni)

ε, permittivity; E, electric field; μ, magnetic permeability; B, magnetic flux density; and x, electrode gap
Sources: Judy (2001) and Niachos (2003).

(Von Hippel 1959). Apparently, there are cross-over points from magnetic actuation to electrostatic actuation at the microscale. The points can be estimated by assuming that the maximum electric field is a function of the electrode gap and the maximum magnetic flux density is a constant. They are determined from the above assumption that

$$U_{\text{electrostatic\_micro\_max}} = U_{\text{magnetostatic\_micro\_max}} \quad [2]$$

in which

$$\begin{aligned} U_{\text{electrostatic\_micro\_max}} &= f(x) \\ U_{\text{magnetostatic\_micro\_max}} &= const \end{aligned} \quad [3]$$

This simplified approach gives an order of magnitude of ~2 μm, considering that the most common magnetic materials and structures used for magnetic actuators are iron- and nickel-based alloys (e.g., $10^6\,\text{J m}^{-3}$ for saturated Fe systems and $10^5\,\text{J m}^{-3}$ for saturated Ni systems). In practice, however, the macroscopic assumption is not valid in magnetic microactuators. The size of magnetic domains, i.e., regions of a material with uniform magnetization, is typically on the scale of micrometers in permalloys (NiFe), which are commonly used in magnetic microactuators. Practical issues, such as magnetic domain wall structure, shape, and magnetocrystalline anisotropy as a function of thickness, should be addressed for a more accurate prediction. Still, magnetic actuation is advantageous above a boundary range from 1 to 10 μm gap or deflection (Niarchos 2003).

2.02.2.2 Theory

2.02.2.2.1 Lorentz force

An electromagnetic actuator utilizes the force generated from the magnetic field either through the Lorenz force or through magnetic induction, which we now discuss. Where does the magnetic field come from? Experiments show that it comes from moving electric charges. A charge sets up an electric field irrespective of whether the charge is at rest or is moving. However, a charge sets up a magnetic field only if it is moving. Where are these moving electric charges? In permanent magnets, these are the spinning and circulating electrons in the iron atoms that make up the magnet. In the electromagnets, these are the electrons circulating through the coils of wire that surround these magnets.

In principle, we can set a test charge q in motion in various directions and with various speeds, and can record the force $\mathbf{F}_B$ that acts on the moving charge. If we analyze the results of many such trials, we find that the vector $\mathbf{F}_B$ is related to the velocity vector $\mathbf{v}$ by the following equation:

$$\mathbf{F}_B = q\mathbf{v} \times \mathbf{B} \quad \text{(Lorentz force law for magnetism)} \quad [4]$$

where $\mathbf{B}$ is the magnetic field vector and the SI unit of $\mathbf{B}$ is $\text{N C}^{-1}\,\text{m}^{-1}\,\text{s}$). For convenience, this is called the tesla (T). Recalling that $1\,\text{C s}^{-1} = 1\,\text{A}$, we have

$$1\,\text{tesla} = 1\,\text{T} = 1\,\text{N A}^{-1}\,\text{m}^{-1} \quad [5]$$

An earlier non-SI unit for $\mathbf{B}$, still in common use, is the gauss; the relation is as follows:

$$1\,\text{tesla} = 10^4\,\text{gauss} \quad [6]$$

Note that the earth's magnetic field near the earth's surface is about 10^{-4} T (1 gauss).

If we set up a wire segment of length L making an angle ϕ with a magnetic field (**Figure 2**), the magnetic force is given by the following equation:

$$\mathbf{F}_B = i\mathbf{L} \times \mathbf{B} \quad [7]$$

where $\mathbf{L}$ is a vector that points along the wire segment in the direction of the current. Eqn [7] is equivalent to eqn [4] in that either can be taken as the defining equation for the magnetic field vector $\mathbf{B}$. Equivalently, we can express the magnetic force in terms of the current density $\mathbf{J}$ as

$$\mathbf{F}_B = \int_V \mathbf{J} \times \mathbf{B}\,dV \quad [8]$$

and we can find the resultant force on any given structure of currents by integrating eqn [8] over that structure.

A fundamental fact of electrostatics is that two charges exert forces on each other. Charges produce

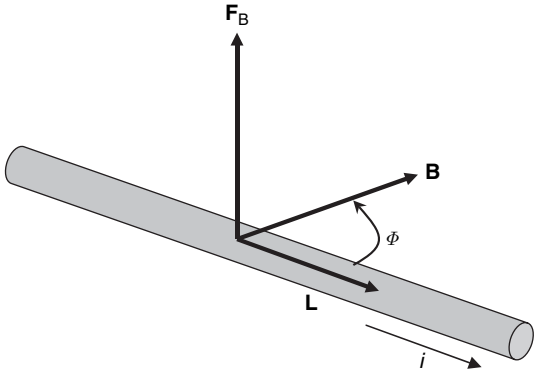

Figure 2 A wire segment of length L makes an angle Φ with a magnetic field.

electric fields and electric fields exert forces on charges. A fundamental fact of magnetics is that two parallel wires carrying currents also exert forces on each other. Currents produce magnetic fields and magnetic fields exert forces on currents. The magnitude of electric field d**E** is given by the following equation:

$$\mathrm{d}\mathbf{E} = \frac{1}{4\pi\varepsilon_0}\frac{\mathrm{d}q}{r^3}\mathbf{r}\,(\text{Coulomb's law}) \qquad [9]$$

where **r** is the distance from the charge element to point P and ε_0 is the permittivity constant. A charge element $\mathrm{d}q$ establishes a differential electric field element d**E** at the point P. By analogy, we can easily guess the magnitude of the magnetic field contribution. The magnetic field contribution d**B** at point P by a given current element is given by the following equation:

$$\mathrm{d}\mathbf{B} = \frac{\mu_0}{4\pi}\frac{i\,\mathrm{d}\mathbf{s}}{r^3} \times \mathbf{r}\,(\text{Biot–Savart law}) \qquad [10]$$

where the vector d**s** is a differential element of length, pointing tangent to the wire in the direction of the current, and μ_0 is the permeability constant. A current element i d**s** establishes a differential magnetic field d**B** at the point P. Eqn [10], called the Coulomb's law for magnetism, is more often called the Biot–Savart law. We at once note a complexity in our analogy of the electrostatic case; the differential charge element $\mathrm{d}q$ is a scalar quantity but the differential current element i d**s** is a vector quantity.

One of the simplest problems in magnetism is that of a long straight wire carrying a current i. The magnitude of the magnetic field $B(r)$ at a perpendicular distance r from such a wire is given by the following equation:

$$B(r) = \frac{\mu_0\, i}{2\pi\, r}(\text{long straight wire}) \qquad [11]$$

Two long parallel wires carrying currents exert forces on each other. **Figure 3** shows two such wires, separated by a distance d and carrying currents i_A and i_B. Wire A produces a magnetic field B_A at all points. The magnitude of B_A at the site of wire B is, from eqn [11], is given as follows:

$$B_\mathrm{A} = \frac{\mu_0\, i_\mathrm{A}}{2\pi\, d} \qquad [12]$$

Wire B, which carries a current i_B, finds itself immersed in an external magnetic field $\mathbf{B}_\mathrm{A}$. A length L of this wire experiences a sideways magnetic force given by eqn [7], whose magnitude is given as follows:

$$F_\mathrm{BA} = i_\mathrm{B}\, L\, B_\mathrm{A} = \frac{\mu_0\, L i_\mathrm{B}\, i_\mathrm{A}}{2\pi\, d}(\text{two long parallel wires}) \qquad [13]$$

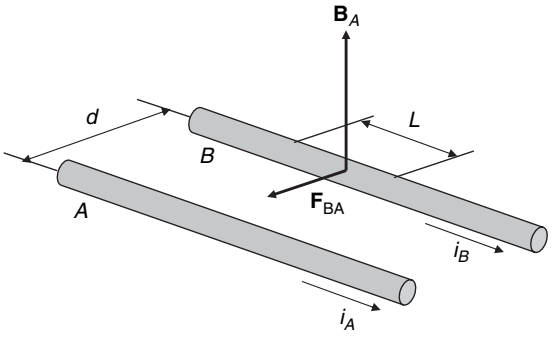

Figure 3 Two parallel wires carrying currents in the same direction attract each other. The magnetic field at wire B set up by the current in wire A is shown. For antiparallel currents, the two wires repel each other.

The rule of vector products says that $\mathbf{F}_\mathrm{BA}$ lies in the plane of the wires and points to the left.

2.02.2.2.2 Magnetic induction

In magnetic actuation, the magnetic field can also be generated by a permanent magnet or a coil. **Figure 4** shows two simple tabletop experiments, which will

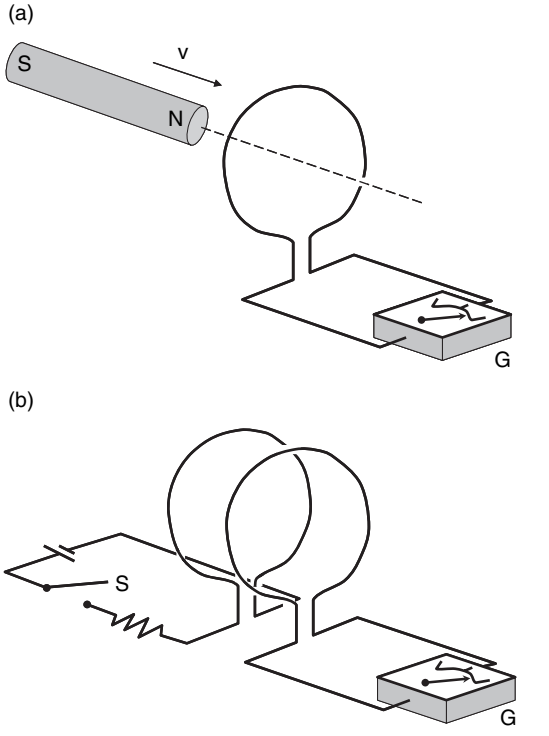

Figure 4 Two simple tabletop experiments guides us to understand Faraday's law of induction. (a) Galvanometer G deflects when the magnet is moving with respect to the coil. (b) Galvanometer G reflects momentarily when switch S is closed or opened. No physical motion of the coils is involved.

guide us to understand the Faraday's law of induction. An induced electromotive force (emf) appears only when something is changing. An induced emf appears in the right-hand loop of **Figure 4** only when the number of magnetic field lines that pass through that loop is changing. Whether you push the magnet toward the loop or pull it away from the loop, you will always experience a resisting force and will thus have to do work. In a static situation, in which no physical objects are moving and the currents are steady, there is no induced emf. This law, with a coil of N turns, in the equation form is as follows:

$$\text{emf} = -N\frac{\mathrm{d}\Phi_\mathrm{B}}{\mathrm{d}t}\,(\text{Faraday's Law}) \qquad [14]$$

where the magnetic flux Φ_B is defined from the following equation:

$$\Phi_\mathrm{B} = \int \mathbf{B}\cdot\mathrm{d}\mathbf{A} \qquad [15]$$

where d**A** is a differential element of surface area, and the integration should be carried out over the entire surface. If the magnetic field has a constant magnitude B and is everywhere at right angles to a plane surface of area A, the absolute value of the flux is $\Phi_\mathrm{B} = BA$. If the rate of change of flux is in webers (1 weber = 1 Wb = 1 T m^2) per second, the induced emf will be in volts.

An inductor is a coil such that if a current i is established in its windings, a magnetic flux Φ links each winding and the inductance L is given by

$$L = N\frac{\Phi}{i}\,(\text{inductance}) \qquad [16]$$

where N is the number of turns and the SI unit of inductance is henry (1 henry = 1 H = 1 T m^2 A^{-1}). By combining eqns [14] and [16], the self-induced emf is given as

$$\text{emf} = -N\frac{\mathrm{d}\Phi}{\mathrm{d}t} = -L\frac{\mathrm{d}i}{\mathrm{d}t} \qquad [17]$$

Thus, in any inductor, such as a coil, a solenoid, or a toroid, a self-induced emf appears whenever the current changes with time.

The two long, rigid, parallel wires (**Figure 3**) carrying current in the same direction attract each other, and energy has to be applied to pull them apart. We can get this stored energy back at any time by letting the wires move back to their original positions. In the case of magnetic actuation, the induction through the magnetic material results in a change in the stored energy U_B, which is given by

$$U_\mathrm{B} = \frac{1}{2}L\,i^2 \qquad [18]$$

In magnetic actuation, the attractive force induced by the current energizing the coil will be

$$F_\mathrm{B} = \frac{\partial U_\mathrm{B}}{\partial x} = \frac{1}{2}i^2\frac{\mathrm{d}L(x)}{\mathrm{d}x} \qquad [19]$$

To achieve a high stored magnetic energy and thus a large attractive force, both the magnetic film and the microcoil need to be designed and fabricated in such a way that they produce the large volume in a given planar area. The reader is referred to a study of an energy-based design criterion for magnetic actuation by one of the authors and colleagues (Nami *et al.* 1996). It suggests that the energy stored in the gap has a maximum value when the magnetic reluctance of the gap is equivalent to the magnetic reluctance of the magnetic core.

2.02.2.2.3 Magnetic torque

In magnetic actuation, a magnetic torque is widely used to rotate cantilever beams in micromirrors and microswitches. As shown in **Figure 5**, when the length l of a soft magnetic cantilever is much larger than its thickness t and width w, the direction along its long axis becomes the preferred direction for magnetization. When such a cantilever is placed in a uniform magnetic field $\mathbf{H}_0$, a magnetic torque $\boldsymbol{\tau}_\text{magnetic}$ exerted on the beam is (Ruan *et al.* 2001a, b)

$$\boldsymbol{\tau}_\text{magnetic} = \mathbf{m}\times\mathbf{B}_0 = \mu_0\mathbf{m}\times\mathbf{H}_0 \qquad [20]$$

where the magnetic induction of the applied uniform permanent magnetic field $\mathbf{B}_0$ and the magnetic moment $\mathbf{m}$ are defined by the following equation:

$$\mathbf{B}_0 = \mu_0\mathbf{H}_0\ (\text{magnetic induction}) \text{ and} \qquad [21]$$

$$\mathbf{m} = \mathbf{M}\,V\,(\text{magnetic moment}) \qquad [22]$$

where μ_0 is the permeability constant, $\mathbf{M}$ is the magnetization in the beam, and V is the volume of the beam.

When the magnetic force is large enough to overcome the mechanical force, the cantilever beam with one fixed end will deflect, as shown in **Figure 5**. According to the elasticity theory, the corresponding mechanical torque $\boldsymbol{\tau}_\text{magnetic}$ needed to cause a deflection Δz at the free end of the cantilever is (Benham *et al.* 1996)

$$\boldsymbol{\tau}_\text{mechanical} = \frac{3EI\Delta z}{l^2} = \frac{Ewt^3\Delta z}{4l^2} \qquad [23]$$

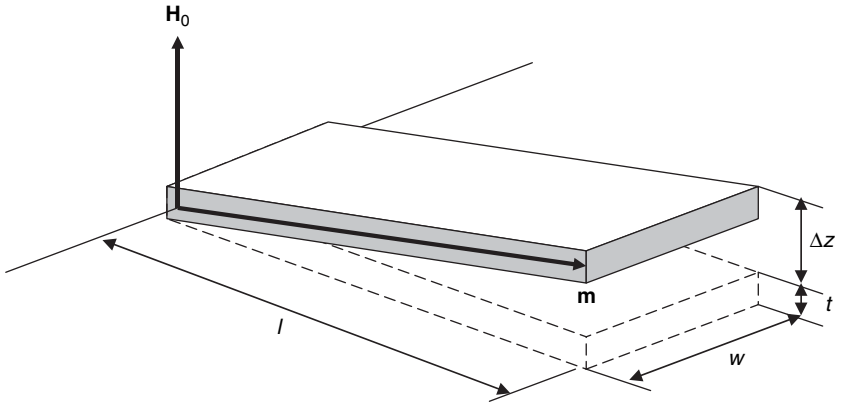

Figure 5 Schematic illustration of a soft magnetic cantilever beam actuator.

where E is Young's modulus of the cantilever beam material and I is the moment of inertia. When $\boldsymbol{\tau}_{\text{magnetic}} > \boldsymbol{\tau}_{\text{mechanical}}$, the cantilever beam will deflect. The larger deflection is possible with a stronger uniform magnetic field $\mathbf{H}_0$ and a stronger magnetization in the beam material.

2.02.2.2.4 Magnetic field gradient

In magnetic actuation, nonuniform magnetic field or magnetic field gradient is often used to transport and manipulate magnetic particles. A magnetic field gradient is required to exert a translation force. As studied in Section 2.02.2.2.3, a uniform field can produce a torque, but no translational action. According to electromagnetic field theory, the magnetic force of attraction acting on the magnetic moment $\mathbf{m}$ from the magnetic field $\mathbf{B}$ can be written as the derivative of the magnetic energy (Gijs 2004, Zborowski *et al.* 1999)

$$\mathbf{F}_{\mathbf{m}} = \nabla(\mathbf{m} \cdot \mathbf{B}) \qquad [24]$$

When we assume that the magnetic moment of the particle is not varying in space ($\nabla \cdot \mathbf{m} = 0$), the magnetic force on the magnetic particle is of the following form:

$$\mathbf{F}_{\mathbf{m}} = (\mathbf{m} \cdot \nabla)\mathbf{B} \qquad [25]$$

$$\mathbf{m} = V \chi_{\text{m}} \mathbf{H} \qquad [26]$$

where V is the volume of the magnetic particle, χ_{m} is the magnetic susceptibility of the particle, and $\mathbf{H}$ is the applied magnetic field intensity. By combining eqns [25] and [26], the magnetic force on the magnetic particle becomes

$$\mathbf{F}_{\mathbf{m}} = V \chi_{\text{m}} (\mathbf{H} \cdot \nabla)\mathbf{B} \qquad [27]$$

Eqn [27] can be expressed in x-, y-, and z-directional forces:

$$F_{\text{m},x} = V \chi_{\text{m}} \left(H_x \frac{\partial}{\partial x} + H_y \frac{\partial}{\partial y} + H_z \frac{\partial}{\partial z} \right) B_x \qquad [28]$$

$$F_{\text{m},y} = V \chi_{\text{m}} \left(H_x \frac{\partial}{\partial x} + H_y \frac{\partial}{\partial y} + H_z \frac{\partial}{\partial z} \right) B_y \qquad [29]$$

$$F_{\text{m},z} = V \chi_{\text{m}} \left(H_x \frac{\partial}{\partial x} + H_y \frac{\partial}{\partial y} + H_z \frac{\partial}{\partial z} \right) B_z \qquad [30]$$

Eqn [28] is preferred, for example, when the magnetic particles are constrained to move in a microchannel in the x-direction. This equation shows that both the magnitude of the applied magnetic field intensity for inducing a large moment and the magnetic field gradient need to be large to have a strong magnetic actuation force.

2.02.2.2.5 Magnetization

Several forms of magnetic behavior have been observed in different materials, including diamagnetism, paramagnetism, and ferromagnetism (Kittel 1996). Ferromagnetism is the normal form of magnetism that most people are familiar with, as exhibited in permanent magnets. However, unlike ferromagnetic materials, diamagnetic and paramagnetic materials do not retain any magnetization in the absence of an externally applied magnetic field. Diamagnetism is the most common magnetic behavior, which is proportional and opposing to the applied magnetic field. Diamagnetic materials are usually considered by nonphysicists as nonmagnetic and include water, DNA, most organic compounds such as oil and plastic, and many metals such as gold and bismuth. Paramagnetic materials present a

magnetization that is proportional to the applied field and adds force to it. Paramagnetism varies inversely with temperature and is characterized by the material's saturation magnetization. Another special case of paramagnetic materials is superparamagnetic particles that are magnetized in a magnetic field. However, once the external field is removed, the particles redisperse and behave like a nonmagnetic material.

The relationship between B and H can be described using the following equation:

$$B = \mu_0 H + M = \mu_0(H + \chi_m H) = \mu_r \mu_0 H \qquad [31]$$

where μ_0 is the magnetic permeability constant, μ_r is the relative permeability of the magnetic material, and M is the internal magnetization. The magnetic susceptibility χ_m is defined as

$$\chi_m = \mu_r - 1 \qquad [32]$$

Diamagnetic materials are repelled by the applied magnetic fields, and therefore they have a negative magnetic susceptibility ($\chi_m < 0$). Paramagnetic materials are attracted toward the applied magnetic fields, and therefore they have a positive magnetic susceptibility ($\chi_m < 0$). Diamagnetic and paramagnetic effects are usually so small that their effects are not observable in our daily lives. In general, the magnetic susceptibility on the order of 10^{-5}–10^{-6} with the negative sign for most diamagnets and on the order of 10^{-3}–10^{-5} with the positive sign for most paramagnets. Therefore, the relative permeability is very close to 1 for diamagnetic and paramagnetic materials.

For ferromagnetic materials such as iron, nickel, cobalt, and some rare earths, the values of the relative permeability are very large ($\chi_m \gg 0$). Ferromagnetic materials are often used in magnetic actuation applications. The linear relationship between B and H (eqn [31]) is valid only within a certain range of H. Ferromagnetic materials can present spontaneous magnetization, and this gives rise to the $B-H$ (or $M-H$) hysteresis loops. Ferromagnetic materials can be characterized by their permeability, Curie temperature (temperature of the phase change to paramagnetic behavior), coercive field (field strength needed to demagnetize the material), and remanent magnetization (magnetization at zero external field).

Hysteresis, the lack of retraceability, is well known in ferromagnetic materials. Magnetization curves for ferromagnetic materials do not retrace themselves as we increase and decrease the applied external magnetic field H. **Figure 6** shows the following operations with a sort of S-shaped loop:

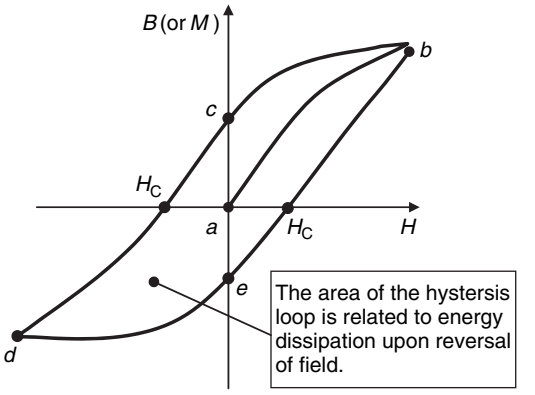

Figure 6 A magnetization curve (ab) for a ferromagnetic specimen and an associated hysterisis loop (bcdeb).

(1) Starting with an unmagnetized material (point *a*), increase the external magnetic field until H has the value corresponding to point *b*.
(2) Reduce the field back to zero (point *c*).
(3) Reverse the field and increase it in magnitude until point *d* is reached.
(4) Reduce the field to zero again (point *e*).
(5) Reverse the field once more until point *b* is reached again.

Note that at points *c* and *e* the material is magnetized, even though there is no field; this is the familiar phenomenon of permanent magnetism, and is called the remanent magnetization. This memory effect of magnetic materials is essential for the magnetic storage of information, as in cassette tapes or computer disks.

The coercivity of a ferromagnetic material is the intensity of the applied magnetic field required to reduce the magnetization of that material to zero after the magnetization of the sample has been driven to saturation. Coercivity is usually measured in oersted (Oe) or ampere per meter units and is denoted as H_C, as shown in **Figure 6**. The area enclosed by the hysterisis curve indicates the amount of magnetic energy stored in the magnetic material. When the coercive field of a ferromagnet is large, the material is said to be a hard or a permanent magnet. A ferromagnet with a low coercive field is said to be a soft magnet. For example, in magnetic actuation, soft magnetic materials such as permalloy (80Ni–20Fe) or orthonol (50Ni–50Fe) are most frequently used for their preferable magnetic properties with high permeability, saturation, and low coercivity.

2.02.2.3 Actuation Mechanisms

As discussed in Section 2.02.3.2, a magnetic field can be used to produce force, torque, and displacement of microstructures or magnetic induction. One can conceptually understand magnetic actuation: materials, initial orientations, and magnetic field uniformities, as illustrated in **Figure 7** (Liu 2006). Two pieces of permanent magnets (pieces A and B) and two soft magnets (pieces C and D) are used as examples. Their initial orientations are different. Pieces A and C are oriented such that their internal magnetization is parallel to the applied magnetic field lines. Pieces B and D are intentionally misaligned.

Under a uniformly applied magnetic field, the soft magnets become polarized so that they are magnetized. When the internal magnetization is parallel to the applied magnetic field, no force or moment is generated (pieces A and C). However, if the internal magnetization is placed at a given angle with respect to the applied magnetic field, the magnetic pieces B and D will experience torques, but not a translational net force. However, a nonuniformly applied magnetic field produces the translational net force. The summary of the force and the torque for each piece under these three situations is provided in **Table 3**.

Note that the direction of the internal magnetization of pieces B and D is aligned along their longitudinal axes, rather than being parallel to the direction of the applied magnetic field. Easy axis refers to the energetically favorable direction of the spontaneous magnetization in a ferromagnetic material. This axis is determined by various factors, including the magnetocrystalline anisotropy and the shape anisotropy. For example, as shown in **Figure 5**, a thin cantilever beam of a ferromagnetic material can exhibit strong magnetization in the plane of the beam rather than vertical to the beam surface, even when the applied induction field $\mathbf{H}_0$ is primarily aligned to the normal direction of the beam surface. This phenomenon is a consequence of energy

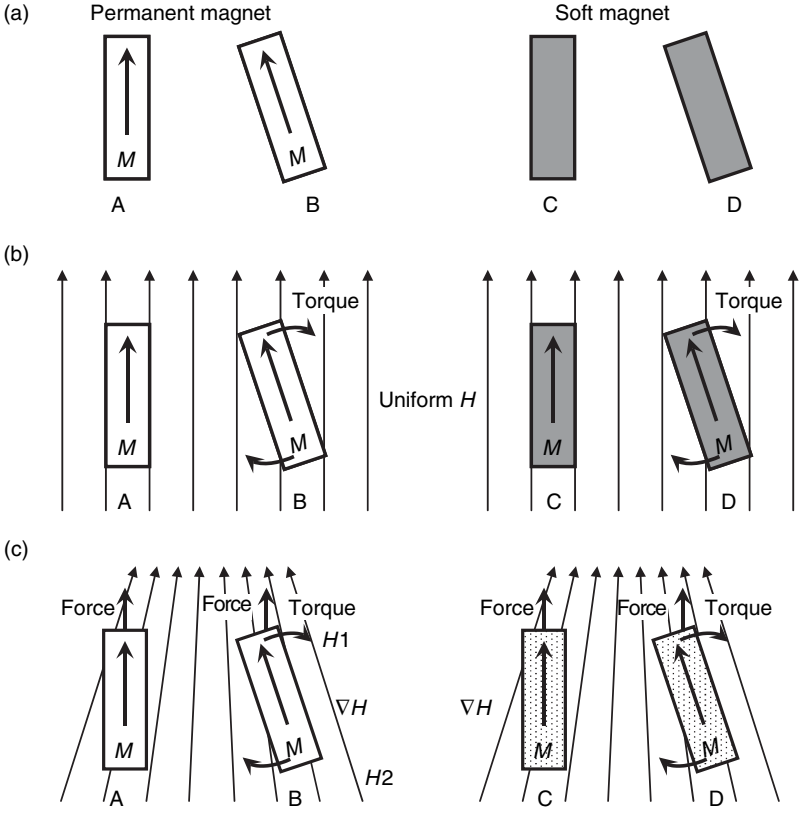

Figure 7 Magnetization states and force states in magnetic field lines. Net magnetic force and torque for each piece are indicated under each biasing case. (a) No applied magnetic field, (b) uniformly applied magnetic field, and (c) nonuniformly applied magnetic field. *H* is the local strength of the biasing magnetic field. ∇H is the difference of the magnetic driving field at two monopoles. (Source: Liu C 2006 *Foundations of MEMS*. Pearson Education, Upper Saddle River, NJ.)

Table 3 Presence of magnetic translational force and rotational torque

	No field (H = 0)				*Uniform field*				*Nonuniform field*			
Pieces	*A*	*B*	*C*	*D*	*A*	*B*	*C*	*D*	*A*	*B*	*C*	*D*

Rotational torque	No	No	No	No	No	Yes	No	Yes	No	Yes	No	Yes

minimization to align magnetic domains. It simply takes less energy to magnetize along the longitudinal direction than that to magnetize to the normal direction of the in-plane direction of the magnetic pieces.

Magnetic actuators shown in **Figure 8** can be categorized according to the types of magnetic sources and the microstructures involved. The source of magnetic field can be an external solenoid, an integrated electromagnetic coil, or a permanent magnet. Multiple types of sources can be used in a hybrid manner. A permanent magnet easily generates a magnetic induction of 0.5–1 T, while the magnetic induction of a simple planar electromagnetic coil with about 10 windings is in the millitesla range (Gijs 2004). An external electromagnet solenoid with increased number of coil windings can generate better magnetic induction than the integrated electromagnetic coil. The microstructures in magnetic actuators, located on a chip, can be a permanent magnet (or hard ferromagnet), a soft ferromagnet (permalloy), or an integrated electromagnetic coil. The movable parts under magnetic source can be in the forms of a membrane, a beam, a spherical ball, magnetic particles, or a ferrofluid plug. The relation among these cases according to the classification scheme is summarized in **Table 4**. For example, in **Figure 8(a)**, a microstructured membrane is directly bonded to a core of external solenoid so that the membrane is movable upward or downward. In **Figure 8(h)**, a beam integrated with microcoils is placed between two permanent magnets, and rotates by Lorentz forces when current passes through the coils.

With a well-designed magnetic structure, magnetic forces can be controlled by changing coil currents in external solenoids or integrated electromagnets. By alternating the currents positively or negatively, the coil can also give different magnetic poles, north or south. In coil-free magnetic actuation, the magnetic forces are generated by permanent magnets, which are usually stationary. Sometimes, the permanent magnets are useful in handling moving balls, particles, or ferrofluids in microfluidic channels to continuously produce the magnetic fields and forces without any external energy. Most magnetic actuators require continuous power to keep the actuators on. This problem can be solved by bistable actuations that require power only in a transient mode between two stable positions. Unique bistable (Bohm *et al.* 2000, Capanu *et al.* 2000, Maekoba *et al.* 2001, Ren *et al.* 1997) and bidirectional (Bhansali *et al.* 2000, Cho and Ahn 2003) actuators can be realized by taking advantages of magnetic pole interactions between the permanent magnet and the electromagnets.

Table 4 Types of magnetic actuators and corresponding case from **Figure 8**

		Movable part

2.02.3 Materials and Fabrication

2.02.3.1 Deposition of Magnetic Materials

Magnetic materials exhibit many unique and useful properties apart from the high permeability of soft magnet materials and the high coercivity of permanent magnet materials. It is well known, for example, that soft magnetic materials enhance the magnetic induction B in the material over what would be achieved in free space by the same applied magnetic field H. In magnetic actuation, it is necessary to fabricate both the permanent magnets and the electromagnets with required properties.

Permanent magnet and electromechanical devices can be found in a wide variety of products (e.g., audio and video players, telecommunications equipment, personal computers, printers, copiers, automobiles, appliances, power tools, data storage devices, and biomedical apparatus) that have an impact on our daily lives (Furlani 2001). A good permanent magnet should produce a high magnetic field with a low mass, and should be stable against influences that would otherwise demagnetize it. In terms of a magnetic moment, miniature magnets fare much better than coils as their size is reduced. The desirable properties of such magnets are typically stated in terms of the remanence and coercivity of the magnet materials. **Table 5** contains some data about materials used as permanent magnets (Myers 1997). Both the coercivity and remanence are quoted in tesla, the basic unit for magnetic field *B*. Besides coercivity and remanence, a quality factor for permanent magnets is the quantity $(BH_0)_{max}$. A high value for this quantity implies that the required magnetic flux can be obtained with a lesser volume of the material, making the device lighter and more compact. The most common and the most powerful micromagnets currently used in magnetic actuators are individually micromachined from bulk Nd–Fe–B or Sm–Co magnets. However, this method is incompatible with full integration or batch fabrication (Yan *et al.* 2001).

Besides the form of bulk permanent magnets, the form of film permanent magnets is very useful in magnetic actuators (Chin 2000). Since biasing of magnetoresistive transducers by permanent magnets films was demonstrated for high-resolution recording head (Bajorek and Thompson 1975), various applications based on permanent magnet films have been developed. Some films are thin films up to a few hundred nanometers, while others are thick layers of a few micrometers, even to tenths of a millimeter. These films can be deposited by metallurgical processes (e.g., sintering, pressure bonding, injection molding, casting, extruding, and calendaring), vacuum processes (e.g., evaporation, sputtering, molecular beam epitaxy, chemical vapor deposition), and electroplating processes (Myung *et al.* 2003). Electroplating (Cho *et al.* 2000, Liakopoulos *et al.* 1996) and screen printing of bonded powders (Dutoit 1999, Lagorce *et al.* 1999) are very well adapted to microfabrication but the resulting magnetic properties are relatively poor compared to bulk permanent magnets. Other techniques such as sputtering (Jeong *et al.* 2000, Lileev *et al.* 2002), pulsed laser deposition (Hannemann *et al.* 2002), or low-pressure plasma spraying (Rieger *et al.* 2000) give excellent magnetic properties but either the thickness of the deposited layer is too thin or the process is too difficult to adapt to microtechnology and batch fabrication due to high deposition temperature, chemical pollution, slow deposition rate, small deposition surface. Various permanent magnet films for microelectromehanical systems (MEMS) applications have been reviewed by several authors (Chin 2000, Cugat *et al.* 2003, Gibbs *et al.* 2004, Myung *et al.* 2003, Niarchos 2003) and summarized in **Table 6** (Chin 2000).

Micromachined thick CoNiMnP permanent magnet arrays on a silicon substrate were fabricated by electroplating (Liakopoulos *et al.* 1996). The magnet arrays had 1500 micromagnets of 40 μm × 40 μm × 50 μm dimension in a cubic shape. They had high vertical coercivity of $0.6 - 1.0 \times 10^5$ A m^{-1}, a remanence of 0.2–0.3 T, a saturation magnetic induction of 1.2–1.3 T, and a maximum energy density of 14 kJ m^{-3}. Electroplated thick CoNiMnP-based permanent magnet arrays with controlled direction of magnetization and improved magnetic properties were reported by applying external magnetic fields during electroplating (Cho *et al.* 2000). The optimized processing conditions with external magnetic fields applied during electroplating have improved the coercivity and the retentivity of the magnets by more than 200% and 350%, respectively,

Table 5 The coercivity, remanence, and a quality factor $(BH_0)_{max}$ for permanent magnets

Material	*Coercivity (T)*	*Remanence (T)*	*$(B H_0)_{max}$ (kJ m^{-3})*

compared with those processed without external magnetic fields. As shown in **Figure 8(g)**, using integrated spiral coils around the electroplated magnets enables microactuators, microsensors, and other MEMS devices.

As discussed, electroplating is very well adapted to microfabrication for depositing ferromagnetic materials, as shown in **Figure 9**. The process used in electroplating is called electrodeposition, and it is analogous to a galvanic cell acting in reverse. The sample to be coated is placed into a container containing a solution of one or more metal salts. The sample is connected to an electrical circuit forming the cathode (negative) of the circuit, while an electrode typically of the same metal source to be plated forms the anode (positive). When an electric current is passed through the circuit, metal ions in the solution take up excess electrons from the sample, resulting in the deposition

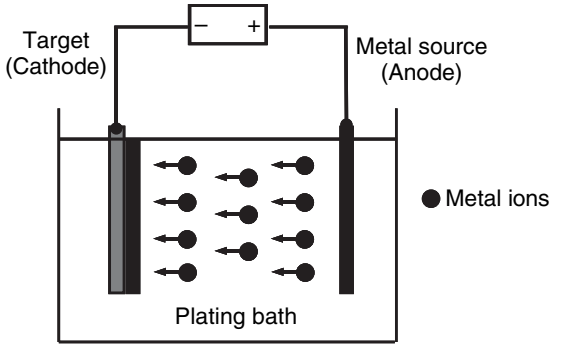

Figure 9 Typical electroplating bath. A target is connected to the cathode and a metal source is connected to the anode.

of a layer of metal on the sample. The electroplating process is often desirable over other vacuum-based thin-film deposition methods because it is relatively easy and cheap to reach appreciable thickness from a few micrometers up to hundreds of micrometers. The electroplating rate can be controlled by the applied current density; the greater the current density, the faster the electroplating.

Electroplating is a very useful process for producing metal structures (e.g., Au, Ag, Cu, Ni, Pt, hard and soft magnetic materials) above the target substrate in predefined patterns followed by photolithography, as shown in **Figure 10**. Since the wafer is not conductive, the surface of a wafer is first coated with a thin-film conductive metal layer called the seed layer. Common seed layer materials are copper, aluminum, or gold. Thin metal layers of Cr or Ti are often used to enhance adhesion between the seed layer metal and the substrate. A thick mold, typically using thick photoresists (PRs) (e.g., AZ4620, SU-8, Futurrex NR-9000), is deposited and patterned on top of the seed layer. The wafer is immersed in an electroplating solution, and magnetic materials grow in the open windows where the seed layer is exposed to the electroplating bath. Depending on the current density and the duration of electroplating, the thickness of the electroplated magnetic materials can be controlled. After removing the thick PR mold, the electroplated magnetic materials remain on the surface of the wafer, as shown in **Figure 11**.

Soft magnetic materials such as permalloy, with about 20% iron and 80% nickel content, or orthonol,

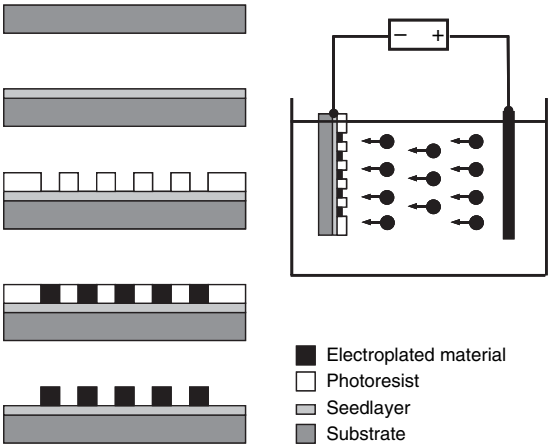

Figure 10 A process for the electroplating of magnetic materials and its typical electroplating bath.

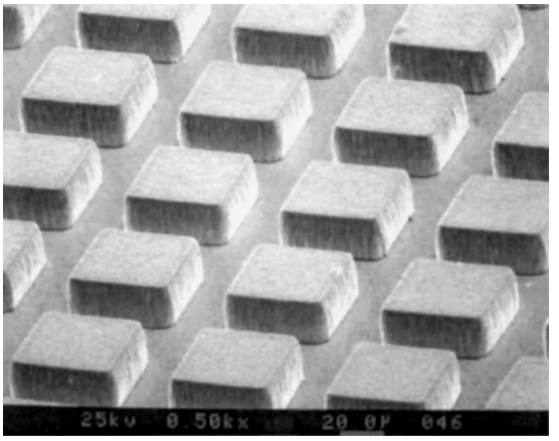

Figure 11 After removing the thick photoresist (PR) mold, the electroplated magnetic materials remain on the surface of the wafer. (Source: Cho H J, Bhansali S, Ahn C H 2000 Electroplated thick permanent magnet arrays with controlled direction of magnetization for MEMS application. *J. Appl. Phys.* **87**, 6340–2.)

with about 50% iron and 50% nickel content, are most frequently used for their preferable properties and availability of electroplating methods and baths. Permalloy is a commonly used soft magnetic material in MEMS because of its relatively high magnetic saturation ($B_S = \sim 1$ T), low coercivity (low hysteresis loss), near-zero magnetostriction (i.e., magnetic properties not affected by film stress), and significant anisotropic magnetoresistance (Myung *et al.* 2003, Niarchos 2003). Permalloy has been used for many years for the fabrication of magnetic heads in the recording industry and for magnetic microactuators. **Table 7** gives typical plating bath compositions for soft and hard magnetic materials, including permalloy, orthonol, and CoNiMnP (Cho *et al.* 2000, Liakopoulos *et al.* 1996, Park and Allen 1998).

2.02.3.2 Fabrication of Electromagnetic Coils

At the macroscale, conventional electromagnets usually have a solenoid shape, which can be manufactured by simply winding many turns of a conducting coil around a ferromagnetic core. However, miniaturization of integrated electromagnetic coils in magnetic microactuators is a very challenging task due to limited thickness and cross section. Although a hybrid approach can be found in the assembly of wound coils (Fischer and Guckel 1998, Guckel *et al.* 1991, 1992), for true integration, the planar fabrication methods are favorable. Three types of integrated electromagnetic coils, spiral type, solenoid type, and meander type, are possible, as illustrated in **Figures 12** and **13** (Ahn and Allen 1998).

The easiest form of integrated electromagnetic coils is a single-layer spiral-type planar coil with an air core. However, this coil cannot generate a strong magnetic flux due to the lack of a magnetic core and the lateral spreading of coils away from the center. It is difficult to guide the magnetic flux to the required point in this structure without using a magnetic core. By adding a magnetic core made of a high permeability soft magnetic material, a spiral-type planar coil with the core can perform better than the coil without the core. Furthermore, an arrangement of multilayer, spiral-type coils with a core to increase the number of turns can improve its performance.

To fabricate solenoid-type electromagnetic coils on a planar substrate, quasi 3D micromachining techniques are suggested (Ahn and Allen 1998). This solenoid- or bar-type planar coil with a closed magnetic circuit can be considered as one of the favorable structures as a magnetic flux generator in microscale, since the wires wrapped around a closed magnetic core result in low leakage flux, and the generated flux can be flexibly guided to the required points.

Brief fabrication steps for a solenoid-type electromagnetic coil are shown in **Figure 14**, which has been applied for the magnetic actuation of microvalves (Sadler *et al.* 1999). In this integrated coil, the process involves first etching and electroplating magnetic vias or through-holes, and then building the electromagnetic coil on top of the through-hole

Table 7 Electroplating bath compositions for soft and hard magnetic materials

Magnetic material	*Electroplating solution*	*Amount*
Permalloy: Ni(80%)–Fe(20%)	$NiSO_4 \bullet 6H_2O$ (g l^{-1})	200

wafer using a multilayer thick PR process. Through-holes are patterned onto the backside of a 250-μm-thick silicon wafer using standard photolithography and are then etched in a 45% KOH solution. After etching is completed, the empty through-holes are electroplated with NiFe permalloy using a backside Cr/Cu/Cr metal layer as an electroplating seed layer. The through-holes are plated until they reach the top of the wafer, thus forming the magnetic vias, which allow magnetic flux to pass through the silicon wafer. After the magnetic vias are complete, the solenoid-type coil is ready to be fabricated on the topside of the wafer. Fabrication of coil on top of the through-hole wafer is based on a thick PR process. AZ-4000 series PR is used to produce a 25-μm-thick electroplating mold. Copper lines are then electroplated on top of the mold from an underlying Ti/Cu seed using standard electroplating techniques. After removing the PR and the seed layer, a new layer of PR is spun, via openings are patterned, and the PR is hard cured at 220°C to form a permanent and planarizing dielectric layer. Another seed layer is then deposited from which first vias and then a magnetic core are patterned and electroplated. Conductor vias are electroplated copper with a cross section of 50 μm × 50 μm and a thickness of 25 μm. The magnetic core is formed from electroplated NiFe permalloy and is also 25 μm thick. Then photoresist and seed layers are removed, and a layer of photoresist is spun and hard cured to form another permanent and planarizing dielectric layer. Finally, top conductor lines are patterned and grown from another seed layer using exactly the same method as for the bottom conductors. Again, the conductor thickness is 25 μm.

An integrated meander-type coil can be realized, where meander refers to the wrapping approach, by interchanging the roles of the conductor wire and the magnetic core in the solenoid-type coil. In the meander-type electromagnetic coil, a magnetic core is wrapped around a conductor line, i.e., a multilevel magnetic core is wrapped around a planar conductor. This structure has the advantage that a relatively short, planar conductor is used, thus reducing the total conductor resistance. Using this coil structure, a planar magnetic micromotor and a micropump with a fully integrated stator and wrapped coils were realized (Ahn and Allen 1995, Ahn *et al.* 1993).

2.02.3.3 Magnetic Particles

In addition to the thin films or mechanical structures of hard and soft magnetic materials, mobile magnetic particles, ranging in size from a few nanometers to many micrometers, offer tremendous applications in microfluidic-based magnetic actuation (Gijs 2004, Pamme 2006). Due to the presence of embedded magnetic entities, they can be magnetically manipulated by magnetic fields, in parallel with normal microfluidic or biological processes. In magnetic actuation, nonuniform magnetic field or magnetic field gradient is frequently used to transport and manipulate these magnetic particles.

The majority of magnetic particles are superparamagnetic. Superparamagnetic particles are magnetized in a magnetic field since the particles have a core of small iron oxide crystals encased by a polymer shell. Iron oxides, such as magnetite (Fe_3O_4) or maghemite (γ-Fe_2O3) are more stable against oxidation, and are preferentially used as core material instead of iron. Biomolecules such as DNA strands, antigens, or antibodies can easily be attached to their surface due to their engineered polymer shell surface for selectively binding the biomolecules of interest. However, since they have no magnetic memory, once the external field is removed, the particles redisperse and behave like a nonmagnetic material. Once suspended magnetic particles are selectively removed from a solution using a magnetic field, they remain suspended even after the removal of the field. Therefore, it is very easy to manipulate the magnetic particles in microfluidic-based magnetic actuation. Another advantage of using small particles is a large surface-to-volume ratio for chemical binding.

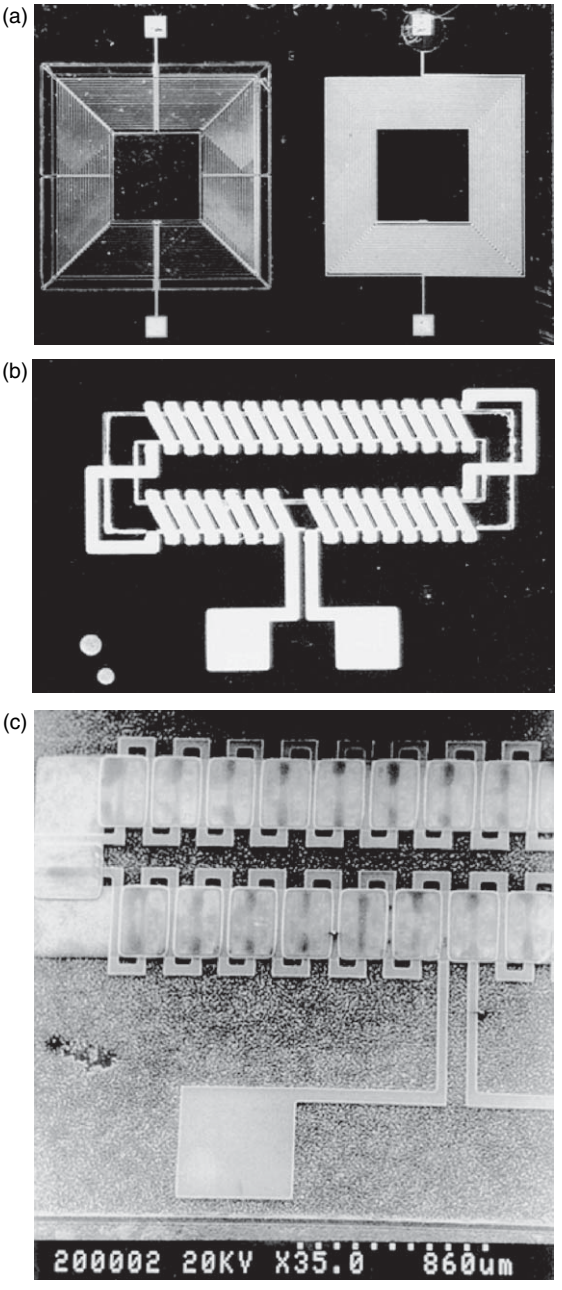

Figure 13 Fabricated examples of three types of integrated electromagnetic coils: (a) spiral type without a core and with a core, (b) solenoid type, and (c) meander type. (Source: Ahn C H, Allen M G 1998 Micromachined planar inductors on silicon wafers for MEMS applications. *IEEE Trans. Ind. Electron.* **45**, 866–76.)

Magnetic fluids or ferrofluids are another class of superparamagnetic material that can be used in microfluidic devices. Developed by NASA in the 1960s, ferrofluids are used today in many applications such as loudspeakers, CD-ROMs, computers,

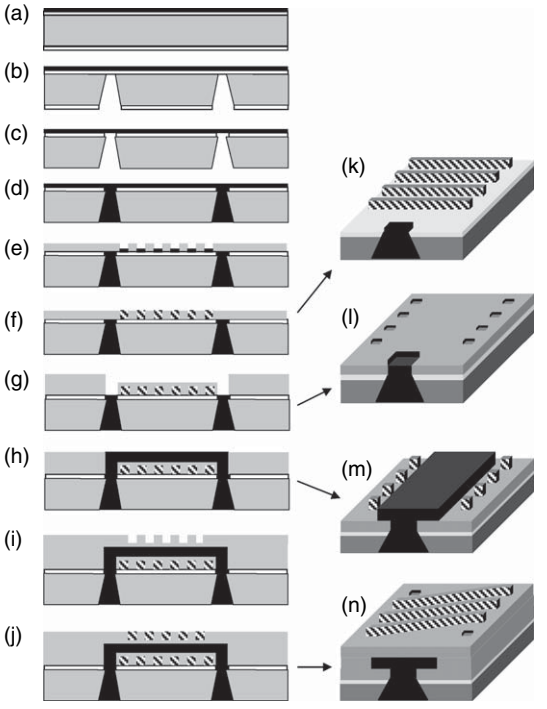

Figure 14 Bar-type magnetic actuator fabrication steps: (a) silicon wafer with Cr/Cu seed layer; (b) through-hole etch in KOH; (c) oxide removal; (d) NiFe through-hole plating; (e) thick photoresist (PR) patterning for copper conductor lines; (f, k) electroplating of thick copper conductor lines; (g, l) via opening and PR hard curing; (h, m) electroplating of vias and magnetic core; (i) thick PR patterning for copper conductor lines; and (j, n) via opening on second PR layer, hard curing, and top conductor line electroplating.

and semiconductor fabrication (Rosensweig 1985). The ferrofluid is a stable colloidal suspension of subdomain magnetic particles in a liquid carrier such as water or an organic solvent. The particles, which have an average size of about 10 nm, are coated with a stabilizing dispersing surfactant, which prevents particle agglomeration even when a strong magnetic field gradient is applied to the ferrofluid. Therefore, in microfluidic channels the ferrofluid is a good plug that moves easily by external magnetic forces.

2.02.4 Applications

2.02.4.1 Microfludics: Valves, Pumps, and Mixers

In microfluidic systems, magnetic actuators such as valves, pumps, and mixers have been realized for many years. The research on microfluidics, including

microvalves (Hesketh *et al.* 2004, Oh and Ahn 2006), micropumps (Laser and Santiago 2004, Woias 2005), micromixers (Nguyen and Wu 2005), and world-to-chip microfluidic interfaces (Fredrickson and Fan 2004) has been thoroughly reviewed. In this section, selected examples of magnetically driven microvalves, micropumps, and micromixers are covered.

2.02.4.1.1 Microvalves

Solenoid-shaped external electromagnets are routinely used in magnetic actuation, and can be simply attached to the microvalve structures. In 1979, a miniaturized electromagnetic microvalve was demonstrated using a solenoid plunger, which was physically connected to a silicon micromachined membrane (Terry *et al.* 1979). The microvalve was the first active micromachined valve, and a component of an integrated gas chromatography system, as shown in **Figure 15** and also indicated in **Figure 8(a)**. A microvalve with a thin permalloy membrane as a cap inside a small tube and a solenoid coil mounted outside was built by Yanagisawa *et al.* (1993). Various types of ball-type microvalves making use of solenoid-shaped electromagnets were reported (Fu *et al.* 2003, Krusemark *et al.* 1998, Oh *et al.* 2001). Although some pinch valves are commercially available (from Bio-Chem Valve, Boonton, NJ), a miniaturized pinch-type valve using a stand-alone conventional solenoid compliant with a surface-mountable scheme on an integrated microfluidic biochemical detection system for magnetic bead-based immunoassay has been reported (Choi *et al.* 2002, Oh *et al.* 2005a, b).

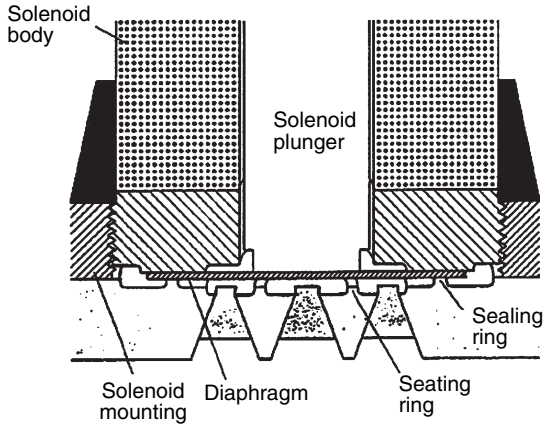

Figure 15 The microvalve with a solenoid plunger as a component of an integrated gas chromatography system. (Source: Terry S C, Jerman J H, Angell J B 1979 A gas chromatographic air analyzer fabricated on a silicon wafer. *IEEE Trans. Electron. Devices* **26**, 1880–6.)

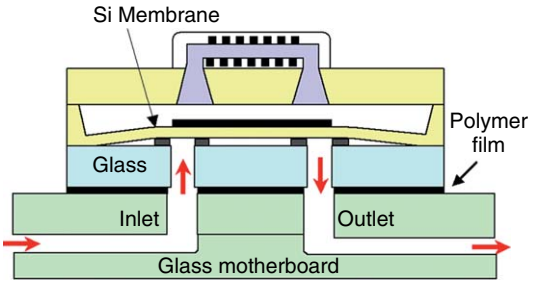

Figure 16 The normally closed magnetic microvalve with an integrated electromagnet. (Source: Oh K W, Han A, Bhansali S, Ahn C H 2002 A low-temperature bonding technique using spin-on fluorocarbon polymers to assemble microsystems. *J. Micromech. Microeng.* **12**, 187–91.)

Active microvalves with a fully integrated solenoid-type electromagnet (see **Figure 14**), a deflectable silicon membrane with a permalloy thin film, and a stationary inlet/outlet valve seat were developed (Cho *et al.* 2001, Choi *et al.* 2001a, b, Oh *et al.* 2002, Sadler *et al.* 1999). A schematic representation of the microvalve mounted on a glass motherboard is shown in **Figure 16**. The electromagnet, valve components, and the glass motherboard were fabricated individually and then bonded together using a low-temperature polymer bonding technique to fabricate the microvalve (Oh *et al.* 2002). The electromagnet acted as a flux generator and produced sufficient forces to pull the silicon membrane by magnetically coupling with the NiFe permalloy electroplated on the silicon membrane. The achievable flow rate increased quickly after an applied current of about 250 mA for N_2 gas.

Movable membranes hybrid integrated with permanent magnets to increase magnetic forces with low power consumption are possible in two ways: integrated with coils (in this case, the permanent magnet is fixed) (Bosh *et al.* 1993, Goettsche *et al.* 2005, Meckes *et al.* 1999) or mounted with permanent magnets (the permanent magnet is free to move by actuating external coils) (Bae *et al.* 2002, 2003, Jerman 1994). Most microvalves require continuous power to keep the valves on or off. This problem can be solved by bistable actuations that require power only in a transient mode between two stable positions. Unique bistable microvales can be realized by taking advantages of magnetic pole interactions between the permanent magnet and the electromagnets (Bohm *et al.* 2000, Capanu *et al.* 2000, Maekoba *et al.* 2001,

Ren and Gerhard 1997) or by combining electromagnetic and electrostatic actuation (Bosh *et al.* 1993).

In addition, a novel phase change bistable microvalve using a paraffin-based ferrofluid plug was reported, as shown in **Figure 17** (Oh *et al.* 2005a, b). The material (called Ferro-Wax) was formed by mixing ferrofluids and paraffin waxes in a volume ratio of 1:2. The Ferro-Wax plug was essentially leak-proof because of the phase change nature of the material; once the plug is solidified, it forms a solid seal. A top glass substrate with holes (φ 500 μm) and microchannels (a width of 300 μm and a depth of 150 μm) was anodically bonded with a wet etched silicon wafer using a Ti/Pt heater/sensor. For injection of the paraffin-based ferrofluid plug, the chip (20 mm × 20 mm × 0.8 mm) was heated to 80°C on a hot plate and the plug of 0.2 μl was loaded into the stem hole. The meltable magnetic plug changed the phase from solid to liquid by an on-chip heating and moved remotely in a channel by magnetic actuation without pneumatic air/vacuum systems. The bistable microvalve performed excellently up to 50 psi. The use of only ferrofluids as microvalves (Hartshorne *et al.* 2004) and micropumps (Hatch *et al.* 2001, Yamahata *et al.* 2005) has also been suggested.

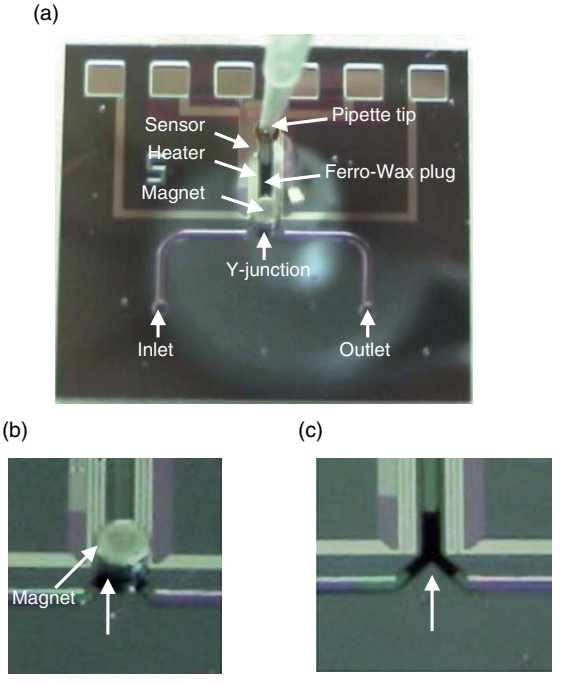

Figure 17 (a) The chip was heated to 80°C on the hot plate and meltable magnetic plug of 0.2 μl was loaded into the vent hole, (b) the molten plug was stopped at the Y-junction in the presence of the permanent magnet, and (c) the plug was solidified after cooling to 60°C.

2.02.4.1.2 Micropumps

A planar magnetic micromotor and a micropump with a fully integrated stator and wrapped coils were realized (Ahn and Allen 1995, Ahn *et al.* 1993). A meander-type integrated inductive component was used in the motor for flux generation (see **Figure 12(c)**). As shown in **Figure 18**, the stators were made of the meander-type integrated electromagnets, whereas the rotor was made of a permalloy material. The pump actuator was based on the variable reluctance magnetic micromotor with fully integrated stator and coils, which had 12 stator poles in three phases and 10 rotor poles. When phase I coils were actuated, the rotor poles located closest to the excited stator poles were attracted to the stator pole. The actuated phase coils were turned off, and the next phase II coils were actuated for continuous rotation. In this design, the wound poles of all phases were arranged in pairs of opposite polarity to achieve adjacent pole paths of short lengths. The stator and coils arranged in one or more sets and phases were actuated in sequence to rotate the rotor, therefore a rotary magnetic micropump can be demonstrated.

When three microvalves are serially connected and controlled sequentially, they can work as a peristaltic micropump. Zhang and Ahn (1996) built a peristaltic micropump using fully integrated three solenoid-type electromagnets on a silicon wafer. Pan *et al.* (2005) presented a polydimethylsiloxane

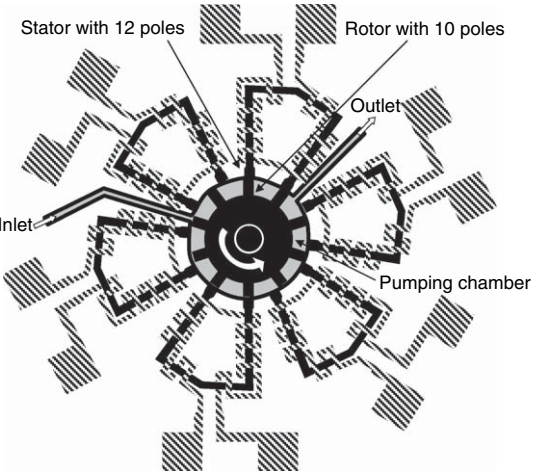

Figure 18 A planar magnetic micromotor and a micropump with a fully integrated stator and wrapped coils.

(PDMS) peristaltic micropump encapsulated with three small permanent magnets in three small chambers. A small DC motor with three permanent magnets stagger-mounted on its shaft was used to pull down and actuate the membrane-mounted magnets to generate a peristaltic waveform. Oh *et al.* (2005a, b) developed a pinch-type peristaltic pump by connecting three pinch-type valves in series, showing self-priming and bidirectional pumping capabilities.

Magnetic micropumps can be easily built by incorporating two check valves in an inlet and an outlet with a pumping chamber where the magnetic actuator produces a stroke volume. McDonald *et al.* (2004) used a PDMS membrane, driven by magnetic force of two miniature permanent magnets, with two one-way microball valves in the inlet and the outlet. A small DC motor with two permanent magnetic disks (NdFeB) mounted on its shaft is used to actuate the membrane-mounted magnet. Santra *et al.* (2002) fabricated a magnetic micropump in a modular fashion using a thin valve membrane sandwiched between two molded bodies and a magnetically oriented permanent magnet composite pumping membrane on top. Bohm *et al.* (1999) developed an electromagnetic actuator consisting of a permanent magnet placed in a coil and secondly a disk. By sandwiching a thin plastic membrane between two molded parts, planar passive membrane valves with low opening pressure resulted.

Magnetic pumping using ferrofluids has also been implemented without using mechanical moving parts in the microstructure. A micropump consisting of two serial check valves converted the periodic motion of a ferrofluidic plug into a pulsed quasi-continuous flow (Yamahata *et al.* 2005). The ferrofluid was actuated by the mechanical motion of an external NdFeB permanent magnet. A planar rotary micropump using ferrofluids in a circular microchannel with an inlet and an outlet was designed (Hatch *et al.* 2001). Two permanent magnets were used, one as a valve actuator and another as a plug actuator: a fixed magnet to create a stationary ferrofluid plug between the inlet and the outlet and a rotational magnet to create a moving plug. By separating the plug into one stationary and one moving plug, the fluid was primed into the inlet and pushed out of the outlet. However, in this pumping method there is a risk of cross-contamination of the fluid with the ferrofluid plugs due to the direct contact. Using an indirect contact method between the fluid and the ferrofluid plugs, a peristaltic rotary pump was miniaturized (Kim *et al.* 2006). Rotating rollers were replaced with rotating ferrofluid plugs that gently squeeze a silicon rubber-based microchannel and that push the fluid from the inlet to the outlet.

Several magnetohydrodynamic (MHD) micropumps have been reported where current-carrying ions in aqueous solutions are subjected to a magnetic field to impart a Lorentz force (eqn [7]) on the liquid and to induce flow. The flow direction depends on the direction of the magnetic field and the direction of the applied electrical field, as shown in **Figure 2**. Because the Lorentz force acts on the bulk fluid and creates a pressure gradient, MHD pumps generate a parabolic velocity profile, similar to pressure-driven flow. Jang and Lee (2000) reported a MHD micropump with a 40-mm-long pumping channel with hydraulic diameter on the order of 1 mm. To avoid electrolysis associated with DC operation, Lemoff and Lee (2000) used a miniaturized electromagnetic coil operating (along with the electric field) at 1 kHz. Several papers have discussed microscale applications of MHD effects (Bau *et al.* 2001, Huang *et al.* 2000, Leventis and Gao 2001, Zhong *et al.* 2002).

2.02.4.1.3 Micromixers

Due to the laminar flow effect at the microscale, mixing multiple streams of fluids with short mixing length for LOC applications has been a difficult task. Various methods for mixing fluids in microscale channels have been demonstrated (Nguyen and Wu 2005). If one can stir fluids in the microchannels, rapid mixing will be produced at the stirrer site, which can be easily done by magnetic actuation. When a rotating external magnetic field is presented, a magnetic microstirrer will experience a torque through interaction between its internal magnetization and the external field. A simple magnetic stir bar structure was integrated directly into a channel (Lu *et al.* 2002, Ryu *et al.* 2004). The permalloy stir bar of 400 μm width can be fitted into a microchamber of 420 μm diameter, as shown in **Figure 19**. The stir bar was activated using the rotating magnet in a commercial hotplate/stirrer. Small magnetic nickel bars controlled by three external electromagnets were also suggested for mixing in microchannels (Barbic *et al.* 2001).

A chain of magnetic microparticles bonded together with linker molecules has been used to mix fluids in a microchannel (Biswal and Gast 2004). A rotating magnetic field generated by two pairs of electromagnets, mixed fluids quickly upon rotation of the chains. A dye and two buffer streams all

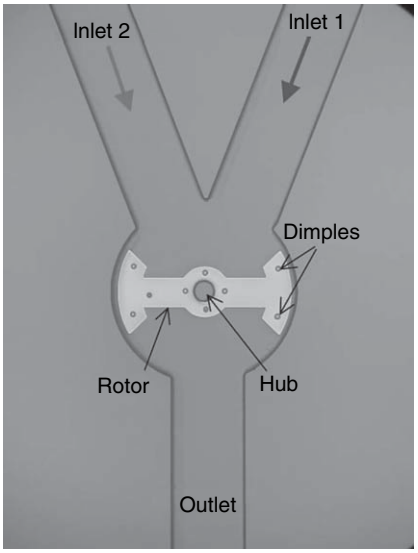

Figure 19 Magnetic mixing with a permalloy rotor controlled by a conventional benchtop stirrer plate. (Source: Ryu K S, Shaikh K, Goluch E, Fan Z F, Liu C 2004 Micro magnetic stir-bar mixer integrated with parylene microfluidic channels. *Lab Chip* **4**, 608–13.)

containing particle chains were merged and mixed. Also, an acid and a base were mixed in the presence of a fluorescent pH indicator. Magnetic particles moving at random were also suggested for mixing of two fluid streams (Rida and Gijs 2004). A plug of magnetic particles was formed in a microchannel by means of an electromagnet, and the particles were moved over short distances due to the ever-changing magnetic field, which was modified by an arbitrary waveform generator. Chaotic mixing was reported in a serpentine microchannel with copper wire electromagnets, embedded transversely to the direction of flow to attract nearby magnetic particles (Suzuki *et al.* 2004). The combination of time-varying magnetic fields and the serpentine geometry resulted in efficient mixing.

MHD flow, described above as a pumping method, can also be utilized for mixing fluids by integrating several MHD pumps into a microfluidic device and by utilizing time-varying flow patterns in order to achieve mixing. Bau *et al.* (2003) reported a circulatory fluid motion to mix fluids in a microchamber with several electrodes along the walls and additional electrodes at the bottom with a large Nd magnet. Time and space variations in the electric field led to chaotic motion and thus mixing, as visualized using a dye. West *et al.* (2003) used a circulating fluid in a circular channel with a MHD micropump for fluid circulation. Two solutions were injected into the channel and the MHD parabolic flow profile led to a large increase in interfacial surface area and thus to mixing.

2.02.4.2 Microoptics: Mirrors

A digital micromirror device has been fabricated with great success by Texas Instruments using electrostatic actuation for large-scale projection (http://www.dlp.com). An alternative good candidate to replace the electrostatic actuation in micromirrors is the magnetic actuation due to its large angular deflection. In addition, arc failure, which is a problem in the electrostatic actuation, can be avoided due to its current-driven actuation. However, the magnetic micromirrors may not be suitable for high-frequency modulation of more than a few kilohertz when compared to the electrostatic one.

One successful example of magnetic micromirrors was an electromagnetic optical scanner for horizontal scanning of a commercial confocal laser scanning microscope by Olympus (Miyajima *et al.* 2003). Magnetic actuation, suitable for moving large structure, was selected because of its millimeter-sized mirror, and single-crystal silicon hinge was used for realizing high-speed scanning (~4 kHz) with sufficient scan angle (2.1–16°). In order to maintain a mirror flatness for high-quality optical requirement, the whole wafer thickness (300 μm) was used as the mirror, resulting in a large moment of inertia. Lorenz force between a planar spiral-type coil on the mirror body and a large magnetic field produced by a bulk permanent magnet was used to actuate the mirror, as shown in **Figure 20** (see also **Figure 8(h)**). A pair of permanent magnets were magnetized in the x-direction, causing the magnetic field mainly in the x-direction, and parts of the actuation coil adjacent to the magnets had currents in the $\pm y$-direction (parallel to the axis of rotation). Therefore, Lorentz force was generated in the $\pm z$-direction, causing torsional actuation. It has successfully satisfied all the specifications including not only the fundamentals such as resonant frequency and scan angle but also the ones for the commercial product such as scanning stability and reliability.

An alternative approach using a hard magnetic CoNiMnP thick film as a permanent magnet component and an external solenoid electromagnet as a variable field source was reported by Cho and Ahn (2002, 2003). **Figure 21** shows a schematic view of a serpentine torsion beam-type scanner with bidirectional scanning capability and **Figure 22** shows its

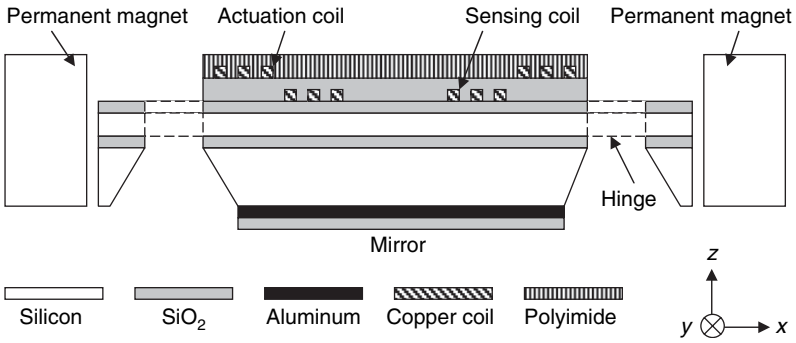

Figure 20 A cross-sectional view of an electromagnetic optical scanner for horizontal scanning of a commercial confocal laser scanning microscope by Olympus.

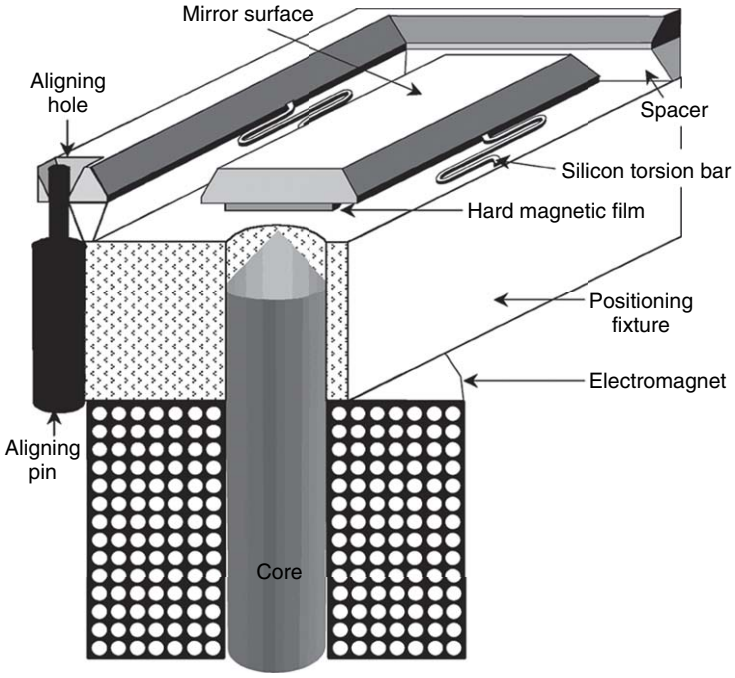

Figure 21 Schematic view of the bidirectional magnetic scanning mirror. (Source: Cho H J, Ahn C H 2003 Magnetically-driven bi-directional optical microscanner. *J. Micromech. Microeng.* **13**, 383–9.)

bidirectional scanning motion. The scanner can be operated bidirectionally with a large deflection of $\pm 70\,\mu m$ with actuation currents of $\pm 60\,mA$ under the condition of a static operation. Under dynamic operation, the prototype scanner showed stable bidirectional scanning performance at the operating frequency of 30 Hz, corresponding to 60 Hz in the regular unidirectional scanner. The average power consumption was 63 mW for AC operation, which is considerably lower when compared to the conventional scanner. At a scanning frequency of 30 Hz, the product of the scan angle and the mirror size $\theta \times D$ (deg $\times$ mm) was 5.0, which is large enough for practical applications. This unique function, moving a large mirror bidirectionally with a large deflection, cannot be easily obtained by using any other actuation mechanism.

Different types of magnetically driven optical micromirrors, scanners, and optical switches have also been studied: a deformable mirror for application to adaptive optics in astrophysics (Divoux *et al.* 1998), an out-of-plane micromirror array for hologram

Figure 22 Bidirectional scanning motion of the magnetic scanning mirror: (*top*) pull; (*middle*) rest; and (*bottom*) push. (Source: Cho H J, Ahn C H 2003 Magnetically-driven bi-directional optical microscanner. *J. Micromech. Microeng.* **13**, 383–9.)

memory devices (Jang and Kim 2003), mirror arrays for 3D optical switching application (Bernstein *et al.* 2004), a magnetoresistive 2D optical scanner (Bourouina *et al.* 2002, Debray *et al.* 2004), a galvanometric scanner (Ferreira and Moehlecke 1999), an electromagnetic 2×2 optical switch (Ji *et al.* 2004), and a double-focus zoom lens by a magnetic mirror for a thin camera (Kinoshita *et al.* 2006).

In addition, a magnetic fluid-based optical switch was designed and characterized (Horng *et al.* 2004). The optical switch was formed by sealing a magnetic fluid between two glass prisms. When light was incident on one side of one of the prisms, the reflected light from the magnetic fluid film came out from the same prism, whereas the transmitted light through the film was emitted from the other prism. It was found that the intensity ratio of the reflected light to the transmitted light can be manipulated by varying the external magnetic field strength.

2.02.4.3 Microelectronics: Switches

Microelectromechanical systems (MEMS) switches or relays have been miniaturized for applications in the areas of automotive control, power electronics, and communications. Most of the MEMS switches (or relays) reported to date have used electrostatic actuation (Gretillat *et al.* 1999, Kruglick and Pister 1999, Receveur *et al.* 2005, Schiele *et al.* 1998). To overcome the disadvantages of high actuation voltage and low mechanical stability in electrostatic actuation, a fully integrated magnetic switch was suggested by Taylor *et al.* (1998). The device with a single-layer coil to actuate a movable upper magnetically responsive platform can make and break 1.2 A of current through the relay contacts when the relay was electromagnetically switched. However, the actuation required continuous power during a given switching period.

For on–off switching operations, bistable latching is preferred, which can eliminate or reduce power consumption, heat generation, and thermal distortion (Cho *et al.* 2005, Cugat *et al.* 2006, Ruan *et al.* 2001a, b). Ruan *et al.* (2001a, b) reported a magnetic switch with the bistable latching operation. The structure and the principle of the bistable magnetic switch is illustrated in **Figure 23** (see **Figure 5**). A cantilever beam

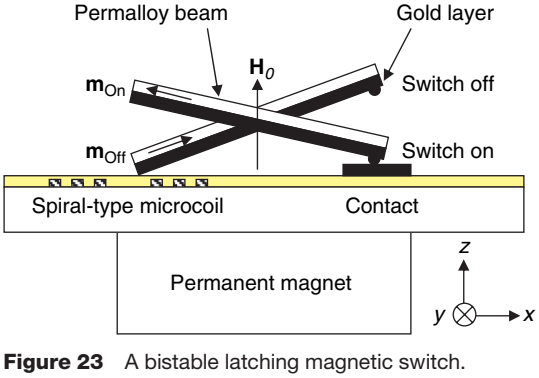

Figure 23 A bistable latching magnetic switch.

consisting of permalloy film on the top and a layer of gold on the bottom was elevated above the substrate by a torsion support. When the beam was placed on a uniform magnetic field $\mathbf{H}_0$ in the z-direction by a permanent magnet, a magnetic torque $\boldsymbol{\tau}_{\text{magnetic}} = \mu_0 \mathbf{m} \times \mathbf{H}_0$ (see eqn [20]) was exerted in either the clockwise or the counterclockwise direction, depending on the initial orientation of the beam with respect to the magnetic field. The bottom permanent magnet was used to hold the beam in one state until the next switching took place. A spiral-type planar microcoil beneath the beam generated switching magnetic field lines pointing in both the x- and z-directions. The magnetic field in the x-directional component was mainly responsible for the switching. When a switching field was a sufficient magnetic field greater than a critical field to toggle the orientation of the $\mathbf{m}$, the induced magnetic field caused a magnetization toggling between $\mathbf{m}_{\text{on}}$ and $\mathbf{m}_{\text{off}}$, resulting in rotation of the beam. By reversing the current in the coil, the original position was restored.

By combining electromagnetic and electrostatic actuation with a latching mechanism, two types of radio frequency (RF) MEMS switches (series type and shunt type) have been demonstrated by Cho *et al.* (2005). The switch used electromagnetic force only during switching transition periods and for the rest of the holding period it used electrostatic force to maintain low power consumption. When a spiral-type coil was excited counterclockwise, a membrane with the coil was actuated downward by Lorentz force in an external magnetic field by a permanent magnet and the contact metal made an electrical connection to the underlying coplanar waveguide signal line. Then, electrostatic force between the coils and the bottom electrode was activated to hold the membrane for maintaining its on state. For switching its state back to the off state, a reverse current was applied and then the contact metal was detached from the bottom signal line by Lorentz force as well as by the mechanical restoring force.

2.02.4.4 LOC: Magnetic Manipulation and Separation

Magnetic actuation has also been used in various LOC devices for bioassay processes such as sample preparation, sample injection, sample manipulation, reaction, separation, and detection. A magnetic field gradient was used to either remotely manipulate or selectively separate biological materials attached to magnetic particles, as well as cells. Magnetic actuation is generally not affected by surface charges, pH, ionic concentrations, or temperature; therefore the use of magnetic particles in biomedical devices gives an additional degree of freedom. **Figure 24** shows several concepts to manipulate magnetic particles as well as magnetically labeled cells in microfluidic devices (Pamme 2006). Magnetic particles can be transported by time-varying electromagnetic fields along a track of meandering gold wires (Deng *et al.* 2001), along a sawtooth gold wire (Wirix and de Boeck 2004), and along a gold wire mesh (Lee *et al.* 2004). In magnetic transport, manipulation of magnetic particles is a difficult task because the magnetic susceptibility of the magnetic particles is rather weak due to small magnetic core volumes and the demagnetization effects of the particles. On the other hand, magnetic separation is different from magnetic transport in the sense that the magnetic particles are captured and therefore separated by magnetic actuation, but are transported using a liquid flow (Gijs 2004).

Magnetic separation of cells (magnetic-activated cell separation, MACS) labeled with magnetic beads in tubes or capillaries has become a common method for the separation of antigens, antibodies, DNA, and even cells (Dunnill and Lilly 1974, Kondo *et al.* 1994, Koneracka *et al.* 2002, Kourilov and Steinitz 2002, Mosbach and Andersson 1977, Rashkovetsky *et al.* 1997). In microscales, H-shaped channel networks can be used for continuous flow magnetic separation as illustrated in **Figure 25**. Kim and Park (2005) reported a microfluidic immunoassay utilizing binding of superparamagnetic nanoparticles to beads and deflection of these beads in a magnetic field as the signal for measuring the presence of analyte. The superparamagnetic 50-nm nanoparticles and fluorescent 1-μm polystyrene beads were immobilized with specific antibodies. When target analytes reacted with the polystyrene beads and superparamagnetic nanoparticles simultaneously, the superparamagnetic nanoparticles were attached to the microbeads by the antigen–antibody complex. With a high-gradient magnetic field, only the microbeads conjugated with superparamagnetic nanoparticles by analytes moved to the magnetic fields and were consequently separated through a corresponding outlet channel.

Pamme and Manz (2004) demonstrated on-chip free-flow magnetophoresis capable of separating magnetic from nonmagnetic particles as well as separating magnetic particles of different sizes from

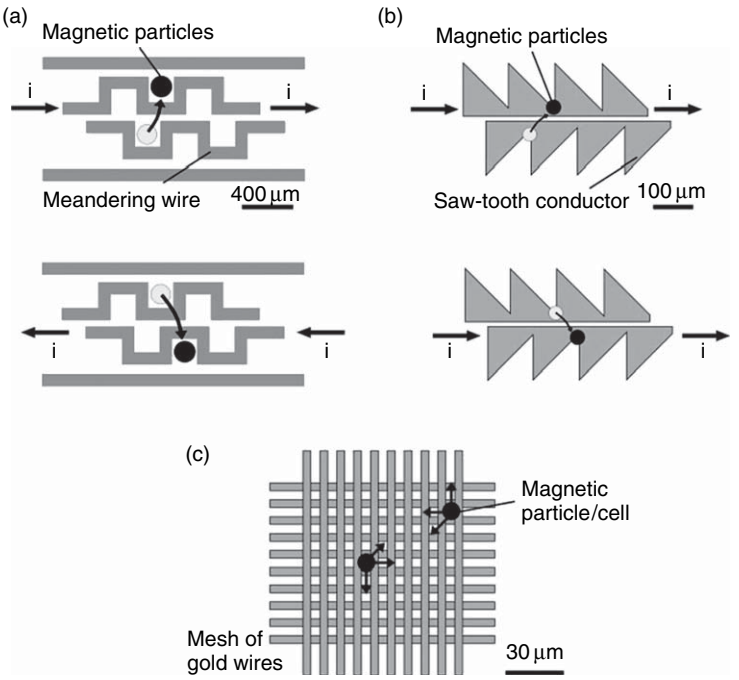

Figure 24 Magnetic particles can be transported by time-varying electromagnetic fields: (a) along a track of meandering gold wires; (b) along a sawtooth gold wire; and (c) along a gold wire mesh. (Source: Pamme N 2006 Magnetism and microfluidics. *Lab Chip* **6**, 24–38.)

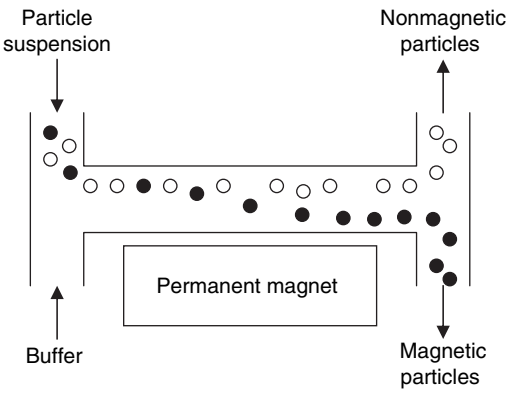

Figure 25 Principle of H-shaped separators for continuous flow separation.

each other (see eqn [27]). In continuous flow, magnetic particles were deflected from the direction of laminar flow by a perpendicular magnetic field by means of an assembly of NdFeB magnets, depending on their magnetic susceptibility and size and on the flow rate. The 4.5-μm particles with larger susceptibility were deflected further from the direction of laminar flow than the 2.0-μm magnetic particles. Nonmagnetic 6-μm polystyrene beads, however, were not deflected at all.

Instead of using permanent magnets to generate nonuniform magnetic field or magnetic field gradient for trapping magnetic particles in flow, Choi, Ahn, and coworkers reported several microfluidic devices with integrated electromagnets. Ahn and coworkers fabricated 3D electromagnets with poles adjacent to a microchannel (Ahn *et al.* 1996), spiral-type electromagnets (Choi *et al.* 2001a), and serpentine-type electromagnets (Choi *et al.* 2000, 2001b, 2002). Depending on the electromagnet design, currents of 500–30 mA were required to capture magnetic particles at the electromagnet poles. **Figure 26** shows the concept of magnetic particle-based bioseparation using the serpentine-type electromagnet for the case of antigen–antibody sandwich immunoassay. Antibody-coated magnetic particles are introduced on the electromagnet (**Figure 26(a)**) and are separated by applying magnetic fields. While holding the antibody-coated magnetic particles (**Figure 26(b)**), antigens are injected into the channel (**Figure 26(c)**). Only target antigens are immobilized and, thus, separated onto the magnetic particle surface due to antigen–antibody interaction (**Figure 26(d)**). Other antigens are washed out with the flow. In a subsequent step, labeled secondary antibodies are introduced and incubated with the immobilized

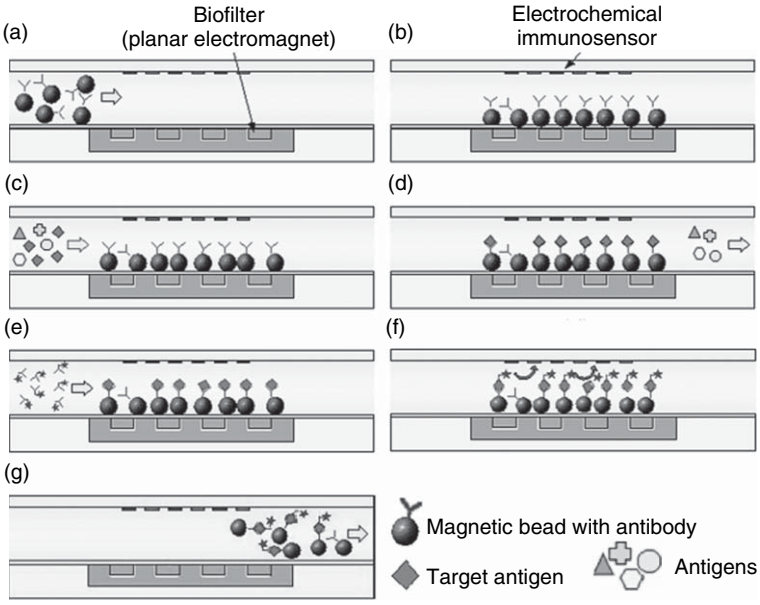

Figure 26 Conceptual illustration of biosampling and immunoassay procedure using magnetic particle approach: (a) injection of magnetic particles labeled with antibody; (b) separation and holding of particles; (c) flowing sample; (d) immobilization of target antigen; (e) flowing labeled antibody; (f) electrochemical detection after adding enzyme substrate; and (g) washing out magnetic particles and ready for another immunoassay. (Source: Choi J-W, Oh K W, Thomas J H, Heineman W R, Halsall H B, Nevin J H, Helmicki A J, Henderson H T, Ahn C H 2002 An integrated microfluidic biochemical detection system for protein analysis with magnetic bead-based sampling capabilities. *Lab Chip* **2**, 27–30.)

antigens after which the chamber is rinsed to remove all unbound secondary antibodies (**Figure 26(e)**). The substrate solution, which will react with the enzyme, is injected into the channel and the electrochemical detection is performed (**Figure 26(f)**). Finally, the magnetic particles are released and the bioseparator is ready for the next sample (**Figure 26(g)**).

At the microscale, magnetic microparticles coated with biomolecules were often used as solid supports for antigens/antibodies (Choi *et al.* 2002, Kim and Park 2005), DNA (Fan *et al.* 1999, Liu *et al.* 2004), RNA (Jiang and Harrison 2000), and even cells (Furdui *et al.* 2003). However, in the cases of red blood cells (Han and Frazier 2006) and magnetostatic bacteria (Lee *et al.* 2004) the additional magnetic particles coated with specific biomolecules were not necessary due to their natural magnetophoretic properties. Furlani (2006) used analytical analysis to study magnetophoretic particle transport and capture a microsystem consisting of an array of integrated soft magnetic elements embedded in a nonmagnetic substrate beneath a microfluidic channel. In addition to magnetophoretic particle transport, manipulation, and separation, the magnetic properties of the particles can also be used for detection using sensitive magnetic sensors such as giant magnetoresistive (GMR) sensors, spin-valve sensors, superconducting quantum interference devices (SQUID), and miniaturized hall sensors (Pamme 2006).

2.02.5 Summary

Magnetic actuation is one of the most widely used actuation principles found in our daily lives. In this chapter, we studied magnetic actuation and discussed several related topics including basic magnetic theory, scaling effect, the Lorentz force, magnetic induction, magnetic force and torque, magnetic field gradient, magnetization, and magnetic actuation mechanisms pertaining to microscale magnetic actuators. We also discussed representative magnetic materials such as permanent magnets, hard and soft magnetic materials, and magnetic particles. Fabrication processes such as electroplating of ferromagnetic materials and electromagnetic coils that are key building blocks in the magnetic microsystems were also covered. Finally, selected examples of magnetic microactuators in the areas of

valves, pumps, mixers, mirrors, switches, as well as manipulation of magnetic particles and magnetic cell separation were reviewed. In addition to magnetic actuation, the magnetic microsystems can also be advantageous to magnetic sensing. With advancements in these magnetic-based microsystems, magnetic actuation will be widely applicable to many microsystems.

Biographies

Kwang W. Oh joined the Department of Electrical Engineering at the University at Buffalo (UB), the State University of New York, Buffalo (SUNY-Buffalo), NY, in March 2006. After receiving his Ph.D. degree from the University of Cincinnati in 2001, he worked as a technical staff member in the biolab at Samsung Advanced Institute of Technology, Korea. At Samsung, he was responsible for microfluidics in developing lab-on-a-chip (LOC) platforms for clinical diagnostic applications. His main research activity in SMALL (nanobioSensors and MicroActuators Learning Laboratory) at UB is Small (nano & micro) Science & Technology, including sample-to-answer nano/microfluidic system; nonobiosensors and microactuators; world-to-chip interfacing and packaging; and single cell manipulation, sorting, and detection. He has an excellent record of publications with more than 42 journal and conference proceeding papers, including one topical review paper on microvalves and 24 patents in the fields of MEMS, BioMEMS, and microfluidics.

Chong H. Ahn received his Ph.D. degree in Electrical and Computer Engineering from the Georgia Institute of Technology, Atlanta, GA, in 1993. From 1993 to 1994, he was a postdoctoral associate at the Georgia Institute of Technology and at IBM T.J. Watson Research Center, Yorktown Heights, NY. In 1994, he joined the Department of Electrical and Computer Engineering and Computer Science at the University of Cincinnati, Cincinnati, OH, where he currently holds the rank of professor in the Departments of Electrical Engineering and Biomedical Engineering. He is also the director of the microsystems and Bio-MEMS lab at the University of Cincinnati. He has published approximately 170 journal and conference proceeding papers related to the MEMS, BioMEMS, and microfluidics.

2.03.1 Introduction

The microactuator is one of the key components to form a real comprehensive microsystem. Other key components are microsensors, control circuits, and communication interface (Najafi *et al.* 1994). Over the past two decades, extensive efforts have been devoted to the microactuator development. Different actuation mechanisms have been described and summarized in detail (Que and Gianchandani 2005). Those most widely explored so far include electrostatic (Tang *et al.* 1989), thermal (Que *et al.* 2001a, b), piezoelectric (Schiller and Polla 1993), shape memory alloy (SMA) (Ma *et al.* 2000), electromagnetic (Guckel *et al.* 1992), solid–liquid phase change, thermopneumatic (Zdeblick *et al.* 1994), and microbubble and microsteam (Lin *et al.* 1991, Sniegowski 1993).

Output force F, displacement u, volume v, and response time t are four critical parameters to quantify the performance of microactuators. Another useful parameter, work output per unit volume (W), is defined as

$$W = \frac{\vec{F} \cdot \vec{u}}{v} \qquad [1]$$

Typically, as the displacement of an actuator increases, the available force at that displacement decreases. Usually, the displacement of a microactuator refers to the peak displacement with no loading force under a fixed actuation voltage, current, or

power, whereas the output force refers to the peak force with no displacement at the same actuation condition. The offered output force at each intermediate displacement can be obtained based on those two peak values. Several performance parameters for major actuators are summarized in **Table 1**.

The thermal actuator can provide both high force (up to several millinewtons) and large displacement (up to several hundred micrometers), but its speed spans from several hertz to several tens of kilohertz depending on the structural material, design, and target displacement, which is limited by the cooling procedure during each actuation cycle. However, its actuation voltage can be kept <15 V, which is compatible with standard integrated chip (IC) testing. More will be discussed in the following sections.

2.03.2 Thermal Actuation

2.03.2.1 Basic Theory

The thermal expansion or contraction property of a material is the basis for thermal actuation. Therefore, the materials can be gas, liquid, or solid as far as they are expandable or shrinkable when heated or cooled down, respectively. The heating of the structural material can be generated by either passing current through an embedded resistor (Joule heating) or using optical excitation (optothermal effect) (Oliver *et al.* 2003). In contrast, the cooling of the structural material can be achieved by immersing the actuator into a low-temperature environment, such as low-temperature liquid or water.

Even though the materials for thermal actuation cover a very broad range and the configurations of each specific actuator are different, a basic heat transfer model can be applicable to all of them (Que 2000). This model can help to analyze the performance of thermal actuators, including their displacement, volume expansion, output force, response speed, power consumption, and even their reliability. Therefore, it provides an excellent guidance and tool for the thermal actuator design. In order to describe this model and understand its basic principles and approaches, a specific actuator design is illustrated in the following.

In this case, a simple bent-beam electrothermal actuator is used as an example to analyze the heat transfer process (Lott *et al.* 2002, Que and Gianchandani 2005). The basic schematic diagram of a bent-beam actuator is shown in **Figure 1**, which includes all the design parameters essential for the simulation. The device consists of two connected shallow-angled beams suspended above the substrate while their ends are anchored to the substrate. The device is typically operated in air at temperature T_{air}. When the current I is applied, the temperature of the beams rises due to Joule heating. There are three different heat dissipation mechanisms: (1) the heat directly conducts through the beam itself, to the anchor, and then to the substrate; (2) the heat is dissipated by conductive and convective mechanisms through the air; and (3) the heat is dissipated into the environment in the form of infrared radiation.

Table 1 Major actuators and their typical performance

Actuator type	*Displacement (μm)*	*Output force (μN)*	*Actuation voltage (V)*	*Speed (Hz)*	*W (J m^{-3})*	*Comments*
Electrostatic	0.1–30	0.1 to 1×10^3	~50 to 120	3×10^3	7.0×10^2 to 1.8×10^5	Parallel plate Comb drive Force array

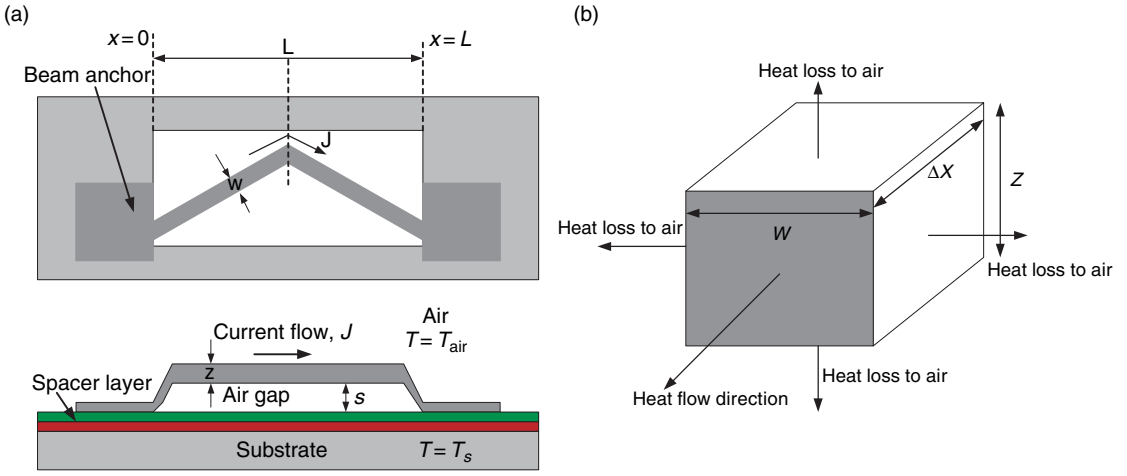

Figure 1 (a) Top view and cross-sectional view of the bent-beam actuators and (b) the differential element of the bent beam.

In order to set up a finite difference model, the device should be divided into discrete volume elements. The differential element of the bent beam of width w, thickness z, and length Δx is given in Figure 1(b). The heat balance equation for the element is

$$Q_{\text{total}} = P_{\text{g}} + Q_{\text{conduction}} + Q_{\text{convection}} + Q_{\text{radiation}} \quad [2]$$

where Q_{total} is the net rate of the change of the internal energy of the element, P_{g} the power generated inside the element by the Joule heating, $Q_{\text{conduction}}$ the conduction heat loss in the element, $Q_{\text{convection}}$ the convection heat loss, and $Q_{\text{radiation}}$ the radiation heat loss.

Specifically, Q_{total} is expressed as

$$Q_{\text{total}} = \rho_{\text{m}} cwz\Delta x\left(\frac{\partial u}{\partial t}\right) \quad [3]$$

where c and ρ_{m} are the specific heat and density of the beam material, respectively, and u is the average temperature. The power generated by Joule heating is given by

$$\begin{aligned} P_{\text{g}} &= \mathcal{J}^2 \rho(u) wt\Delta x \\ &= \mathcal{J}^2 \rho_0 wz\Delta x(1 + \text{TCR} \times (u - T_0)) \end{aligned} \quad [4]$$

where $\mathcal{J}$ is the current density in the element, ρ_0 its resistivity at T_0 (room temperature), and TCR the temperature coefficient of the resistivity of the material.

The conductive loss component consists of two parts. One is the conduction through the beam itself, e.g., through adjacent differential elements to the substrate to dissipate in the anchor region, and the other is the conduction of heat through the air to the substrate. It is given by

$$\begin{aligned} Q_{\text{conduction}} = &- k_{\text{b}} wz\left(\left.\frac{\partial u}{\partial x}\right|_x - \left.\frac{\partial u}{\partial x}\right|_{x+\Delta x}\right) \\ &- k_{\text{air}} \eta w\Delta x \frac{u - T_{\text{s}}}{s} \end{aligned} \quad [5]$$

where k_{b} and k_{air} are the thermal conductivity of the beam material and the air, respectively, and η is the excess flux coefficient. η accounts for the fringing heat flux of each differential element and s is the air gap between the beam and the substrate.

The convection loss component is expressed as

$$Q_{\text{convection}} = 2b(V_{\text{air}}, P)(w + z)\Delta x(u - T_{\text{air}}) \quad [6]$$

where $b(V_{\text{air}}, P)$ is the convective heat transfer coefficient from the beam to the air as a function of the air flow velocity V_{air} and the absolute pressure P.

Assume that the upper and side faces of the beam radiate to the surrounding air, and the bottom face radiates to the substrate. The radiation loss component is given by

$$\begin{aligned} Q_{\text{radiation}} = &\sigma_{\text{b}}(w + 2z) \\ &\Delta x(u^4 - T_{\text{air}}^4) + \sigma_{\text{b}} w\Delta x(u^4 - T_{\text{s}}^4) \end{aligned} \quad [7]$$

where σ_b is the Stefan–Boltzmann constant for the structural material. Based on eqns [6] and [7] and boundary condition

$$u(x)|_{x=0} = u(x)|_{x=L} = T_{\text{s}} \quad [8]$$

the steady-state solution of this system can be obtained. For most cases, the heat loss by infrared radiation is negligible since the average actuation temperature of

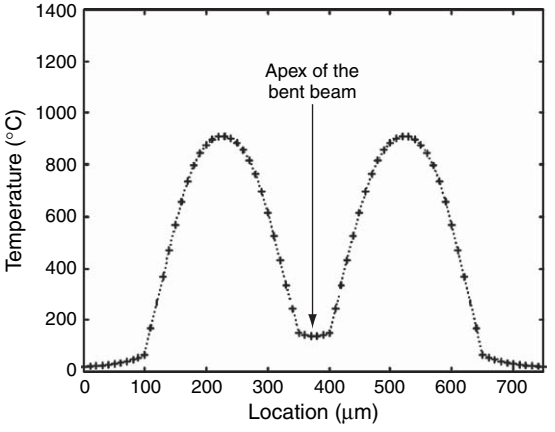

Figure 2 A descriptive calculated temperature profile showing the temperature drop around the apex of the bent-beam actuator. (Source: Lott C, Mclain T, Harb J, Howell L 2002 Modeling the thermal behaviour of a surface-micromachined linear-displacement thermomechanical microactuator. *Sensors and Actuators A* **101**, 239–50.)

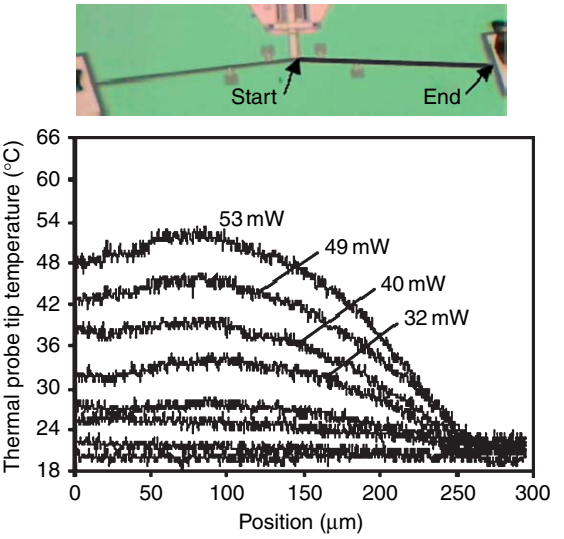

Figure 3 Range on the bent beam of the temperature measurement (*upper*) and measured temperature profile (*lower*). (Source: Chu *et al*. 2006.)

the bent-beam actuator does not exceed 600°C. If the actuator is driven in a vacuum system, the convection loss is also negligible due to very little free molecule air conduction. The average temperature of the beam is obtained by integrating the temperature profiles along the beam length and dividing by the beam length. It is numerically calculated by

$$T_{\text{average}} = \frac{\int_0^L u(x)\mathrm{d}x}{L} \qquad [9]$$

Once the temperature variation and profile in the structure are obtained, the output force and displacement can be estimated.

For a qualitative description, a calculated temperature profile of the bent-beam actuator based on eqn [9] is given in **Figure 2** as an example (Lott *et al.* 2002). The apex region of the bent beam has a relatively lower temperature, while the peak temperature actually occurs roughly at 2/3 of the distance from the anchor to the apex, which results from the significant larger heat loss through the connected beam at the apex (**Figure 2**). The descriptive temperature profile along the beam has also been measured by thermal scanning microscopy (**Figure 3**) (Chu *et al.* 2006). The length of each beam is 300 μm and the width is 7.4 μm. It shows a trend similar to the modeling results. Particularly, the larger the applied actuation power, the more similar the trend of the temperature profile to the modeling results, indicating the validation of the analytical model. It can be anticipated that if there is no additional beam connected at the apex, the peak temperature should be around this region. The thermal properties of the widely used structural materials in microactuators are summarized in **Table 2**.

2.03.2.2 Major Fundamental Thermal Actuators

2.03.2.2.1 Bimorph and multimorph

If two or more layers of dissimilar materials are grown adjacently to each other, actuation can be generated when heated since they have different coefficients of thermal expansion (CTE). These kinds of actuators are called bimorphs or multimorphs, depending on the number of the layers of the materials. A simple mathematical model can be used to describe their performance.

A bimorph or a multimorph typically consists of a cantilever with two or more layers, respectively. One layer of heating resistor is sandwiched between them (**Figure 4**). Assume that each layer is homogeneous in the X- and Y-directions. The length L of each layer is the same. When the current is passed through the heating resistor layer, a thermal stress σ_{T} will be generated between different layers due to the temperature difference ΔT_i. It is given by

$$\sigma_{\mathrm{T}} = E_i \alpha_i \Delta T_i \qquad [10]$$

where E_i and α_i denote the Young's modulus and the CTE of the ith layer, respectively. The thermal stress causes the cantilever to bend. The bending amount and direction of each cantilever depends on the CTE

difference, temperature difference, dimensional parameters, and mechanical properties of adjacent contacting materials.

For a bimorph actuator, the displacement of the cantilever tip at a small deflection angle is given as follows (Zhang *et al*. 1999):

$$\delta=\frac{3W_1W_2E_1E_2t_1t_2(t_1+t_2)(\alpha_2-\alpha_1)\Delta T\times L^2}{(E_1W_1t_1^2)^2+(E_2W_2t_2^2)^2+2W_1W_2E_1E_2t_1t_2(2t_1^2+3t_1t_2+2t_2^2)} \quad [11]$$

and the output force is given as follows:

$$F=\frac{3EI}{L^3}\times\frac{3\times\Delta\alpha\times\Delta T\left(1+\frac{t_1}{t_2}\right)L^2}{t_2\left\{\left(\frac{W_1E_1}{W_2E_2}\right)\left(\frac{t_1}{t_2}\right)^3+\frac{W_2}{W_1}\frac{E_2}{E_1}\left(\frac{t_2}{t_1}\right)+2\left[2\left(\frac{t_1}{t_2}\right)^2+3\left(\frac{t_1}{t_2}\right)+2\right]\right\}} \quad [12]$$

where t_i and W_i are the thickness and the width of the *i*th layer, respectively, $\Delta\alpha=\alpha_2-\alpha_1$, $\Delta T=T_2-T_1$, and *EI* is the equivalent stiffness of the bimorph cantilever, which is given by

$$EI=\frac{W_2^3t_1E_1E_2}{12(E_1t_1+E_2t_2)}K \quad [13]$$

$$K=\left[4+6\frac{t_1}{t_2}+4\left(\frac{t_1}{t_2}\right)^2+\frac{E_1}{E_2}\left(\frac{t_1}{t_2}\right)^3+\frac{E_2}{E_1}\frac{t_2}{t_1}\right] \quad [14]$$

These equations can be used as a guide to design bimorph actuators to fulfill the required performance, including desired displacement and output force. Typical displacement can be up to several hundred micrometers while the speed of the actuators as high as 1 kHz was obtained.

For a multimorph actuator, similar equations can be obtained to describe its performance and can be used to design a specific multimorph to fulfill a specific requirement.

One of the major issues for bimorph or multimorph is the bending of the actuator along the perpendicular direction of the layered structure once it is released from the substrate, resulting in an unpredictable initial position. The bending is caused by residual stress in each layer. The residual stress consists of two components: thermal stress and intrinsic stress. While the thermal stress due to CTE mismatch is the basis for thermal actuation, the intrinsic stress affects the repeatability and the reliability. The intrinsic stress results from the defects, grain size, reorganization of the structural material, etc., during fabrication process flow. Research found that the intrinsic stress can be mitigated by ion beam machining and rapid thermal annealing (RTA) (Bifano *et al*. 2002, Huang *et al*. 2006), therefore eliminating the initial bending of the released bimorph actuator.

Experiments found that bimorphs showed very nice reliability with less than ±2% hysteretic error

(Xie *et al.* 2003) and that they can be operated up to several-million-cycle actuation without observable degradation.

2.03.2.2.2 Pseudo-bimorph actuator

While bimorph and multimorph typically offer displacement and force perpendicular to the substrate, the other type of thermal actuator called the pseudo-bimorph actuator can offer displacement and force parallel to the substrate. It was first reported by Henry Guckel in the early 1990s (Guckel *et al.* 1992). This actuator is made of just one single layer of the structural material and the thermal expansion difference, resulting from different Joule heatings due to different resistances, is because of the two different shapes in the structure.

It has two types of designs. In both the cases, it has two arms connected in a U-shape. One design has two connected arms of different widths but the same lengths (**Figure 5(a)**). The other design, in contrast, has two arms of same width but different lengths (**Figure 5(b)**) (Pan and Hsu 1997). The actuator shown in **Figure 5(a)** consists of two beams of different widths. When the current is passed through the beams, the narrower beam becomes hotter than the wider one due to its larger resistance. Thus, it expands more than the wider beam. Since the two arms are joined at the free end, an arc deflection of the tip of the actuator toward the cold wider beam occurs. A deflection of several tens of micrometers and an output force of several tens of micronewtons can be generated for a 200- to 300-μm-long polysilicon actuator with power consumption of about 40 mW. The operating frequency can reach 2.5 kHz.

Assuming that the temperature difference between the hot and the cold beam is T_{HC}, the deflection of the tip is given by the following equation (Guckel *et al.* 1992):

$$\Delta X = \frac{\alpha \Delta T_{HC} L^2}{g\left(0.7707 + 0.3812\,\frac{t^2}{g^2}\right)} \qquad [15]$$

where α is CTE, g the gap between the hot and the cold beam, L the half-length of the hot and cold beams, and t the thickness of the structural material. For this structure, the deflection of the tip is independent of the Young's modulus E of the material, which is confirmed by measured data and a finite element model (Guckel *et al.* 1992).

In the design shown in **Figure 5(b)**, when the current is passed through the beams, the heat generated in the conductive long and short beams causes the temperature to change. Because of the difference between the temperature increment ΔT_L in the long beam and the temperature increment ΔT_S in the short beam ($\Delta T_L > \Delta T_S$), and because of the different beam lengths ($L_L > L_S$), the long beam has more elongation than the short beam. Therefore, the long beam curls toward the short beam.

Out-of-plane actuation to the substrate can be realized by arranging and modifying the pseudo-bimorphs properly. Two designs are schematically shown in **Figure 6** (Cowan and Bright 1997).

The vertical displacement is achieved by the thermal mismatch between the hot and the cold arm when current is applied through the beams. Experiments and modeling both found that the

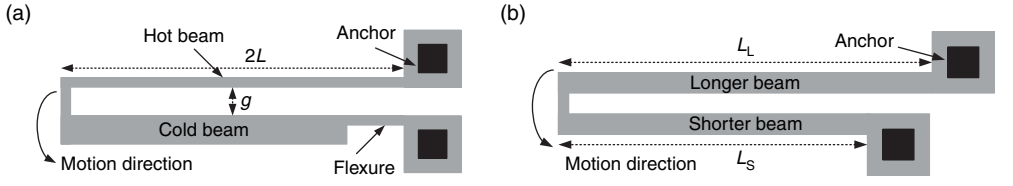

Figure 5 Schematic of (a) design I and (b) design II of pseudo-bimorph actuator.

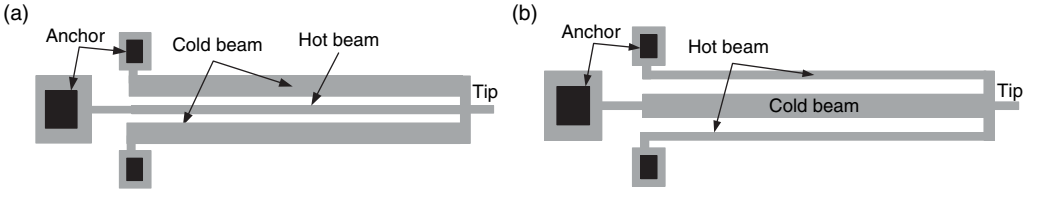

Figure 6 Two designs of a vertical electrothermal actuator: (a) hot beam in the middle and (b) cold beam in the middle.

device with the hot beam in the middle (**Figure 6(a)**) is a better design, because it has a consistent temperature difference between the hot and the cold beam and thus can maintain the repeatable up-and-down movement.

Reliability testing on loaded pseudo-bimorphs fabricated using the SUMMiT™ process developed has been performed. Some devices can be operated up to 980 million cycles at 2 kHz and still reach their full deflection at the end of the operation (Comtois *et al.* 1997).

2.03.2.2.3 Bent-beam actuator

Using just one single structural material, a class of widely used electrothermal actuators, bent-beam actuators (Cragun and Howell 1999, Que 2000, Que *et al.* 1999, 2001a, b, 2003), has been developed by Gianchandani's group in 1998 and Howell's group in 1999. It offers large in-plane, rectilinear displacement and high output force, different from the pseudo-bimorphs providing arc motion described above.

The sketch of the basic and one-level cascaded bent-beam electrothermal actuator is shown in **Figure 7**. It consists of a V-shaped beam anchored at both ends. When an electric current is passed through the beam, thermal expansion caused by Joule heating pushes the apex outward. The displacement of the apex is a function of the beam dimensions and slope, given the same actuation voltage. The force generated at the apex is linearly related to the displacement. It can easily offer peak force up to the range of several millinewtons, about 200× the forces in electrostatic comb drives of similar dimensions. Furthermore, the output force and displacement can easily be scaled by modifying the dimensions and slopes of the beams. Larger forces can be generated by placing these actuators in parallel, whereas larger displacements up to several hundred micrometers can be obtained by cascading the actuators.

The lifetime of a bent-beam actuator can extend beyond several tens of millions of cycles, depending on design and actuation temperature. The speed of the actuator has been evaluated experimentally and can be estimated by the electrothermal model previously described as well (Lott *et al.* 2002). Besides the thermal mass, the different heat transfer paths in air and vacuum also affect the temperature response time, thus the speed of the bent-beam actuator. By using the mathematical model, it has been shown that the time for the cooling cycle is much shorter in air than in vacuum, since the heat loss and conduction is much faster in the air. The theoretical predictions match reasonably well with experimental results. Typical responding time is in the order of milliseconds and can be reduced into the submilliseconds range if the thermal mass is cut or the displacement is reduced as mentioned earlier. Furthermore, as discussed in Section 2.03.2.5, the response can be enhanced and power consumption can be reduced dramatically if pulsed actuation or burst-pulsed actuation scheme is implemented. More details can be found in Que *et al.* (2004) and Shimamura *et al.* (2006).

2.03.2.2.4 Thermal responsive polymer actuator

The thermal actuators described so far can only offer either in-plane or out-of-plane actuation. In other words, they can only offer 1-directional or 2-directional actuation. Polymer-based thermal actuators are a group of actuators very attractive in microfluidics and bioapplications in that they can offer all-directional actuation since their volumes can be dynamically changed in all directions.

Polymers used for thermal actuation are usually cheap, biocompatible, and compatible with standard micromachining technology, thus good for disposable and for bioapplications. Furthermore, the most important feature of polymer-based actuation is that it can be integrated with the microfluidic lab-on-chip

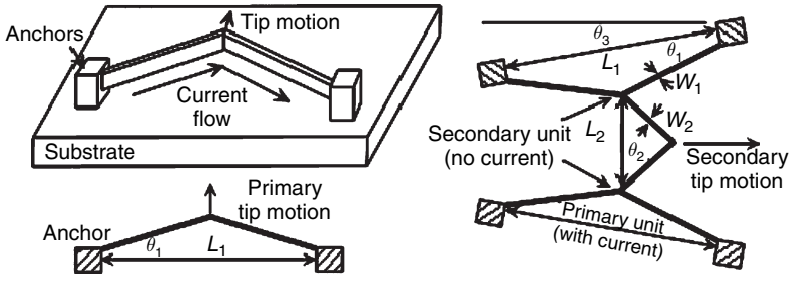

Figure 7 A basic (*left*) and one-level cascaded (*right*) bent-beam actuator.

systems much more easily than other actuation mechanisms, such as electrostatic, magnetic, piezoelectric, and bimorph actuation.

The thermally responsive polymers and microspheres can be either expandable or shrinkable with increased heating or cooling, respectively. Paraffin (Selvaganapathy *et al.* 2003), SU8 (Chronis and Lee 2005), poly(dimethylsiloxane) (PDMS) and microspore mixture (Samel *et al.* 2003) exhibit volume expansion if heated, whereas the volume of poly(*N*-isopropyl acrylamide-*co*-allyl methacrylate) (polyNIPAAm) (Mutlu *et al.* 2003) is shrinkable with increased temperature. Their major properties are summarized in **Table 2**. The volume change of the UV-patterned features of polyNIPAAm is given in **Figures 8** and **9**. PolyNIPAAm is one of the best-known temperature-sensitive polymers with a photoresist-like film characteristic. It shrinks rapidly with reversible phase transition from extended hydrated chains (swollen state) to collapsed hydrophobic coils (shrunk state) from the lower critical solution temperature (LCST) of 32°C to the temperature above LCST. Experiments found that its volume has a 2.5-fold increase as the temperature decreases from 28 °C to 10 °C. The build-up pressure, therefore, increases from ~16 to ~20 psi. The response time is about 7 s by repeatedly measuring the polymer swelling and shrinking (Multu *et al.* 2003). All the experiments for proof-of-principle were performed in water, the temperature of which can be tuned relatively easily.

2.03.2.3 Power Management and Solution

Thermal actuators are based on the heating or cooling of the structural materials; therefore, one important issue is about the power consumption and management. For any microsystem, the power consumption should ideally be minimal. This not only saves the operation power but also significantly extends its lifetime and reliability.

Several efforts have been explored to address this problem for silicon-based devices (Que *et al.* 2002, 2004). One efficient way is to reduce the thermal mass. The power P required for a certain temperature change is given in the following equation:

$$P = \frac{V^2}{R} = c \times M \times \Delta T \qquad [16]$$

where V is the actuation voltage, R the resistance of the bent beam, c the specific heat, M the thermal mass, and ΔT the temperature change.

The power consumption is proportional to the thermal mass if the temperature change is fixed. Therefore, for the same material, reduction of

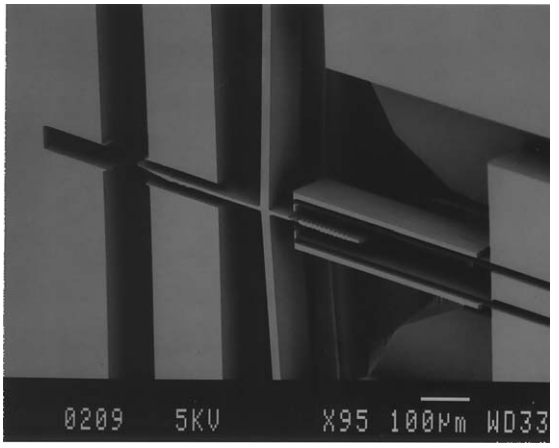

Figure 10 Scanning electron micrograph (SEM) of the digital latching micromechanics. (Source: Que *et al*. 2003.)

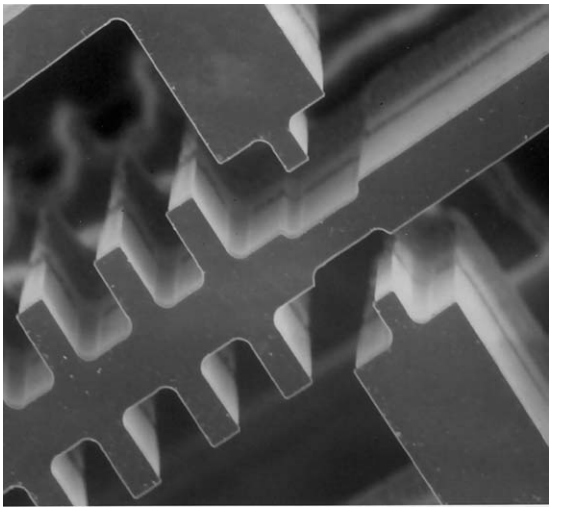

Figure 11 Close-up view of the fabricated digital latching micromechanics. (Source: Que *et al*. 2003.)

thermal mass is a way to cut the power consumption. However, the disadvantages are the potential complexity of the fabrication process and the constant power consumption still needed to maintain the position of the actuator.

The latching micromechanics (Que *et al.* 2002, 2004), in contrast, is the other efficient approach to abate the power consumption. This mechanism works for solid-state material-based actuators, such as silicon or metal actuators. Digital and analog latching are two representatives for this purpose. For both versions, the basic idea is to be able to turn off the power once the actuator has reached the target position. Thanks to the latching mechanism, the actuator, therefore, can retain its position. Under this situation, the power is only required during the actuation period, typically 1 ms or less, resulting in significant reduction in power consumption. One example for the digital latching is shown in **Figures 10** and **11** (Que *et al.* 2002). To describe this functionality briefly, the tooth-shaped structures are micromachined in the center beam, which is driven by a bent-beam actuator. The complementary tooth-shaped structures are micromachined into the pseudo-bimorph. These two tooth-shaped structures are used to engage each other to achieve digital latching. The two thermally driven bimorphs first are open, offering a path for the movement of the center beam. Once the center beam moves to the target position, the bimorphs close and the tooth-shaped structures engage to each other; thus, the center beam is locked mechanically. At this time, the power can be removed from the actuator while the center beam still maintains the position. The other digital latching mechanism, i.e., bistable latching, and analog latching mechanism will be described in Section 2.03.3.

2.03.2.4 Thermal Isolation Strategies

Thermal isolation is very important for the thermal actuator in a microsystem. The heat flow can propagate from the actuator to other components due to temperature gradient if no proper thermal isolation is implemented, resulting in the degradation of the performance of the system or even damage in the samples to be manipulated or under test. In order to isolate the heat flowing from the actuator to the other section in the microsystem, several approaches have been proposed. The basic principle for all approaches is the same, whereas different fabrication processes and materials are utilized.

One approach is to design a trench in the region that mechanically connects the actuator and the other components. The trench is formed by deep reactive ion etching (RIE) and later is filled by materials with a low thermal conduction coefficient, such as silicon dioxide or silicon nitride (Que *et al.* 2001a, b). The fabricated structure is shown in **Figure 12**. The other approach deposits a silicon nitride layer, which is used to connect two separated polysilicon beams in **Figure 13**; thus, the heat flow can be minimized from the actuator to the radio frequency (RF) switch (Wang *et al.* 2002). For both cases, the basic idea is to use some materials with low thermal

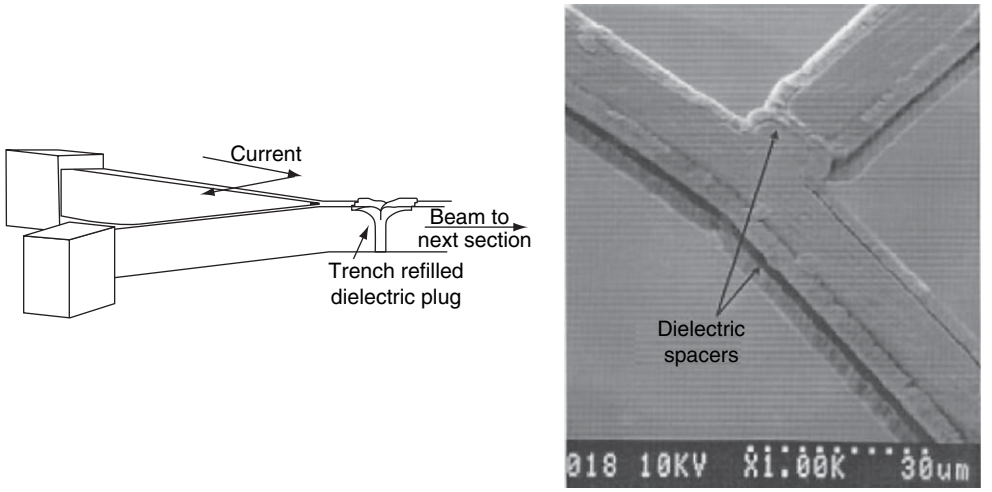

Figure 12 Trench refilled with thermal isolation material silicon dioxide.

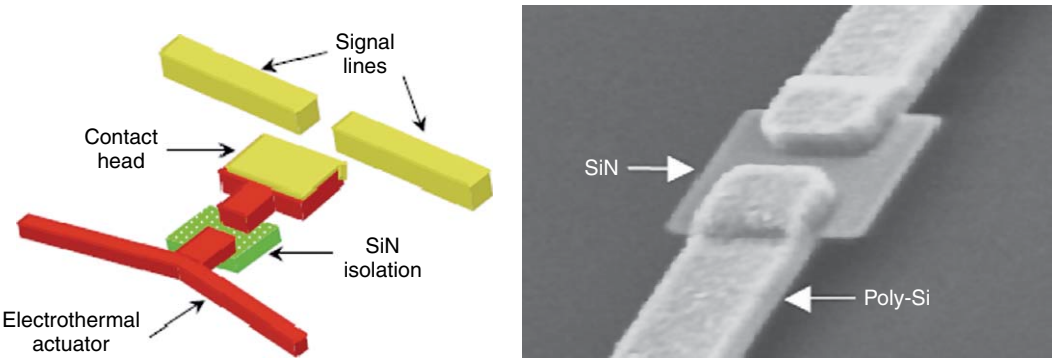

Figure 13 Silicon nitride (SiN) layer connecting polysilicon layer for thermal isolation. (Source: Wang Y, Li Z, McCormik D, Tien N C 2002 Low-voltage lateral-contact microrelays for RF applications. *15th IEEE Int. Conf. Micro-electro-mechanical Systems*, Las Vegas, NV, USA, pp. 645–8.)

conduction to reduce the heat flow, thereby maintaining reasonably low temperature of other parts in the microsystem.

For microfluidics and bioapplications, thermal isolation or mitigation is extremely critical. A scheme using polyimide as an isolation layer for a microvalve is proposed. Its basic idea is similar to the two aforementioned approaches. In contrast, polyimide is used as the thermal isolation material in this case. The sketch of the silicon bimorph and scanning electron micrograph (SEM) of the fabricated device are shown in **Figure 14**. The measurement shows the temperature distribution of the actuator (112°C) and at the thermally isolated region (33°C), indicating excellent thermal isolation between them. Using this approach, a thermally isolated microvalve has been demonstrated (Kawada *et al.* 2003).

2.03.2.5 Response Speed

The heat transfer process directly affects the speed of the thermal actuators, which depends on how fast the resistor can be heated to a target temperature in the heating cycle and how fast the heat can be dissipated in the cooling cycle. The heating process is at the rate of energy transfer between the electron gas and the lattice vibration, and thus quite fast. However, the cooling procedure is relatively slower. Generally, the speed of thermal actuators is limited by this cycle. Therefore, its speed can be potentially increased by integrating heat sink components or cutting the thermal mass.

For both cycles, the effective thermal mass m_{thermal} of the actuator is the major factor in response speed (Lott *et al.* 2002). A bent-beam actuator is used as an example to estimate the speed response of the thermal actuator. Eqns [1]–[8] can be rewritten as the

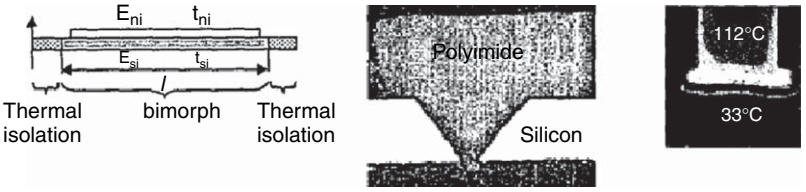

Figure 14 Sketch of the bimorph with polyimide as isolation layer (*left*); scanning electron micrograph (SEM) of the device showing the thermal isolation region (*middle*); and temperature distribution (*right*). (Source: Kawada H, Yoshida H, Kamakura M, Yoshida K, Saitou M, Kawahito K, Tomonari S 2003 Thermally driven microactuator containing thermal isolation structure with polyimide and its application to microvalve. *12th Int. Conf. Solid State Sensors, Actuators and Microsystems (Transducers '03)*, Boston, MA, USA, pp. 1935–8.)

following explicit finite difference model expression. The temperature $T_i(j+1)$ at time $j+1$, therefore, can be obtained using temperatures $T_i(j)$, $T_{i-1}(j)$, $T_{i+1}(j)$ at time j, the current input $\mathcal{J}(j)$, and boundary conditions, where i refers the ith differential element of the bent beam.

$$T_i(j+1) = \frac{\Delta t}{\rho c \Delta V_i}\left[\mathcal{J}^2 \rho_r \Delta V_i + \frac{SA_u}{G_u}(T_{sub} - T_i(j)) + \varepsilon\sigma A_s(T_{sur}^4 - T_i^4(j)) + \frac{k_p A_x}{\Delta x}(T_{i-1}(j) - T_i(j)) + \frac{k_p A_x}{\Delta x}(T_{i+1}(j) - T_i(j))\right] \quad [17]$$

where Δt is the time increment, ρ and c the density and specific heat of the structural material, ΔV_i the element volume, ρ_r the material resistivity, S the shape factor, A_u surface area of the element facing the substrate, G_u the effective thermal conductivity of the element, T_{sub} and T_{sur} the temperature of the substrate and the surroundings, A_s and A_x the area of the exposed surface of the element and cross-sectional area of the element, Δx the length of the element in the direction of heat transfer, k_p the thermal conductivity of the structural material, ε and σ the emissivity of the structural material and the Stefan–Boltzman constant.

The transient temperature response can be calculated using this formula (**Figure 15**). The thermal mass (ρ, c) affects the response.

Pulsed actuation has been explored to improve the transient response and power consumption both theoretically and experimentally by different groups (Que *et al.* 2004, Shimamura *et al.* 2006). It turns out that the response time can be improved while the power consumption is significantly reduced. Furthermore, burst pulse (a series of short pulses) actuation can further improve the efficiency of the actuators. Typically, the response time can be around 0.2 ms compared with several milliseconds for constant current actuation while the required energy is reduced from 1000 to 200 μJ.

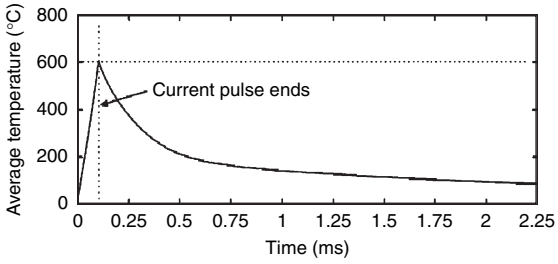

Figure 15 Calculated temperature response of the bent-beam actuator. (Source: Lott C, Mclain T, Harb J, Howell L 2002 Modeling the thermal behaviour of a surface-micromachined linear-displacement thermomechanical microactuator. *Sensors and Actuators A* **101**, 239–50.)

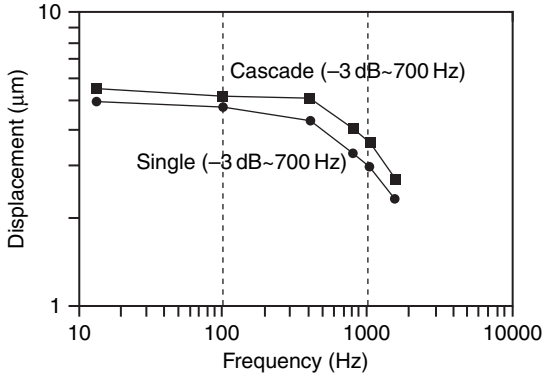

Figure 16 A typical measured response of the bent-beam actuator. (Source: Que *et al*. 2001b.)

One typical measurement result in **Figure 16** shows roughly 1.5 ms response time under constant current actuation (Que *et al.* 2002).

An additional factor on the response speed is the targeted displacement. The smaller the targeted displacement, the lower the heating power required reaching the target temperature, thus the faster the cooling cycle. Experiments found that for pseudo-bimorph, it can be operated as fast as 13 kHz if the displacement is about 2 μm (Comtois *et al.* 1997). It is also true for bent-beam actuators and other thermal actuators.

2.03.2.6 Materials

Theoretically, all materials expandable or shrinkable with increased temperature can be potentially used as the structural material for the thermal actuators. Thus, the material can be gas, liquid, or solid. Widely used materials include doped silicon or polysilicon, electroplated metals, i.e., nickel or copper, and polymers such as SU8, PDMS composite, and Parylene. Recently, some advanced nanoscale materials, such as carbon nanotubes (CNTs), have also been exploited as structural material for optothermal actuation (Lu and Panchapakesan 2005).

While silicon and some metals form the foundation mostly for mechanical microelectromechanical systems (MEMS) applications, the availability of polymers for thermal actuation paves the way for bioMEMS and microfluidics in biological and medical applications. Since these materials are biocompatible and most can be micromachined using a standard microfabrication process, they have been successfully used to construct some major microfluidic components as well as various integrated microfluidic systems. For bioMEMS devices and implantable devices, low voltage is essential for physiologic compatibility; therefore, the thermal actuation has been utilized.

2.03.2.7 Repeatability and Reliability

Repeatability and reliability (lifetime) are two important factors evaluating the performance of the microactuators. The repeatability is that the actuator can always offer the same outputs at the same driving condition at different times. More specifically, the importance of the repeatability is to ensure that the same displacement, volume expansion, or force can be achieved for targeted functionalities; thus, the output of the integrated microsystem can be predictable and dependable, which is the key for maintaining the performance of the integrated microsystem. The hysteresis, for example, of the displacement and driving voltage is definitely not good, and therefore, it should be eliminated or mitigated for robust actuator design.

While repeatability offers the spatial resolution of the actuators, the reliability gives the temporal dependence. The reliability (lifetime) is how long the actuator can maintain the same performance without degradation under continuous actuation. Lifetime is determined by several mechanisms: stress distribution in the actuator, structural material properties, microdefects, microcracks and their propagation in the whole device, etc.

The repeatability and reliability test of bent-beam actuators is used as an illustrative example. The repeatability of bent-beam actuators has been evaluated by measuring the displacements while the driving voltages increase and then decrease in a specific range (**Figure 17**) (Que and Gianchandani 2005). These devices are fabricated using silicon-on-insulator (SOI) wafers; the actuators are micromachined in the device layer, which is single-crystal silicon. Measurements find that as long as the driving voltages are below the upper limit of the voltage, the actuator shows very good repeatability (less than $\pm 1\%$ hysteretic error). Note that at the upper limit of the actuation voltage, too much heating would be generated. Therefore, significant thermal stress and self-annealing would be generated in the device, resulting in inelastic deformation of the actuator. On the contrary, in terms of reliability, the displacement of the actuators has been measured under repeated square-wave-voltage actuation, which shows no degradation after several million actuation cycles for cascaded devices if the actuation temperature is far below the melting temperature at 1412°C (**Figure 18**). In contrast, for the boron-doped (p^{++} Si)

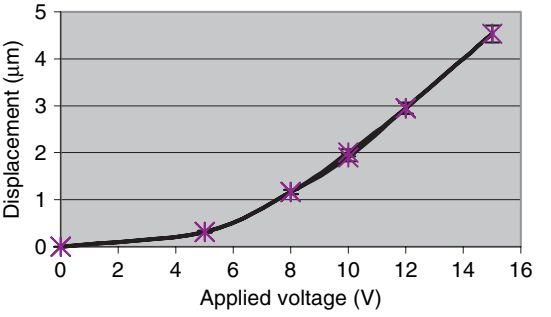

Figure 17 Repeatability test of bent-beam actuator.

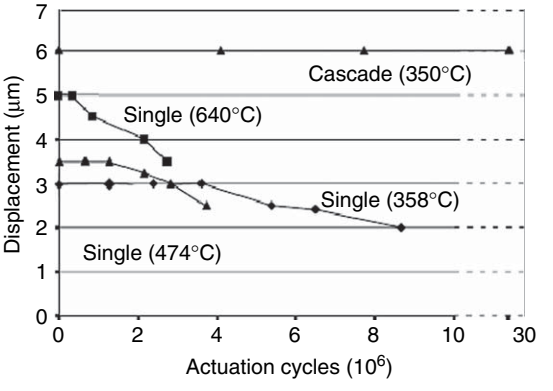

Figure 18 Lifetime test of bent-beam actuator.

devices, microcracks inside the devices and their propagation degraded their performance, SEM and atomic force microscopic (AFM) studies have confirmed this kind of fatigue (Chu *et al.* 2006). For polysilicon devices, thorough measurements have also been performed. It turns out that the micrograins of polysilicon anneal and grow during thermal actuation (**Figure 19**). Changes in the grain structure can affect many of the mechanical, electrical, and thermal properties of the material, and thereby the performance of the actuators.

Other factors, such as plastic deformation, dopant diffusion, and redistribution in the actuator, can also effect its lifetime (Chu *et al.* 2006).

For other thermal actuators, their repeatability and reliability can also be evaluated similarly. Note that for polymer-based devices, their chemical compositions and structures also play an essential part in their performance. Therefore, the synthesis and preparation of the polymer before the micromachining could be very critical.

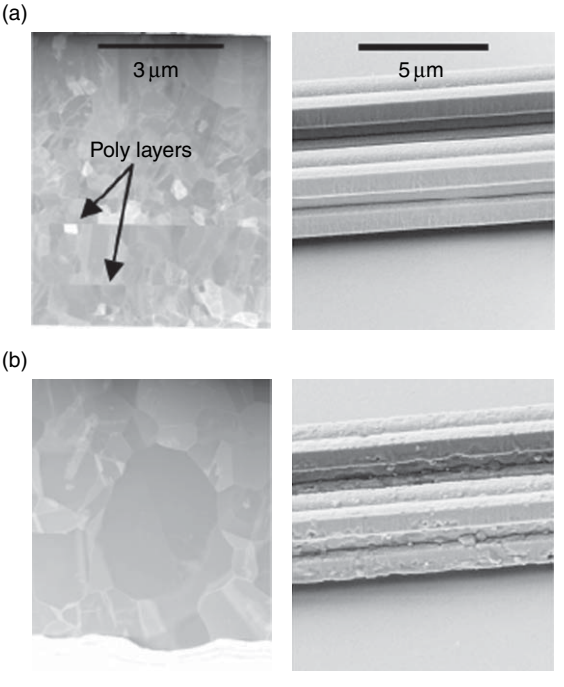

Figure 19 Transmission electron microscopic (TEM) image and scanning electron micrograph (SEM) of bent beams subjected to different levels of actuation power: (a) an unheated section of bent beam and (b) heated after 30 million cycles at 43 mW. (Source: Chu *et al*. 2006.)

2.03.3 Applications

2.03.3.1 Microoptics and Biophotonics

In the field of microoptics, microbiophotonics, and bioimaging, more and more optical elements are required to be integrated in order to form a compact, cost-effective, and high-performance microsystem (Que and Gianchandani 2005). Microoptical scanning functionality plays a very important role and could be essential for some medical diagnostic instrumentations, usually enabled by the micromachined mirrors. For optical communication, dynamic optical power management and configuration of the network also requires reconfigurable optical components, such as variable optical attenuators (VOAs) or optical switches. In addition, for some other specific applications such as dynamic optical pulse shaping for ultrafast optics, one approach is to dynamically change the refractive index or the pitch of the fiber Bragg gratings (FBGs). Therefore, periodic high-force array (typically in the range of millinewtons) offered by arrayed microactuators on FBGs is needed to modify the refractive index of the fiber core. In this case, thermal actuation, which offers a reasonably fast speed (up to kilohertz range), is a good option. In the following, some applications of thermal actuation in biophotonics, microoptics and optical communication will be illustrated and discussed.

Microscanner-enabled OCT. The microscanner has been developed for various applications, from project display for high-definition TV, to maskless lithography for microarrays for genomics (Singh-Gasson *et al.* 1999), to optical coherence tomography (OCT) for biomedical imaging. The actuation mechanism can be electrostatic, thermal, piezoelectric, magnetic, SMA, etc. Thermal actuation-based microscanner typically utilizes the bimorph actuator. One type of MEMS scanning mirror for endoscopic OCT (EOCT) is shown in **Figure 20**, fabricated using complementary metal oxide semiconductor-MEMS (CMOS-MEMS) process (Xie *et al.* 2003).

OCT is an emerging imaging technique that offers cross-sectional images of biological tissue and can offer noninvasive optical biopsy and delineate the tissue micromorphology. EOCT utilizes a mirror to scan the endoscopic laser. Its detailed functionalities can be found in many citations (Xie *et al.* 2003). One of its major components is the scanning mirror. Compared with a macroscale mirror, a micromirror is an ideal option due to its compact footprint and can conveniently fit into the slender endoscopes. The

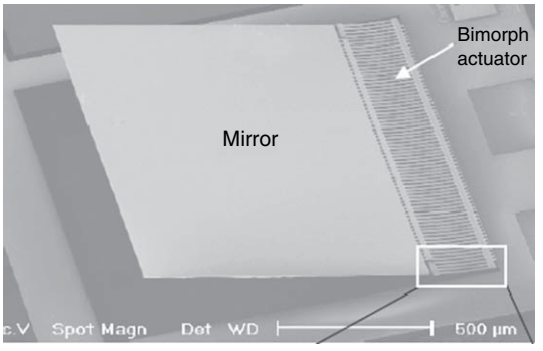

Figure 20 A scanning mirror with bimorph actuator. (Source: Xie T, Xie H, Fedder G K, Pan Y 2003 Endoscopic optical coherence tomography with new MEMS mirror. *Electron. Lett.* **39(21)**, 1535–6.)

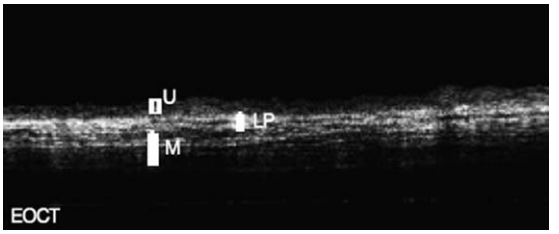

Figure 21 Optical coherence tomographic (OCT) image of a rabbit bladder. EOCT, endoscopic optical coherence tomography. (U = urothelium, M = muscular layer, LP = lamina propria). (Source: Xie T, Xie H, Fedder G K, Pan Y 2003 Endoscopic optical coherence tomography with new MEMS mirror. *Electron. Lett.* **39(21)**, 1535–6.)

MEMS thermally actuated micromirror-enabled EOCT can offer *in vivo* imaging diagnosis of early bladder cancers with good quality as shown in Figure 21.

Latching VOA and switch. Optical power management and network configuration are very important issues for broadband optical communication. The uniformity of optical power in the optical network is desirable to maintain the signal-to-noise ratio (SNR) and convenient for the network design. Dynamic power equalizer is utilized for this and can be built on the VOA array. Similarly, in order to dynamically reconfigure the optical network, programmable add/drop optical channel is essential. Optical switch plays a very important role in this, and tremendous work has been performed to develop MEMS optical switches or arrays. For both optical components, thermal actuators-based MEMS devices proposed by Que *et al.* (2002) have been developed to fulfill the demands.

In order to minimize the thermal power consumption, analog and digital latching mechanisms have

Figure 22 Analog latching variable optical attenuator (VOA). (Source: Que *et al*. 2003.)

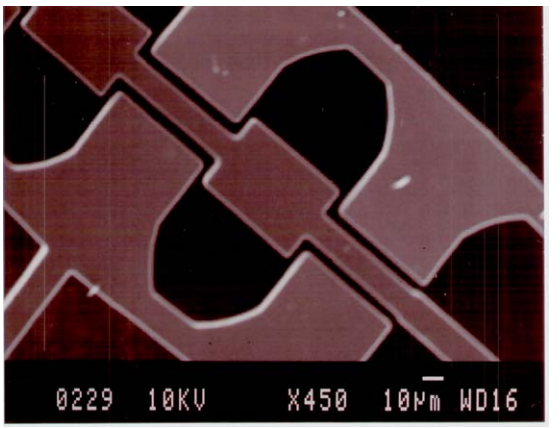

Figure 23 Close-up view of the analog latch region. (Source: Que *et al*. 2003.)

been designed and integrated in the VOAs and switches. The digital latching mechanism has been described previously. For the analog latching mechanism, the friction force between the holding structures and the central beam is the force offered to balance the mechanical restoring force of the central beam (Figures 22 and 23). Since the friction force can be generated continuously along the movable direction of the central beam, continuous latching can be realized. To achieve this, two control circuits for latching structure and central beam, respectively, are required. They should have certain phase difference to ensure proper operation. Typical response time of the VOA is 0.5 ms; power consumption is 200 mW with optimization. Once it is latched, power consumption is zero.

Pulse shaper for ultrafast optics. Ultrashort pulse shaping is used for coherent control of chemical reactions, nonlinear optics, and dispersion compensation in optical communication. Traditional approach

typically utilizes a pair of diffraction gratings and lenses to separate different spectra, after passing spatial light processor and then recombine them by the other pair of diffraction gratings and lenses to achieve the pulse shaping. The major drawbacks are its table-sized setup, tedious optical alignment, and many cautions to avoid dispersion effects through the lenses. A pulse shaper microchip, therefore, has been developed to address these issues (Udeshi *et al.* 2006).

This microchip consists of arrayed bent-beam actuators and chirped fiber Bragg gratings (CFBGs) (**Figure 24**). The principle of FBGs is Bragg reflection. When light propagates through the FBGs, it experiences periodic alternating regions of higher and lower refractive index, with a portion of the light being reflected at each interface. If the spacing between the interfaces satisfies the Bragg condition, the total reflection can be up to 100% for a particular wavelength. In order to reflect a spectrum of wavelengths rather than just a single wavelength, CFBGs are introduced. In CFBGs, the spacing between the interfaces linearly varies along the fiber with a chirped profile. For pulse shaping, the refractive index or the grating pitch should be changed. The integrated actuator array offers periodic localized forces up to millinewtons, thus compressive strain on the CFBGs, resulting in local changes of the refractive index of the fiber core along the fiber, thus the shaping of the reflected spectrum. By altering the applied force, the optical spectrum and the shape of the reflected pulse can be changed dynamically. Measurements found that the pulse width can be modulated from 1.05 to 4 ps with 500 mW power on the actuators (**Figure 25**).

2.03.3.2 Biomedical Microdevices and Microfluidics

In the field of the genomics and proteomics, miniaturized systems or components to manipulate biological samples and monitor the bioreactions are becoming very important and challenging. For instance, many different strategies have been explored for cell positioning, sorting, and separation, resulting in a very active research field. High-precision protein detection has become very important in the field of diagnosis and prognosis (Rickert *et al.* 1999). Previous efforts included resonant (Zhang and Kim 2003), electrochemical (Green 1987), and optical (Ekins 1998, Homola *et al.* 1999) methods. A method is proposed by exploiting the rigidity changing point of a nanomechanical system (Lee and Cho 2004), offering higher precision than the resonant method, and providing a simple and inexpensive approach without any labeling process and optical detection. In neural science and technology, MEMS technology also plays a very important role. Implantable neural microdevices are important for *in vivo* research and monitoring. One example is to monitor single- and multineuronal action using arrays of microelectrodes, which is the key to

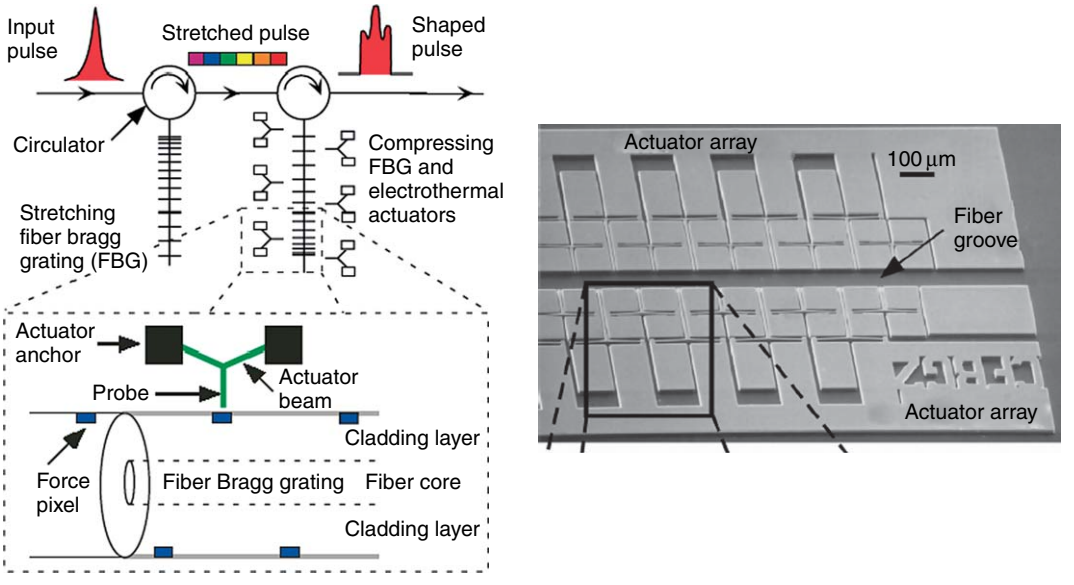

Figure 24 Sketch of the chip (*left*) and fabricated chip (*right*). (Source: Udeshi *et al*. 2006.)

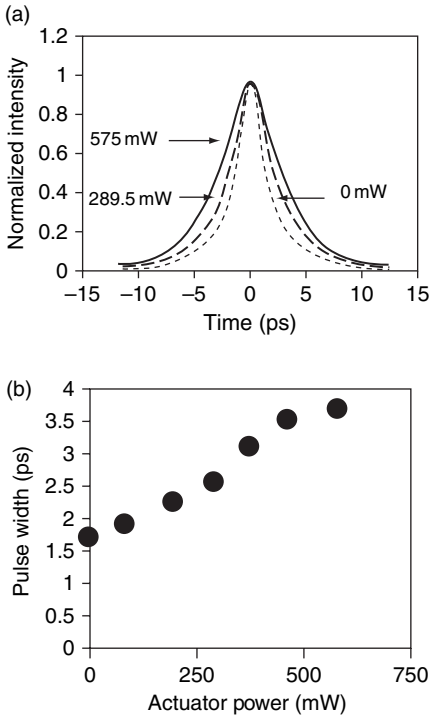

Figure 25 (a) Pulse shaping results and (b) pulse width and actuator power relationship. (Source: Udeshi *et al*. 2006.)

understanding their function, dysfunction, and restoration. In addition, one of the very important directions of bioMEMS technology is the miniaturized drug delivery technology (Reed and Lye 2004), which has been pursued extensively. The micromachined drug delivery devices can provide very accurate doses at nanoliter level, offer painless pinch, and usually are very cheap and thus could be disposable. Microscale hollow needles, liquid dispensers, and micropumps are typically the foundations of the devices in this category. Furthermore, in order to perform complete biochemical analysis at a much more cost-effective and efficient way, and achieve real point-of-care medical applications, emerging microfluidic systems definitely is an ideal technical platform. Many actuation schemes have been applied and adapted for the aforementioned biomedical applications. The thermal actuation becomes intriguing since it has a low actuation voltage, which is essential for most bioapplications, and it offers many attractive features, such as a high force and a small footprint, compared with other actuation mechanisms. In the following, some biomedical microdevices or microsystems based on thermal actuation will be described.

Cell manipulation. Biological samples manipulation in solution is important for genomics and proteomics. Optical tweezers (Ashkin 1997) or optoelectronic tweezers (Chiou *et al.* 2005) are powerful and non-invasive biomanipulation tools. However, they are bulky and expensive approaches. A micromachined SU8-based gripper has been proposed as a mechanical tool to grasp and transport the microscale biosamples to the desired location (Chronis and Lee 2005). Compared with other manipulation approaches (Kim *et al.* 1992), any optical or electrical interaction or interference with biosamples can be avoided. It has been demonstrated and can be operated in ionic environment; therefore, it can be used for single-cell manipulation and positioning, cell isolation, etc.

This SU8 microgripper consists of two pseudo-bimorphs mirror-imaged to each other (**Figure 26**). Its hot and cold arms are made from a thick SU8 layer with an embedded Cr/Au layer as the microheater and they are anchored to the silicon substrate. The microgripper is normally open. Gripping capability is achieved by applying the driving current. Experiments have demonstrated its ability to move a single Hela cell in solution (**Figure 27**). The high CTE of SU8 (52 ppm C^{-1}) is critical since the operation temperature changes can be maintained at less than 32°C and driving voltage can be kept below the electrolysis point. In addition, the high force offered by thermal actuation makes it feasible to operate in the liquid environment with big friction force, opening the door for any type of bioassay requiring sample manipulation.

Label-free biosensing. Label-free biosensing is advantageous when compared with labeled biosensing because the fluorophore is not required, and therefore, the properties of the biosamples cannot

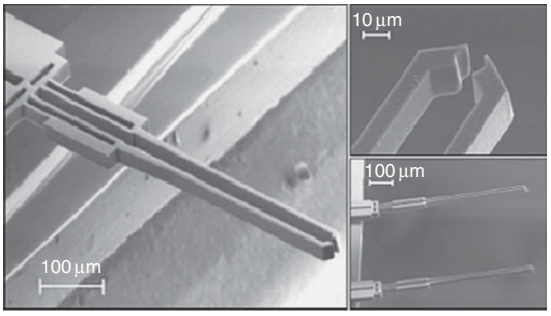

Figure 26 Fabricated microgripper using pseudo-bimorphs. (Source: Chronis N, Lee L 2005 Electrothermally activated SU-8 microgripper for single cell manipulation in solution. *IEEE/ASME J. Microelectromech. Syst*. **14**, 857–63.)

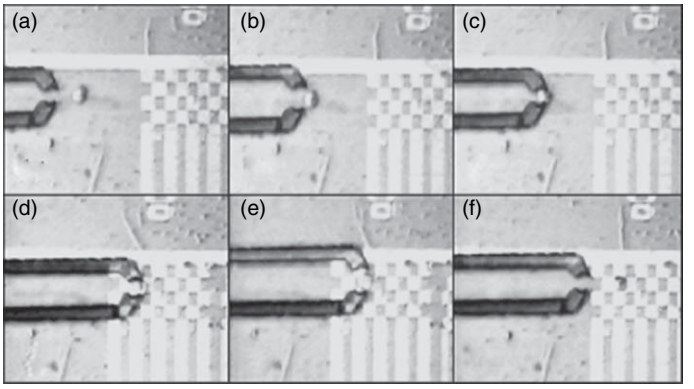

Figure 27 Optical micrographs showing the manipulation of the cell. (Source: Chronis N, Lee L 2005 Electrothermally activated SU-8 microgripper for single cell manipulation in solution. *IEEE/ASME J. Microelectromech. Syst*. **14**, 857–63.)

be perturbed or even modified. Many ways have been exploited for label-free biodetection, such as surface plasmon resonance (SPR), surface-enhanced Raman signal (SERS), and localized surface plasmon resonance (LSPR). Recently the mechanical properties of biomaterials have been exploited for label-free biosensing. By utilizing electrothermal nanogap actuators, the binding of biotin (the receptor) with streptavidin (target protein) can be monitored by the coordinate shift of the rigidity changing points (Lee and Cho 2004). The basic idea is illustrated in **Figure 29**. The device consists of two parallel plates with a nanoscale gap. One is attached to an actuator, and the other is fixed and anchored to the substrate. The receptors are immobilized on the gold-coated surfaces of the plates. The simplified model is given in **Figure 30**. The actuator pushes the push bar with a spring constant k_1. When the push bar touches receptors or the target proteins, the added spring constant k_{rp} changes the effective spring constant of the whole system, resulting in a coordinate shift of the rigidity. Therefore, the presence of the target proteins can be detected since they reduce the free distance of the push bar.

The schematic of the device is illustrated in **Figure 28** and the fabricated device is shown in **Figure 29(a)**. The sidewall surfaces of the nanogap plate, the protein sensing area, are coated with gold for the immobilization of the biotin. The fluorescence image of the nanogap region (**Figure 29(b)**) indicates the presence of the fluorescein isothiocyanate (FITC)-tagged streptavidin, suggesting the binding between the streptavidin and the biotin. The measured coordinate shift of the rigidity changing point (**Figure 29(b)**) is 14.0 ± 7.4 nm before and after the binding between the receptors and the target proteins, which is very close to the size of the streptavidin which is about 10 nm. The nanogap

biosensing area thus offers an enabling technology and technical platform for high-accuracy protein detection.

Single-neuronal activity monitoring. The electrical activity of single neurons is the critical information to understand the neuronal function, dysfunction, and restoration. Micromachined multichannel fixed microelectrode array has been used to monitor a population of neurons simultaneously (BeMent *et al.* 1986, Wise *et al.* 1970). However, with this type of electrodes, each individual electrode cannot be positioned in the array and thus the number of neurons that need to be monitored cannot be maximized. Furthermore, the inability to position and reposition the electrodes makes this type of device undesirable since electrical contact with neurons could be lost due to either a gradual drift of microelectrodes or micromotion of brain tissue during long-term *in vivo* measurements when implanted in the brain of the animal.

The proposed microactuated microelectrodes array addresses the aforementioned issues (Muthuswamy *et al.* 2005). The basic principle is illustrated in **Figure 30**. In this design, the bent-beam actuators are used and coupled to a ratcheting system that drives a center shuttle, part of the microelectrode, up or down. The locking mechanism is similar to that of the digital latching mechanism described in Section 2.03.2. When microelectrode is to be pulled up, the ratchet pawls for the down-drive are disengaged from the shuttle, permitting its free motion. At the end of each actuation cycle, both sets of pawls are in place, therefore preventing the microelectrode from moving in either direction. A similar procedure is required when the microelectrode is to be pulled down. The motion resolution of the microelectrode is determined by the stroke of the actuator and the gap between the ratchet teeth on the shuttle. In summary, the basic sequence of the position and reposition of the microelectrodes includes unlocking, actuation in both directions, and locking of the structure, which is enabled by the use of bent-beam actuators attached to a ratchet system.

The bent-beam actuator offers several advantages over electrostatic actuated microelectrode devices. In addition to smaller footprint and hence higher packing density, it is much less susceptible to mechanical vibration and humidity variations. Much higher force and thus easier penetration of microelectrode in the rodent brain enabled by thermal actuators are also attractive features, when the microelectrodes array chip is implanted for chronic *in vivo* experiments.

The fabricated prototype device, neural probe chip (Muthuswamy *et al.* 2005), is shown in

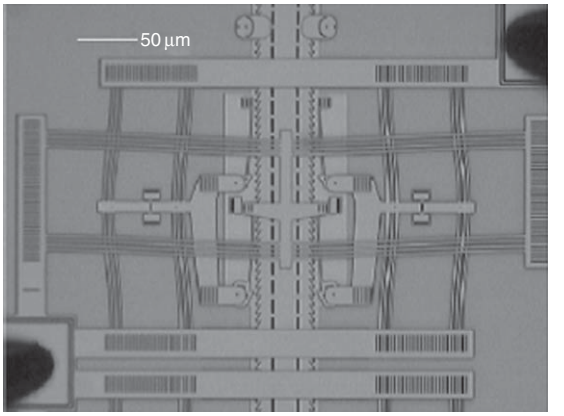

Figure 31 Scanning electron micrograph (SEM) of fabricated device showing microelectrodes with integrated actuators. (Source: Muthuswamy J, Okandan M, Gilletti A, Baker M S, Jain T 2005 An array of microactuated microelectrodes for monitoring single-neuronal activity in rodents. *IEEE Trans. Biomed. Eng.* **52(8)**, 1470–7.)

Figure 31. It has been used successfully to precisely position and reposition microelectrodes in the brain after implantation. Furthermore, it can be potentially used for long-term *in vivo* monitoring of single neurons and for sequential monitoring of multineurons with a single-implant microelectrode.

Micropump, microvalve, liquid dispenser, and thermal ink-jet print heads. Micropumps and microvalves are major components for functional integrated microfluidic networks. Different mechanisms and materials have been explored and implemented for these components. Thermal responsive polymers are attractive since their volumes are changeable, subject to the variation of the temperature. Hence, micropumps, microvalves, and dispensers with no movable parts can be made, resulting in their potential excellent reliability and long-time operation. Furthermore, the utilization of this category of polymer offers the possibility and capability for the integration of large-scale microfluidic systems.

Paraffin, polyNIPAAm, and PDMS mixtures are among those widely used polymers for these applications. In-line microvalves in **Figures 32** and **33** made by paraffin and polyNIPAAm have shown excellent performance (Mutlu *et al.* 2003, Selvaganapathy *et al.* 2003). Both of them are compatible with standard surface micromachining technology. Silicone elastomer composite, consisting of PDMS and expandable microspheres, has been employed to construct single-use drug delivery microdevices with integrated

micropump and dispenser. The concept and fabricated device is shown in **Figure 34**. It consists of two subsystems. The microfluidic transdermal interface (MTI) creates the passages for the liquid through the outermost skin layer using hollow, side-opened microneedles; the dosing and actuation unit (DAU), pumps, and dispensers provide accurate amounts of liquid through MTI at appropriate times. The schematic and working principle of the micropump is illustrated in **Figure 34** (Roxhed *et al.* 2004, Samel *et al.* 2003). Integrated microheaters are used to elevate the temperature of the PDMS-XB composite locally, allowing the composite to be expanded locally without patterning it. The local expansion causes the liquid in the reservoir to be injected into the microchannel for the next step analysis. Thermal ink-jet print heads is another successful example enabled by thermal actuation (Klein 2004).

MEMS gas valve. Gas valve is important to control and manipulate the gas flow for many different applications. MEMS-based gas valve offers several advantages over traditional gas valves, such as compact size and low cost. However, it could experience the oscillation of the device in the presence of the high flow rate of the gas, resulting in degraded performance and even damaging of the devices. This issue has been addressed and solved by using the silicone strap as a damping structure described in the following.

The principle of a MEMS normally closed gas valve is illustrated in **Figure 35** (Knobloch *et al.* 2006). In the top structural layer, a slider in which rectangular slits are micromachined is connected with a bent-beam actuator. When the slider is moved, the gas flow through a series of flow channels in the handle wafer can be modulated. The fabricated

device is shown in **Figure 36**. Experiments show that at high flow rate the gas microvalve experiences oscillation. In order to mitigate the resonance due to a fluid–structure interaction, silicone strap is used as a damping structure between the slider mechanism and the rigid supporting structure around the valve. Experiments found that the dampers show no failure up to 10 000 cycles actuation.

2.03.3.3 Wireless Communication

Many different micromachined components for wireless communication have been developed in the past. MEMS technology shows great promise and potential in this field since it usually offers small footprint and low cost while still maintaining super performance. Although most components utilize the electrostatic actuation for movable parts, significant portions of them use thermal actuation. Low actuation voltage is obviously one of the major advantages.

Specifically, compared to a conventional semiconductor switch and relay, a MEMS RF switch and relay are attractive because they have much better performance in terms of isolation, insertion loss, return loss, power consumption, and linearity. Even though its speed is not as fast as that of semiconductor switches, a MEMS RF switch is good enough for many applications. Similarly, for other RF components, such as voltage-controlled oscillator (VCO), resonator, and filter, their MEMS counterparts offer the similar advantages. Thermal actuation requires low voltage, thus making it very attractive for

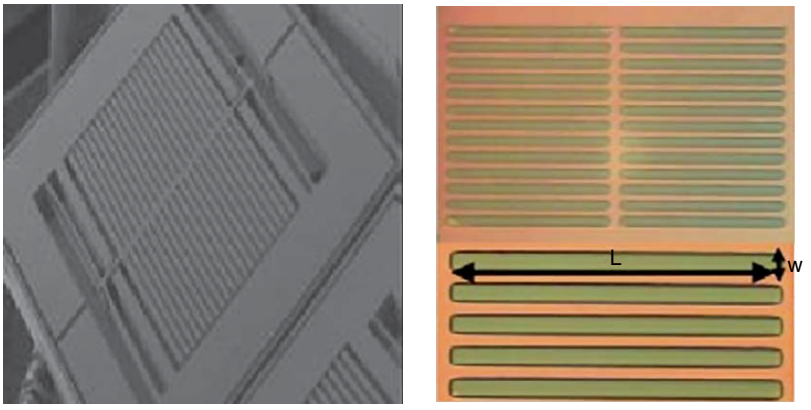

Figure 36 Perspective (*left*) and close-up (*right*) view of the gas valve. (Source: Knobloch A, Seeley C, Mulay A, Saia R 2006 Flow structure instability prevention in a MEMS high flow gas valve. *Dig. Solid-State Sensors, Actuators, and Microsystems Workshop*, Hilton Head Island, SC, USA, pp. 288–91.)

integration with RF components. However, power consumption could be a problem. Several ways have been implemented to abate or avoid this issue as mentioned earlier. In the following, thermally actuated RF switch, variable capacitor, VCO, and filter will be discussed.

RF relay and latching switch. One approach enables high-performance RF switch by combining bimorph actuator and electrostatic actuation (Robert *et al.* 2003). The thermal actuator is for the on/off function with low actuation voltage, whereas the electrostatic actuation is implemented as the latching mechanism ensuring low power consumption.

The sketch of the switch is illustrated in **Figure 37**. The bimorph actuator is formed by the aluminum layer and the silicon nitride layer. A TiN layer is sandwiched between two silicon nitride layers and serves as both the microheating resistors and the latching electrodes. The switch contact is formed by nitride etching and gold layer deposition. The fabricated device is shown in **Figure 38**. Its switching time is about 200 μs with 2 V actuation voltages. The latching voltage is <10 V. More details of its RF performance can be found in Robert *et al.* (2003).

Bistable RF switch and circuit. Bistable RF switch has been designed and implemented using bent-beam

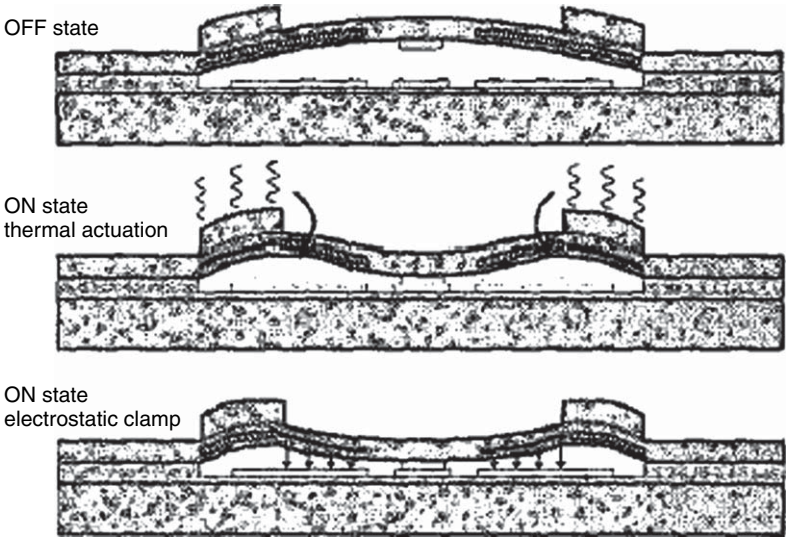

Figure 37 Schematic of the radio frequency (RF) switch combing thermal and electrostatic actuation. (Source: Robert P, Saias D, Billard C, Boret S, Sillon N, Maeder-Pachurka C, Charvet P L, Bouche G, Ancey P, Berruyer P 2003 Integrated RF-MEMS switch based on a combination of thermal and electrostatic actuation. *12th Int. Conf. on Solid-State Sensors, Actuators and Microsystems* vol. **2**. pp. 1714–17.)

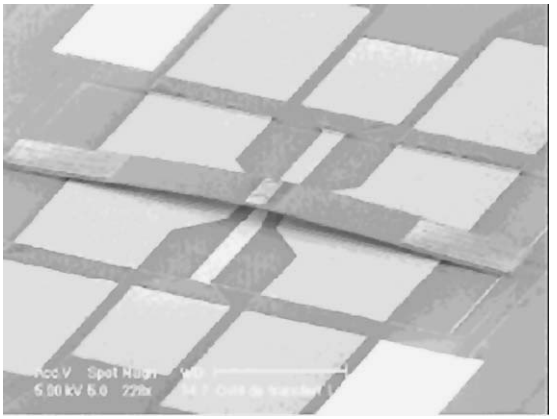

Figure 38 Scanning electron micrograph (SEM) of a fabricated device. (Source: Robert P, Saias D, Billard C, Boret S, Sillon N, Maeder-Pachurka C, Charvet P L, Bouche G, Ancey P, Berruyer P 2003 Integrated RF-MEMS switch based on a combination of thermal and electrostatic actuation. *12th Int. Conf. on Solid-State Sensors, Actuators and Microsystems* vol. **2**. pp. 1714–17.)

actuators as the driving engine (Howell 2001, Que *et al.* 2004). The simple structure and high impact force by the actuator offers unique advantages over other designs (Rebiez 2003).

The bistable structure consists of a suspended beam with a shallow lateral bend. A flexible element in the center offers longitudinal compliance; thus, it can be pushed laterally from side to side. A descriptive calculated potential energy curve as well as the reaction curve is shown in **Figures 39** and **40**, respectively (Que *et al.* 2004). It clearly shows two energy valleys corresponding to two stable positions. The reaction force of the bistable structure is highly

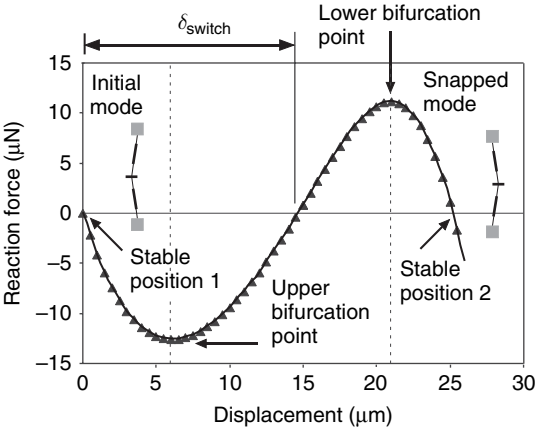

Figure 39 Energy curve showing two energy valleys corresponding two stable positions. (Source: Que *et al*. 2004.)

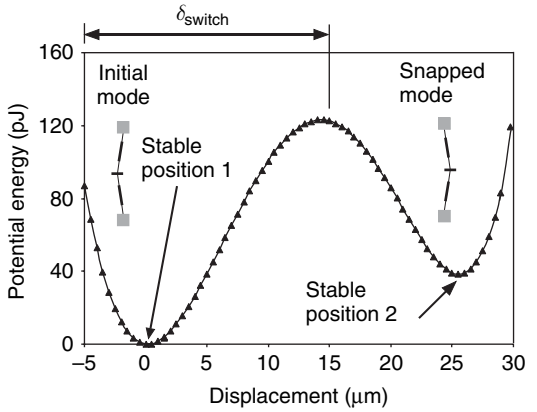

Figure 40 Impact force curve for the bistable structure. (Source: Que *et al*. 2004.)

nonlinear with the displacement. At two stable positions, the reaction force is zero. There are two ways to switch the bistable structure by the driving engine. One way is to impart sufficient kinetic energy so that bistable structure itself overcomes the potential energy peak and snaps to the other stable position. The other way is to gradually push the bistable structure with driving engine until it passes the unstable equilibrium point (energy peak), thereby falling into the other stable position.

The sketch of the designed switch is shown in **Figure 41** and the coplanar waveguide (CPW) transmission line with integrated switch is given in

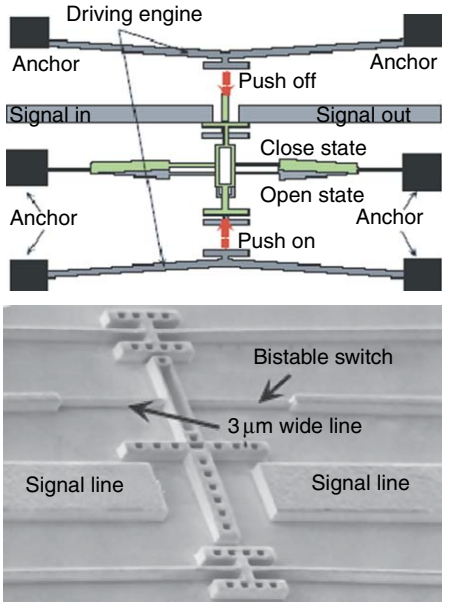

Figure 41 Sketch of the switch (*upper*) and close-up view of fabricated switch (*lower*). (Source: Que *et al*. 2004.)

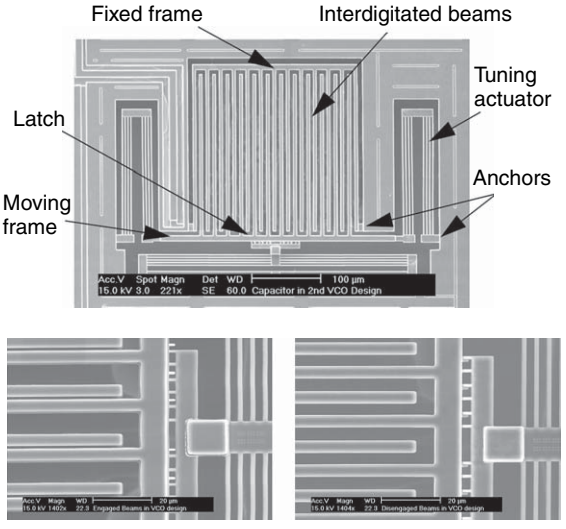

Figure 43 Microelectromechanical systems (MEMS) tunable capacitor: whole device (*upper*). Close-up views showing the latching mechanism at the maximum (*lower left*) and the minimum (*lower right*) capacitance stage, respectively. (Source: Ramachandran D, Oz A, Saraf V K, Fedder G, Mukherjee T 2004 MEMS-enabled reconfigurable VCO and RF filter. *Proc. 2004 IEEE Radio Frequency Integrated Circuits Symposium (RFIC '04)*, pp. 251–4.)

Figure 42 (Que *et al.* 2004). The driving engine is a bent-beam actuator, which can offer an impact force up to the range of millinewtons by scaling its dimensions. Measurements on these devices show excellent RF performance in terms of insertion loss and isolation, and their performance can be optimized readily. The switching speed can be around 0.1 ms if the pulsed driving voltage or current is used. Furthermore, the footprint can be minimized by optimizing the design.

This switch can be used as a basic component to design switching networks and other RF circuits while maintaining the advantages of the switch, such as microstrip line, single-pole N-through, N-pole N-through switch network, phase-shifter, phased array antenna, and tunable and reconfigurable antenna (Rebiez 2003).

Tunable capacitor, VCO, and RF filter. Reconfiguration of RF systems from one frequency to the other is of interest in multifunction radios. MEMS tunable capacitor plays an important role to design reconfigurable VCO and filter circuits by integrating with on-chip micromachined inductors and transistors. It has advantages of lower loss, larger tuning range, and more linear tuning characteristics over solid-state varactors. Significant efforts have been devoted to develop MEMS tunable capacitors during recent years (Rebiez 2003). In-plane tunable capacitor formed by interdigital beams has been developed using a CMOS process as shown in **Figure 43** (Ramachandran *et al.* 2004). The beams can be moved with respect to each other by the integrated thermal actuators, resulting in the changes of the gap between the beams, thereby the capacitance. In order to have zero-standby power operation, a lateral latch consisting of a peg in a slot is used and is shown in **Figure 43**. This capacitor has tuning ranges of 200% or even higher. A VCO is constructed with two variable capacitors, a center-tapped differential inductor at the top and a core circuit at the bottom as shown in **Figure 44**. A switching ability of more than 400 MHz has been demonstrated between frequencies (Ramachandran *et al.* 2004). Similarly, a filter is also built with one differential inductor and four tunable capacitors as shown in **Figure 43**. It has quality factor up to 9.5 and it can reject at least 7.8 dB of the undesirable frequency component.

2.03.3.4 Nanoinstrumentation and Nanotechnology

MEMS technology offers a powerful and flexible platform and infrastructure for nanoscience and nanotechnology research (Fujita 2003). It not only can be used as the infrastructure to implement

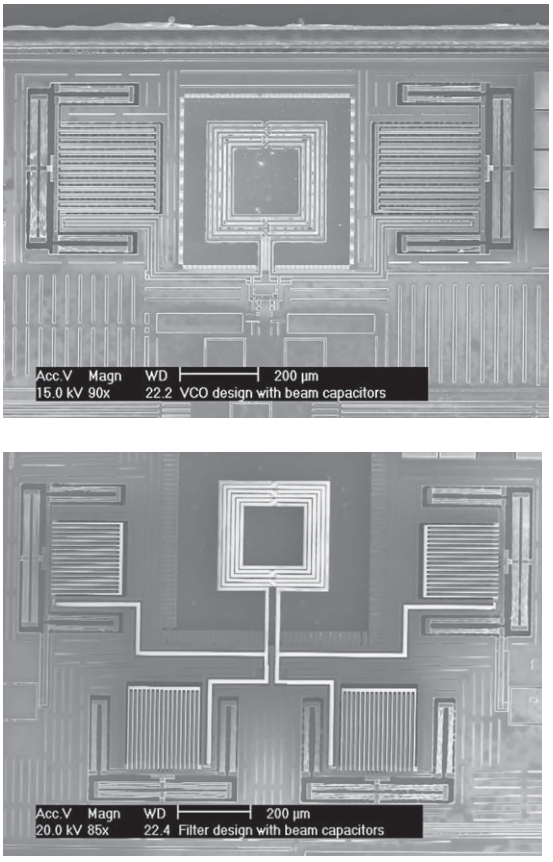

Figure 44 Scanning electron micrographs (SEM) of VCO (*upper*) and filter (*lower*). (Source: Ramachandran D, Oz A, Saraf V K, Fedder G, Mukherjee T 2004 MEMS-enabled reconfigurable VCO and RF filter. *Proc. 2004 IEEE Radio Frequency Integrated Circuits Symposium (RFIC '04)*, pp. 251–4.)

Conf. on Microelectromechanical Systems,* Maastricht, The Netherlands, pp. 426–9.)

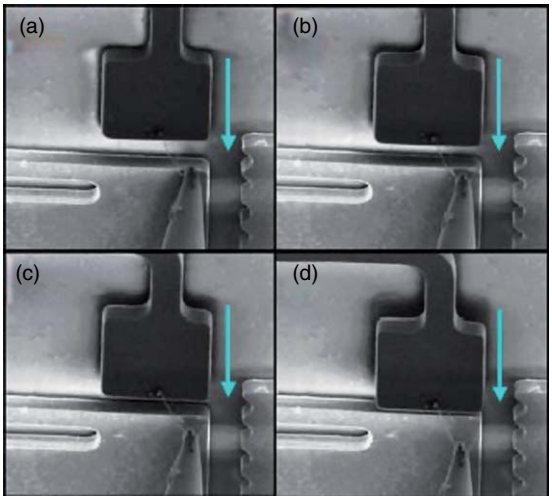

Figure 46 Microelectromechanical systems (MEMS) flexure deflected by an attached carbon nanotube (CNT). (Source: Hartman A, Rice P, Finch D, Skidmore G, Bright V 2004 For-deflection characterization of individual carbon nanotubes attached to MEMS devices. *Proc. IEEE Int. Conf. on Microelectromechanical Systems,* Maastricht, The Netherlands, pp. 426–9.)

nanoinstrumentation but also can be exploited as a platform for the characterization of advanced materials. Again, the thermal actuation plays a very important role in this field since it can offer a high force (up to several millinewtons), which is essential to deform nanoscale materials with high a Young's modulus, such as CNTs. Furthermore, micromachined structure serves as a bridge between the nanoscale domain and the macroscale world, enabling a much more convenient way to interface the input/output. In the following, several examples will be used to illustrate the MEMS-enabled nanoinstrumentation and technical platform.

Mechanical characterization of CNTs. In nanoscience and nanotechnology community, sophisticated and expensive equipment such as transmission electron microscopy (TEM) and AFM has been used to analyze the properties of CNTs. It is a complicated and time-consuming process. In order to address this issue, an *in situ* manipulation, attachment technique of individual CNT to MEMS devices, has been explored.

One approach is to exploit the micromachined pseudo-bimorph as the tensile force generator to characterize the properties of CNTs (Hartman *et al.* 2004). The tensile test device in **Figures 45** and **46** consists of a gauge flexure, a deflection meter, and a

thermal actuator. The individual CNT is attached to the two separated MEMS surfaces (the gauge flexure and the thermal actuator). When the actuator is powered, the CNT is stretched due to the tensile force. The deflection of the gauge flexure, therefore, is measured and is used to evaluate the mechanical properties of CNT.

Nanopositioner. Nanoscale positioning is essential for many instruments and applications such as scanning microscopy, optical switch, wireless communication, and data storage. Some nanopositioners use electrostatic, magnetic, and piezoelectric transduction mechanisms (Guckel *et al.* 1998, Hirano *et al.* 1998), whereas several efforts focused on thermal actuation-based approaches (Chu and Gianchandani 2003, Tuantranont *et al.* 2000).

A positioner that offers subnanometer–resolution positioning is used as an example (Chu and Gianchandani 2003). The schematic of a 2D positioner is shown in **Figure 47**. It consists of the bent-beam actuator, the amplifier, and built-in capacitive position sensor. The device in **Figure 47** is fabricated into a SOI wafer made with fusion wafer bonding. For this particular design, it can achieve 19 μm displacement along each axis at subnanometer resolution (~0.3 nm).

MEMS probes for nanolithography. Maskless lithography is sometimes more flexible in defining nanostructures than is traditional masked lithography. Maskless lithography includes E-beam litho, interference litho, micromirror array-based litho, and AFM tip litho. However, all of them involve coating of photoresist as the mask and the final features are formed by etching processes. Recently, a photoresist-free maskless lithography technique, called dip pen nanolithography (DPN) (Piner *et al.* 1999), has been developed. DPN utilizes scanning probes to deposit chemical and biological materials directly on a substrate. The thermally actuated probe is used to achieve dynamical DPN (Wang *et al.* 2004).

In order to enhance its throughput, a silicon probe array with tips of 100 nm radius of curvature has been fabricated. Schematic and SEM of the fabricated silicon probe array are shown in **Figures 48** and **49**, respectively. Each probe can be addressed with a bimorph thermal actuator on its cantilever, enabling the flexibility of nanoscale pattern generation. It demonstrated parallel writing of different octadecanethiol (ODT) patterns with a sub-50 nm linewidth on the gold substrate.

2.03.3.5 Compliant Mechanism and Other Applications

Owing to space constraints, other thermal actuator-enabled applications are not covered. Compliant micromechanism is a structure deforming elastically to transmit a force or displacement. It will be illustrated since it is the basis for many integrated micromechanical systems and has been explored extensively (Ananthasuresh *et al.* 1994, Kota *et al.* 1999). One example is the mechanical amplifier implemented using compliant micromechanism.

Rectilinear motion amplifier. The mechanical amplifier is implemented with a bent-beam actuator to modify the force–displacement relationships (Chu *et al.* 2002). The topology synthesis using truss elements and dimensional optimization on beam elements are two major design stages. The ultimate goal is to maximize the blocking force and unloaded output displacement under all relevant design constraints.

One optimized design of a rectilinear microtransmission with two inputs is illustrated in **Figure 50(a)**. The optical micrograph of the corresponding fabricated nickel device is shown in **Figure 50(b)**, which is fabricated using single-crystal p^{++} silicon by the dissolved wafer process. The dimensions for this design are $L_0 = 2450\,\mu m$, $L_1 = 2415\,\mu m$, $L_2 = 1750\,\mu m$, $L_3 = 1400\,\mu m$, $L_4 = 1000\,\mu m$, $L_5 = 1210\,\mu m$, $W = 70\,\mu m$, whereas the thickness is $H = 11.5\,\mu m$. For this design, rectilinear nonresonant output displacements up to 100 μm and displacement amplification factors of about 17 were reported. Both displacements and amplification factors can readily be scalable by modifying the dimensions of the device.

Other applications. Thermal actuation has also been widely used for many other different applications, such as microaccelerator, resonator, micromotor (Park *et al.* 2001), tunable electrostatic converter, and thermal oscillator (Udeshi and Gianchandani 2004). Owing to space constraints, only the thermal oscillator is described. The detailed information of

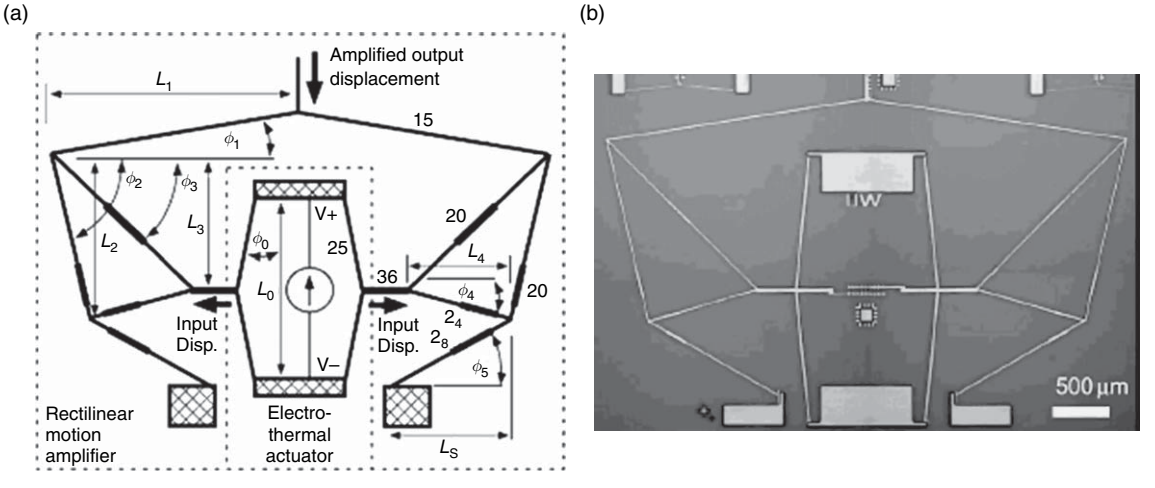

Figure 50 (a) Schematic of an optimized rectilinear microtransmission design and (b) optical micrograph of fabricated device. (Source: Chu *et al.* 2002.)

other devices can be found in their respective citations (Park *et al.*, 2001).

Some micromachined devices either require or exhibit improved performance when driven by a modulating signal, such as strain sensors and pressure sensors (Burns *et al.* 1995), accelerometers, and gyroscopes (Putty and Najafi 1994, Roessig *et al.* 1997). The modulating signal is usually generated by oscillators, typically implemented using standard microelectronic circuits. However, this approach severely limits their voltage and power-handling capacity, making it unsuitable for any application demanding even moderately high voltages or power levels. In addition, even those oscillators that use MEMS components employ electronics to provide the feedback of an amplified signal (Dec and Suyama 2000, Nguyen 1997).

A fully mechanical micromachined oscillator operated using a single DC power source, without the aid of any electronic components, has been developed to address these issues (Udeshi and Gianchandani 2004). The schematic of a mechanical oscillator and its operation procedure is shown in **Figures 51** and **53**. The SEM of the fabricated device is shown in **Figure 52**.

The oscillator is enabled by the bent-beam actuator. The actuator opens a normally closed switch when actuated, resulting in cutting its own current supply. Subsequent cooling of the actuator causes the closure of the switch, thus the cycle to repeat, resulting in oscillations (**Figure 53**). However, hysteresis must be introduced in the system in order to keep the switch open or closed in a controllable manner, allowing the system to remain in unstable equilibrium for a predefined amount of time. Two types of the oscillators have been implemented using different hysteresis mechanisms.

In the Type I oscillator, hysteresis is based on the bistable toggle mechanism (Jensen *et al.* 2001). Initially, the switch is closed and the thermal actuator undeflected. When the voltage is applied, the thermal actuator is heated up, resulting in an increasing force

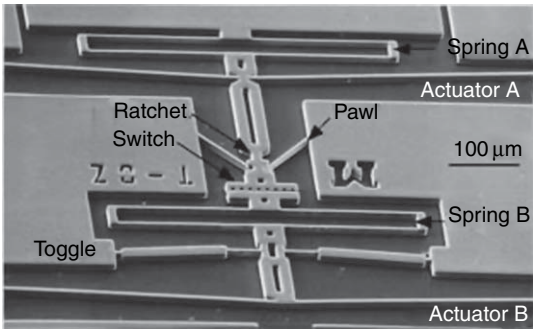

Figure 52 Scanning electron micrograph (SEM) of fabricated oscillator. (Source: Udeshi and Gianchandani 2004.)

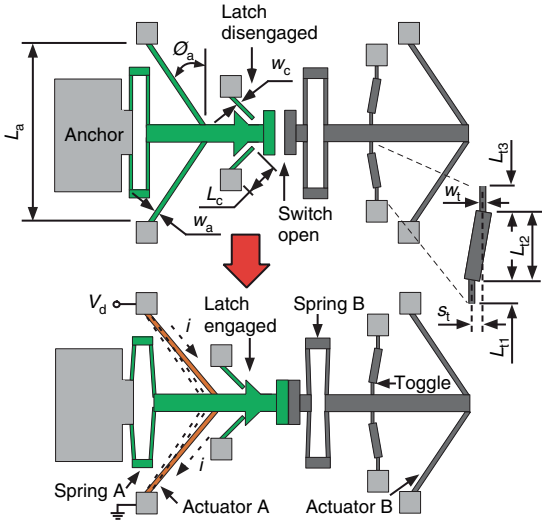

Figure 51 Device configuration: fabricated (*top*) and after priming (*bottom*). Priming is permanent and achieved by driving actuator A. (Source: Udeshi and Gianchandani 2004.)

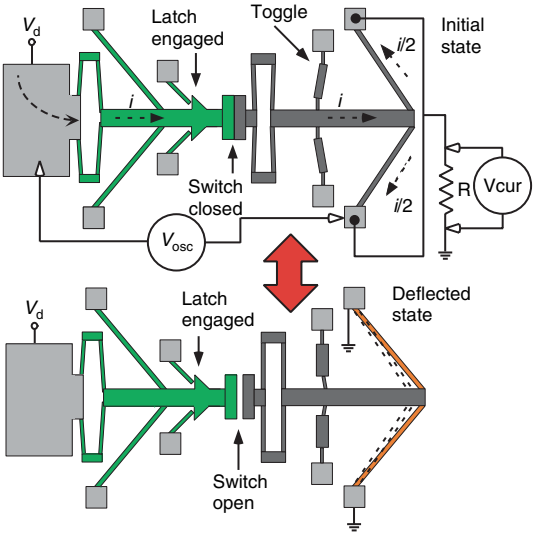

Figure 53 Device operation: current flow when switch is closed (*top*) causes displacement of electrothermal actuator (*bottom*), opening the switch. Subsequent cooling of the actuator closes the switch, permitting repetition. (Source: Udeshi and Gianchandani 2004.)

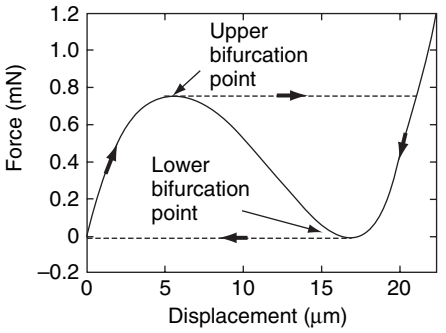

Figure 54 Finite element analysis (FEA) load–displacement response of the bistable toggle element. (Source: Udeshi and Gianchandani 2004.)

on the toggle. Once the force exceeds the force corresponding to the upper bifurcation point of the toggle (**Figure 54**), the toggle snaps through, generating a large displacement, opening the switch, and cutting the current to the actuator, resulting in its deflected state. Without power supply, the actuator cools down due to heat dissipation, decreasing the force applied on the toggle. The toggle snaps back to its original position when the applied force falls below that of the lower bifurcation point, closing the switch and restoring the current to the actuator. The device returns to its initial state, resulting in the repetition of the cycle, and thus oscillation (**Figure 53**).

In the Type II oscillator, the function of bistable element is achieved by the intrinsic thermal hysteresis of actuator B (**Figure 51**), resulting from the duration of heating and cooling time constants of an electrothermal actuator.

Measurements found that the Type I device generates a signal with a relatively constant frequency of about 39 Hz at different power levels, with a variable duty cycle from 0.3 to 0.6. The Type II oscillator is tunable, with a frequency range from 200 to 1200 Hz and a duty cycle from 0.3 to 0.7. Less than 0.5 V is required for the oscillators. The footprint of both devices is measured at about 1 mm × 1 mm (Udeshi and Gianchandani 2004).

2.03.4 Summary and Future Trend

The theory, materials, fabrication, issues, and applications of thermal actuation have been discussed and summarized in this chapter. Thermal actuation is based on thermal expansion or shrinkage of the structural materials, which could be gas, liquid, or solid. A basic mathematical model has been developed and implemented using finite difference method. It is applicable to all types of thermal actuators. The major issues related to thermal actuators are power consumption, response time, and thermal isolation. In order to overcome these issues, specific designs and approaches have been explored, proposed, and implemented. The power consumption can be significantly reduced by cutting the effective thermal mass, using microscale latching mechanisms or implementing more efficient actuation schemes, including pulsed or burst-pulsed actuation. Similarly, all these schemes are also useful for the response speed improvement. In addition, another way to enhance the response is to integrate the cooling microfluidic network with the thermal actuators, accelerating the heat dissipation during the cooling cycle of thermal actuation. As a critical issue for many applications, thermal isolation has been achieved by sandwiching the low-heat-conduction materials between the actuators and other parts of the microsystems. From biomedical imaging, label-free biosensing to cell manipulation and drug delivery; from microfluidics, single-neuron monitoring to optical and wireless communication; from microoptics, ultrafast optical pulse shaping to nanoinstrumentation and nanoscale material characterization; thermal actuation has found a variety of applications and has proven to be an enabling technology.

A new type of thermal actuation that offers high force, consumes low power, and operates faster, however, is still needed. Besides the device design optimization and possible integration of cooling network, exploration of new advanced materials probably is an ultimate way to achieve this goal even though it could be quite challenging.

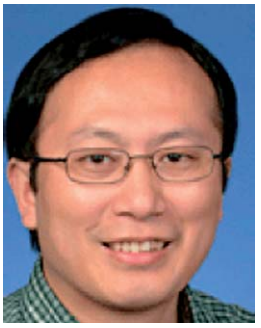
Biography



Long Que received his undergraduate and graduate education in Physics and Communication from Peking University, Beijing, China. He earned his Ph.D. degree in Electrical Engineering focusing on MEMS/nanotechnology from the University of Wisconsin-Madison in 2000.

He is presently with GE Global Research Center as a research staff member, task leader, and project leader. Prior to this, he was with the Center for Nanoscale Materials at Argonne National Laboratory, Argonne, IL, where his research focused on nanoscience and nanotechnology. Prior to this, he was with the Electrical Engineering and Computer Science (EECS) Department and the Center for Wireless Integrated Microsystems (WIMS) of the University of Michigan at Ann Arbor. His research interests are in bioMEMS/optical/RF MEMS, nanoscience, and nanotechnology. He has coauthored a textbook *MOEMS (SPIE* '05), published more than 30 papers in major MEMS/nanotechnology journals and conferences, and has been awarded five US patents, and has more than 10 patents pending.

Dr. Que won Invention Awards from GE in 2006 and 2007, a National Research Award from the Chinese Academy of Sciences in 1997, and the Vilas Professional Development Fellowship from the University of Wisconsin in 2000. He is a member of IEEE and SPIE.

2.04 Pressure Sensors

Andrew DeHennis, Germantown, MD, USA

Junseok Chae, Tempe, AZ, USA

2.04.1 Introduction

Micromachined pressure sensors are one of the most successfully commercialized microdevices. As one of the first developed MEMS devices, for more than four decades, MEMS pressure sensors have matured to significantly impact all commercial sectors. In 2005, the volume of MEMS pressure sensors exceeded 200 million units, dominating the unit volume and representing over 90% of units and 50% of revenues for pressure sensors in markets spanning automotive, medical, industrial, consumer, and military applications (Bryzek *et al.* 2006). A few of the more prominent automotive applications for pressure sensors include engine manifold monitoring, tire pressure monitoring, and both oil and brake fluid pressures. Monitoring of these parameters then improves the fuel economy and automobile safety. High-end automobiles are now equipped with more than 10 pressure sensors. Medical applications cover intraocular, intracranial, arterial pressure measurement, and disposable blood pressure sensors. Disposable blood pressure sensors became one of the most attractive medical applications to lower costs and maintain the level of sterility standards needed in heath care facilities. Other than automotive and medical applications, MEMS pressure sensors provide solutions to applications that demand small size, lightweight, low cost, and low-power consumption. Performance of MEMS pressure sensors and their interface circuitry have improved as manufacturing technologies advance optimizing their sensitivity, dynamic range, accuracy, linearity, and reducing temperature dependence. Device integration has enabled the ability to provide smart pressure sensors that are integrated on a monolithic substrate with their readout electronics. This chapter focuses on the developments that have been made in the realization and application of silicon-based pressure transducers spanning the basic diaphragm functionality to wireless system integration.

2.04.1.1 Historical Perspective

The first silicon micromachined pressure sensor was presented by Gieles (1969). At that time, the standard technologies were minisize pressure transducers that had freestanding diaphragms 2 mm in diameter and 30 μm in thickness. Gieles' device was implemented using microspark erosion and electrochemical etching to obtain a 5- to 25-μm-thick n-type epitaxial silicon membrane as shown in **Figure 1**. The membrane had embedded piezoresistors to sense deflection under pressure. The diameter of the membrane was defined by the size of the electrode used for microspark erosion. A microspark erosion process has been optimized to achieve a surface roughness on the order of 1 μm. To minimize the roughness, electrochemical etching was performed in a fluoric acid bath with a platinum electrode. The etch rate of the electrochemical etching is about 2 μm per minute. The device-to-device uniformity of this process showed a sensitivity variation within 5%.

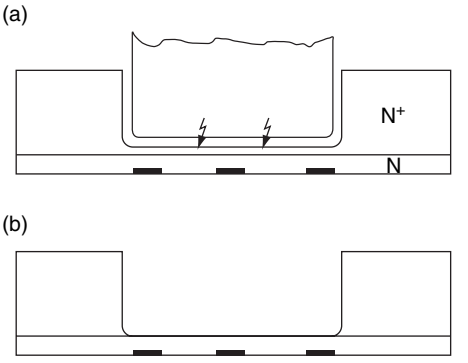


Figure 1 (a) Spark erosion machining and (b) electrochemical etching steps that formed the first micromachined pressure sensor presented by A C M Gieles at ISSCC in 1969. (Source: Gieles A C M 1969 Subminiature silicon pressure transducer. *International Solid-State Circuits Conference (ISSCC)*, Philadelphia, PA, USA, pp. 108–9.)

Another milestone in pressure sensor development was the merging of a sensor and its interface circuitry on a monolithically fabricated die. This was first implemented by Borky and Wise in 1980 with their development of a micromachined piezoresistive pressure sensor integrated into a triple-diffused bipolar circuit process (Borky and Wise 1979). **Figure 2** shows an integrated pressure sensor.

The single-crystal silicon diaphragm is defined by both anisotropic and isotropic chemical etches to achieve a nominal diaphragm thickness between 7 and 10 μm. Owing to the integrated electronics, the pressure sensor requires only two leads for the measurement and has a die size less than 1.2 mm.

2.04.1.2 Performance Parameters

There are a number of parameters that are needed to define the performance of micromachined pressure sensors. Parameters have been developed for

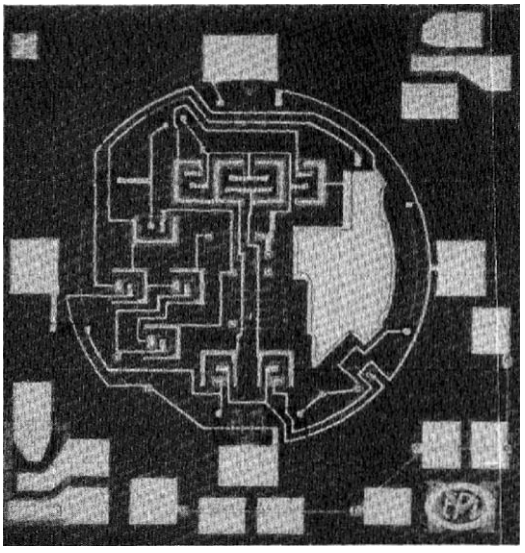

Figure 2 Piezoresistive pressure sensor integrated with signal conditioning circuits on a single chip developed by Borky and Wise. The transducer uses a circular diaphragm transducer with a diameter of 40 mils. (Source: Borky J, Wise K D 1979 Integrated signal conditioning for silicon pressure sensors. *IEEE Trans. Electron Devices* **ED-26**, 1906–10.

both the device and the system level to describe operation. At the device level, a transducer's performance is mainly defined by its sensitivity and dynamic range. The sensitivity of a device describes its conversion from pressure to an electrically measurable signal. Sensitivity is defined as:

$$S = \frac{1}{\vartheta}\frac{\mathrm{d}\vartheta}{\mathrm{d}P} \qquad [1]$$

where ϑ is the transducer's output, $\mathrm{d}\vartheta$ is the change in the output, and $\mathrm{d}P$ is the pressure change differential over which the output change occurred. The transducer's dynamic range states the functional pressure range for which a given set of parameters can describe the sensor's performance. To some extent, sensitivity and dynamic range can be applied at the system level as well, since merging of a transducer with its interface circuitry can affect these parameters. Higher-order parameters such as full-scale output (FSO), temperature coefficient of offset (TCO), and temperature coefficient of sensitivity (TCS) all apply at both the device and the system level. FSO describes the linearity of the output of a sensor by taking maximum percentage offset between the sensor's output and the linear fit of the data. A sensor's TCO is defined as:

$$\mathrm{TCO} = \frac{1}{\vartheta_\mathrm{o}}\frac{\partial\vartheta_\mathrm{o}}{\partial T} \qquad [2]$$

where T is temperature and ϑ_o is the offset extracted from a fit of the sensor's output. The TCO then defines the dependence of the extracted offset on temperature. A sensor's TCS is the dependence of the transducer's output sensitivity on temperature and is defined as:

$$\mathrm{TCS} = \frac{1}{S}\frac{\partial S}{\partial T} \qquad [3]$$

Two of the critical system-level parameters that define a sensor's performance are resolution and accuracy. A sensor's resolution defines the noise floor for a given transducer and its readout circuitry in producing a quantified data point. Sensor accuracy builds on the resolution by incorporating calibration information to determine the preciseness with which a sensor can determine pressure.

2.04.1.3 Pressure Ranges

Many different pressure units have been used in literature although the standard MKS unit is pascal. However, different applications have settled on different standards in their literature. To provide continuity between the various examples in the chapter, **Figure 3** shows a conversion chart between the various pressure units and the pressure ranges for different applications. Most developed micromachined pressure sensors fall into the 10–1000 kPa operating range to accommodate automotive and biomedical applications. Other transducer technologies that are explored in this chapter apply to measurement in a vacuum environment that typically operates in the range between 0.1 and 10 Pa.

Building on the basis of pressure sensor functionality that has been presented defining the parameters used to describe sensor performance, the remainder of the chapter focuses on the actual implementation at both the device and the system level. Section 2.04.2 covers the mechanics that govern the behavior of diaphragm-based transducers. This is then followed by a section that discusses the various transduction mechanisms that can be implemented with silicon-based sensors. Section 2.04.4 discusses issues involved in extending this technology to the actual applications. Section 2.04.5 then presents the chapter's conclusions.

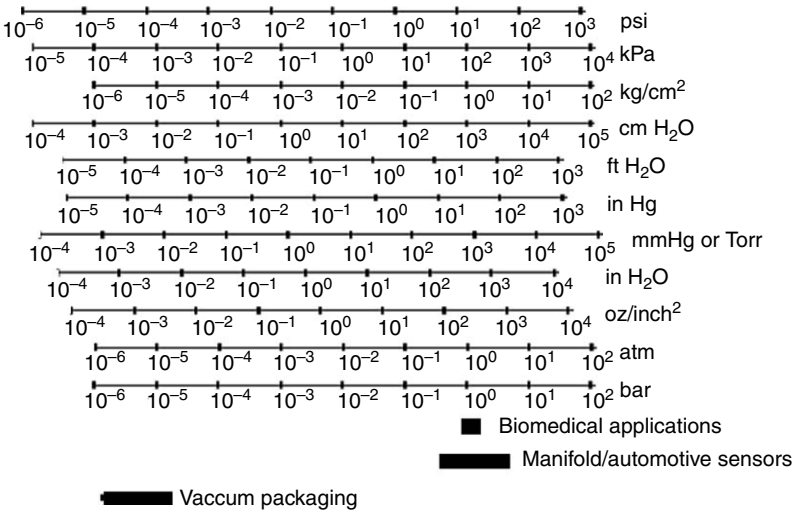

Figure 3 Various pressure units and application ranges.

2.04.2 Device Design

MEMS-based pressure sensors take a variety of forms in terms of fabrication technology and transducer type. However, a majority of the devices are based on the use of a deflectable diaphragm that enables the transduction. The stresses induced within a diaphragm and the corresponding displacement for an incident pressure can be modeled to incorporate the various levels of complexity involved in the device. The fundamental theory that governs the mechanics of diaphragm devices is put forth by Timoshenko (1959). This theory is developed for diaphragms in a variety of configurations and boundary conditions, from which MEMS-based sensor models can then be built.

2.04.2.1 Diaphragm Mechanics

The deflectable diaphragm model begins by defining the diaphragm incident shape and load of the device as well as the boundary conditions for diaphragm deflection. A generic diaphragm is described in **Figure 4**, where a is the radius, h is the thickness, ω is the deflection, with clamped edges supporting the diaphragm's perimeter. The deflection in the center of the diaphragm is defined as ω_c, which is the point of highest deflection for unbounded diaphragm movement.

For a clamped diaphragm under a uniform load, such as pressure, the boundary conditions can then be defined such that the angle of deflection, φ, is equal to zero at the center ($r = 0$) and at the edge ($r = a$) of

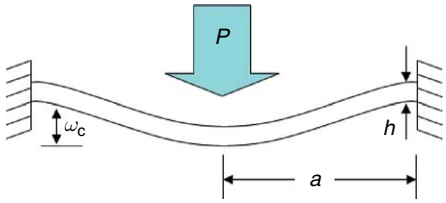

Figure 4 Generalized model for a deflectable diaphragm illustrating the clamped boundary conditions and the diaphragm design parameters.

the diaphragm. The model then builds in the geometry of the device including the layout and the resulting diaphragm thickness. The most straightforward diaphragm structures utilize either square or circular diaphragm designs, both of which have benefits and trade-offs in their implementation.

2.04.2.1.1 Square diaphragm

Due to the availability of anisotropic etchants for bulk silicon (Seidel *et al.* 1990, Tellier and Brahim-Bounab 1994), there are a number of fabrication processes that have been developed and tightly controlled to produce rectangular diaphragm sensors. The deflection of a rectangular diaphragm under incident pressure can be modeled by (Chau and Wise 1987):

$$\Delta P = \frac{Eh^4}{(1-\upsilon^2)a^4}\left[4.20\frac{w_c}{h} + 1.58\frac{w_c^3}{h^3}\right] \qquad [4]$$

where υ is the Poisson's ratio, E is the Young's modulus, and ΔP is the pressure difference across the diaphragm. This equation can be separated into two

regions for small and large deflections. For small diaphragm deflections, where $w_c < h$, the relationship between the differential pressure and the deflection at the center of the diaphragm is relatively linear. For large deflections, where $w_c > h$, the relationship is dominated by the second term in the equation and the pressure shows a third-order response with respect to the deflection of the center of the diaphragm. Utilizing a square or rectangular device will maximize the sensitivity of the diaphragm per unit area for a given sensor design.

2.04.2.1.2 Circular diaphragm

Continuing with the boundary conditions and approximations used in the models for square diaphragms, the deflection of a circular diaphragm's response to pressure, P, is defined by (Eaton and Smith 1997, Timoshenko 1959):

$$w(r) = \frac{3Pa^4}{16Eb^3}\left(1-v^2\right)\left[1-\left(\frac{r}{a}\right)^2\right]^2 \qquad [5]$$

More simply, the center deflection can be modeled in the small deflection region by (Timoshenko 1959):

$$w_c = \frac{3Pr^4}{16Eb^3}\left(1-v^2\right) \qquad [6]$$

Circular diaphragms do have the benefit of a more even stress distribution throughout the device since they eliminate the areas of high stress that occur in the corners of square diaphragms. Circular diaphragms can also provide the platform for building more advanced diaphragm-based devices such as the use of a center boss or operation of the sensors in the touch mode (Chavan and Wise 2001, Ko and Wang 1999). These additional features can then be used to further customize the response of the diaphragm to the needed specifications. From a layout perspective, the parameters available to the designer are only the length and the width of the diaphragm. However, a major factor in the design is developing the fabrication process used to build the device. The process will have the most dramatic effect on the sensor performance and variability in defining the thickness of the diaphragm due to its third-order relationship with the deflection. The diaphragm materials and fabrication processes used for the diaphragm will then define the Young's modulus, the Poisson's ratio, as well as the residual stress. These factors can be utilized to optimize the device performance, but also to introduce higher-order effects in the response of diaphragm-based devices.

2.04.2.2 Nonlinear Diaphragm Effects

The mechanical nonlinearities of a diaphragm need to be addressed to understand their impact on sensor performance. Sensor linearity is an essential parameter when addressing the device at a system level. Given that the transducer's interface circuitry must process the signal and transform it back into a pressure reading, closing this loop is where the linearity of the sensor will have a direct impact on the accuracy of a sensing system. In building on the basic models that have been presented, two main higher-order effects will impact the overall performance of the device: diaphragm stress and trapped gas effects. Diaphragm stress contributes both to the residual stress of the diaphragm's materials and to the stress effects that occur due to the bending and stretching of the diaphragm. The stretching of the diaphragm transforms the linear relationship between pressure and center deflection to a third-order relationship in eqn [4].

2.04.2.2.1 Residual stress

In general, the analytical modeling for diaphragm deflection is done with the assumption that there is no residual stress within the diaphragm. However, practically, fabricated devices all have some finite level of residual stress in the operational diaphragm. A few of the more prominent origins of a diaphragm's residual stress are intrinsic properties of the diaphragm material, thermal mismatch for silicon-on-glass devices, or stress from device packaging. The residual stress that remains on a functional diaphragm has the potential to drastically alter the device's overall performance. **Figure 5** shows the dependence of the diaphragm's sensitivity on the residual stress for both the compressive and the tensile cases.

The generalization of the two cases is that a tensile diaphragm will have decreased sensitivity, whereas a diaphragm left in compression will have increased sensitivity, but has the potential for buckling.

One of the predominate sources of residual stress in some of the bulk micromachined devices is the stress induced from the dopant that is used to form the etch stop in fabricating the device for either electrochemical or etch stop devices. Boron-doped silicon diaphragms exhibit large amounts of tensile

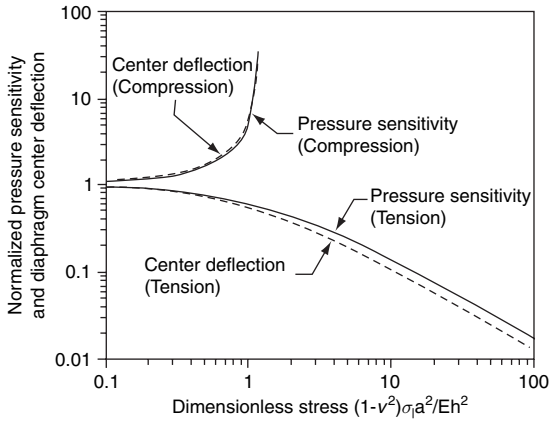

Figure 5 Normalized plot from Cho *et al.* showing the relationship between pressure sensitivity, diaphragm center deflection, and their dependence on intrinsic stress in both tensile and compressive diaphragms. (Source: Chau H-L, Wise K D 1987 Scaling limits in batch-fabricated silicon pressure sensors. *IEEE Trans. Electron Devices* **ED-34**, 850–8.)

stress ranging from 40 to 150 Mpa, the theory for which is that the doping causes irregularities in the lattice due to the smaller radii of the boron atoms when compared with silicon (Smirnov 1977). The residual diaphragm stress can then be compounded by the compressive stresses that develop from the use of high-temperature oxidation steps that drive in and activate the dopants. However, optimization of the fabrication process can use this combination of tensile and compressive stresses to stress-compensate the diaphragm for optimal performance.

2.04.2.2.2 Stress compensation

Stress compensation techniques can be used in device design by the selection of diaphragm materials and fabrication processes. Stacking different materials with both compressive and tensile layers enables building in the resulting stress that will govern the final device. However, attempting to achieve the zero-stress state has the potential to build in device-to-device variability depending on whether the residual stress in the diaphragm is slightly compressive or slightly tensile. Designing a moderate amount of tensile stress, between 5 and 50 MPa, does dampen the sensitivity in the diaphragm; it, however, produces more consistent results for device performance. Composite diaphragm stress can be modeled by taking into account the contribution from each material. The resulting stress of a composite diaphragm can be calculated as (Cho *et al.* 1992):

$$\sigma_c h_c = \sum_m \sigma_m h_m \qquad [7]$$

where σ_m is the composite stress, h_c is the thickness of the stacked layers, and σ_m and h_m are the respective stresses and thicknesses of the m layers in the stack. The ceiling that sets the maximum stress for a device is the fracture stress of the diaphragm material. This ceiling must include both the residual and the operational stresses for the device. For silicon, the fracture stress has been reported by Najafi *et al.* (1990) as 2000 MPa. Cho *et al.* (1992) found that the dependence of the diaphragm's sensitivity to capacitive sensors on the tensile intrinsic stress, σ_i, of a diaphragm can be defined as:

$$S_{\text{tension}} = \frac{a^2}{8\sigma_i hd} \qquad [8]$$

where d is the gap between electrodes. In general, a stress reduction factor of six can be utilized to increase the sensitivity of a diaphragm before membrane buckling becomes a serious concern (Cho *et al.* 1992).

2.04.2.2.3 Trapped gas effects

Trapped gas effects must be considered to assess the performance of absolute sensors that function with a sealed cavity. When combining a sealed cavity along with a deflectable diaphragm, a back-pressure effect is produced from the function of the sensor and the trapped gases temperature dependence. This effect can be modeled by factoring in the sealing pressure and temperature of the device to the TCO, which is defined as given below (Puers *et al.* 1990):

$$\text{TCO}_{\text{gas}} = -\left(\frac{P_{\text{seal}}}{T_{\text{seal}}}\right) \qquad [9]$$

and the TCS, which is defined by:

$$\text{TCS}_{\text{gas}} = -\frac{1}{2}\left(\frac{P_{\text{seal}}}{P_{\max}}\right)\left(\frac{1}{T_{\text{seal}}}\right) \qquad [10]$$

where $P_{\max}$ is the maximum pressure in the device's range, and P_{seal} and T_{seal} are the sealing pressure and temperature, respectively. The effects of the trapped gas can also result from the volume reduction of the sealed cavity due to the deflection of the diaphragm, which can be modeled with the ideal gas law providing matching within 7% compared with finite element modeling (Park *et al.* 2002). Utilizing a

vacuum cavity as the reference pressure for absolute sensors will minimize the effects of any trapped gas. This can be done using a combination of vacuum sealing of the cavity as well as processes that provide gettering of residual air in the cavity or from outgassing of the transducer materials. The residual gas in the cavity can be caused from the finite vacuum levels used during the sealing process. Even with completely sealed bond lines, outgassing has also been shown to occur through the cavity walls (Henmi *et al.* 1994). For sensors that are fabricated on glass substrates, the area of the glass exposure within the cavity should be minimized. This can be done by using an evaporated metal getter, such as titanium, to coat the majority of the exposed glass within the cavity and help maintain the integrity of the vacuum (Chavan and Wise 2002).

2.04.3 Transducer Technologies

There have been a wide variety of micromachined structures that have been designed to read out pressure using various different phenomena. Diaphragm-based devices have been the most pervasive, though these structures then branch out into various ways of converting their deflection into an electrical signal. The more common methods are piezoresistive and capacitive transducers. However, transduction of the diaphragm deflection through an optical readout proves to be advantageous for various applications. These types of devices are then complemented by resonant sensors and Pirani gauges that can be optimized to work in a vacuum environment. **Table 1** presents an overview of silicon micromachined transducer technologies and their system-level application. Although this table does not limit any of the technologies, it does highlight some of the strong points of the various transduction methods.

2.04.3.1 Piezoresistive Sensors

Piezoresistive transduction is one of the earliest demonstrations of mechanisms suitable for microdevices. Piezoresistive sensors are the most widely used sensors in industry today, partially due to their straightforward interface circuitry and the ease of process integration. Piezoresistive transduction utilizes resistive changes that occur due to the mechanical stress or strain of a material. The change in resistance comes from two components: one is by the physical change of the structures due to deformation, the other is by mobility change due to the quantum–physical phenomena (Geyling and Forst 1960). The former does not change the resistivity but changes the resistance while the latter changes resistivity. Strictly speaking, the former does not utilize piezoresistive effects but does add to the sensitivity of the device. The main effect on a thin-film metal resistor's change in response to strain is due to the shape of deformation and not the mobility change. In terms of transduction materials, the most commonly used piezoresistive material in MEMS is silicon due to its high gauge factor, which is the ratio of resistance change to dimensional change, as defined by Liu (2005):

$$\mathrm{GF} = \frac{\Delta R/R}{\Delta l/l} = \frac{\Delta R}{\varepsilon R} \qquad [11]$$

where R is the resistance, l is the length, and ε is the strain. The gauge factor is one of the most important parameters to design piezoresistive devices. Single-crystal silicon has a high gauge factor, which makes it well suited to enable high-sensitivity piezoresistive devices. However, the gauge factor of single-crystal silicon must also take into account the orientation dependence; if piezoresistors are placed on different orientations, a design needs to take into account the respective gauge factors. The π matrix piezoresistance coefficients, which can be found in material

Table 1 Overview of silicon micromachined pressure transduction technologies

Optical				√	√	

databases (Gad-el-Hak 2002), correlate stress and resistivity change as defined by:

$$[\Delta\rho/\rho] = [\pi][T] \qquad [12]$$

where ρ is resistivity, $\Delta\rho$ is the change in resistance, and T is the stress matrix. Therefore, the gauge factor is simply the product of piezoresistance coefficient and the Young's modulus.

Piezoresistive interface electronics often use the Wheatstone bridge configuration as shown in Figure 6. This configuration is particularly useful when a piezoresistive sensor has a differential piezoresistor configuration. For instance, when only one piezoresistor is present, the output V_x is defined by:

$$V_x = \left(\frac{\Delta R}{2R_s + \Delta R}\right) V_s \propto \Delta R \qquad [13]$$

which assumes $R_1 = R_s + \Delta R$, $R_2 = R_3 = R_4 = R_s$. The output is not linear to the change of the piezoresistors. On the other hand, for differential piezoresistors, the output V_x is defined as:

$$V_x = \left(\frac{\Delta R}{R_s}\right) V_s \propto \Delta R \qquad [14]$$

which assumes $R_1 = R_3 = R_s + \Delta R$, $R_2 = R_4 = R_s - \Delta R$. Thus, it is always preferable to have differential piezoresistors for a linear response. As mentioned in the previous sections, one of the drawbacks of the piezoresistive detection mechanism is the dependency on temperature. The dependence is minimized by using the resistors in the Wheatstone bridge configuration. Assuming $R_1 = R_2 = R_3 = R_4 = R$, the variation at the output can be approximated as:

$$\Delta V_x \approx \left(\frac{\Delta R_1 - \Delta R_2 + \Delta R_3 - \Delta R_4}{4R}\right) V_s \qquad [15]$$

As shown above, the temperature dependence of piezoresistors cancels each other out at least for the first-order approximation.

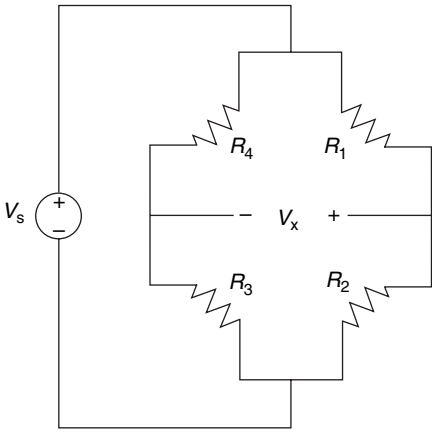

Figure 6 Wheatstone bridge configuration.

2.04.3.1.1 Single-crystal silicon piezoresistors

Piezoresistive pressure sensors using a single-crystal silicon diaphragm have been successfully researched and commercialized over the past four decades. One of the earliest works is a pressure sensor developed by Samaun *et al.* (1971) for biomedical instrumentation applications including cardiovascular catheterization. A 50-μm-thick silicon substrate was used to fabricate a single-crystal silicon diaphragm 1.2 mm in diameter and 5 μm in thickness as shown in Figure 7.

Four resistors are diffused into the diaphragm to form piezoresistors, and the thin diaphragm is formed by an anisotropic wet etch. They also developed a technique to precisely define the thickness of the membrane, within 1 μm thickness, which is shown in Figure 7(b). This technique uses self-terminating detents that are located on to top of the <100> oriented wafer and timed etch stops when the anisotropic etch from the bottom reaches the indicator. One of the critical limitations of piezoresistive-type devices is their sensitivity to temperature. In this work, the temperature sensitivity has been reduced by temperature compensation circuits. The output of the sensor is very linear and the size, critical to biomedical instrumentation applications, can be reduced to as small as 0.8 mm.

To build a completely stand-alone system, signal conditioning circuits are often integrated with pressure sensors. One of the earliest integrated MEMS device was developed by Borky and Wise (1979). A cross section of this device is shown in Figure 8.

This integrated pressure sensor needs only two leads, which makes the sensor very attractive for use in a flexible tube. The thickness of the single-crystal silicon diaphragm is 10 μm and bipolar triple-diffused technology has been used to fabricate the signal conditioning circuitry. The triple-diffused technology provides p+ diffusion as an isolation block, which is critical to the performance of the sensor. The isolation and integrated circuit configurations on the pressure sensor diaphragm are shown in Figure 8. The integrated pressure sensor has

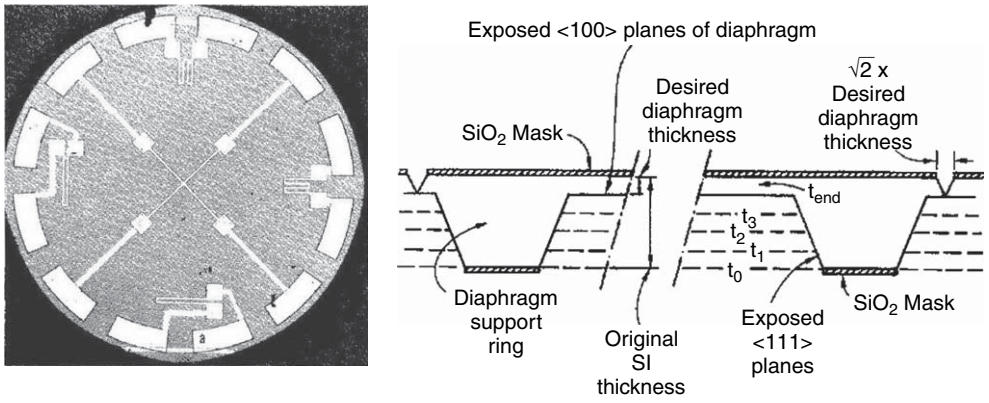

Figure 7 (a) Single-crystal silicon diaphragm device developed by Samaun *et al.* Measures 1.2 mm in diameter and 5 mm in thickness. (b) Process cross section. (Source: Samaun S, Wise K D, Nielsen E, Angell J 1971 IC piezoresistive pressure sensor for biomedical instrumentation. *IEEE International Solid-State Circuits Conference*, Philadelphia, PA, USA, pp. 104–5.)

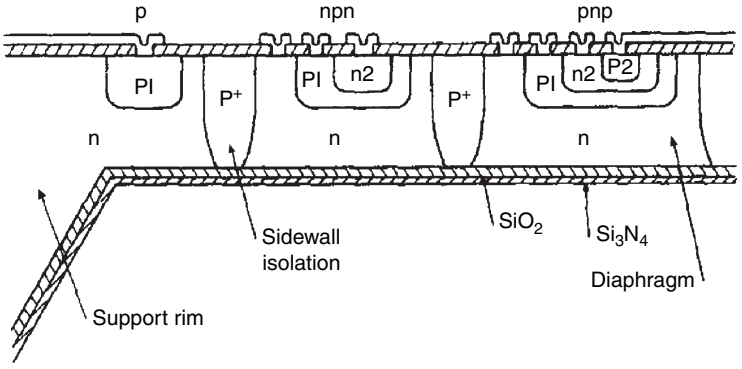

Figure 8 Cross section of the device developed by Borky and Wise in 1979 that integrated a pressure transducer and its interface circuitry on a deflectable diaphragm. (Source: Borky J, Wise K D 1979 Integrated signal conditioning for silicon pressure sensors. *IEEE Trans. Electron Devices* **ED-26**, 1906–10.)

1 mmHg resolution, 0–250 mmHg pressure range, and 1% linearity.

Piezoresistive elements can be easily formed in both bulk crystal silicon and deposited polysilicon. Early work on micromachined pressure sensors utilized piezoresistors to sense the induced strain of a thin membrane. Tufte *et al.* (1962) diffused doping impurities into a single-crystal silicon diaphragm to form piezoresistors as shown in **Figure 9**.

The 7/8″ silicon wafer is lapped and etched to be a thin membrane, ~183 μm, and the diffused strip is located in the middle of the wafer. Depending upon the piezoresistor's location on either convex or concave sides, the sensitivity of the diaphragm to external pressure varies; however, the output resistance change is fairly linear between 0 and 200 mmHg. Since this early work, forming piezoresistors on a single-crystal silicon diaphragm has been very popular for low-cost and low-temperature

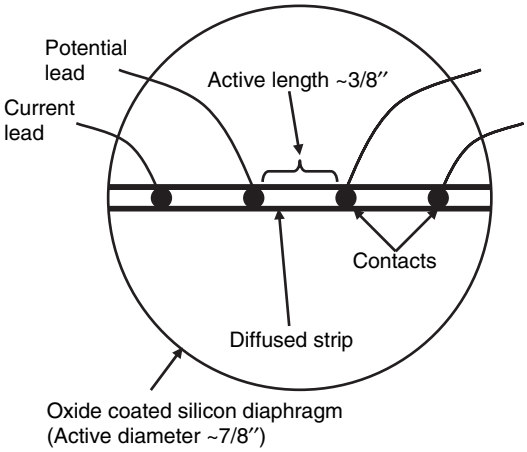

Figure 9 Single-crystal silicon piezoresistors. (Source: Tufte O, Chapman P, Long D 1962 Silicon diffused-element piezoresistive diaphragms. *J. Appl. Phys.* **33**, 3322–7.)

applications. Doping impurities used to define the piezoresistors can be embedded either by diffusion or by ion implantation. Taking advantage of a high gauge factor, single-crystal silicon piezoresistors have been well appreciated in many applications except high-temperature applications.

2.04.3.1.2 Polysilicon piezoresistors

Though single-crystal silicon diaphragm has a number of advantages including low cost, compactness, and a high piezoresistive effect, there are some disadvantages of single-crystal devices in that they suffer from higher temperature sensitivity and limited operating temperature. The temperatures are limited due to the p–n junction isolation scheme for which operating temperatures cannot exceed 120°C. By using polysilicon piezoresistor with silicon dioxide as an isolation layer, the limit for operating temperatures can be increased to over 200°C. One notable material parameter of polysilicon piezoresistors is that the piezoresistive effects of polysilicon is at a maximum 60–70% of the effect on single-crystal silicon.

Schafer *et al.* (1989) developed the polysilicon diaphragm piezoresistive pressure sensor that is shown in **Figure 10**. On a silicon substrate, 0.4-μm-thick polysilicon strain gauges are formed on top of a 0.2-μm-thick silicon dioxide. The polysilicon gauges are doped with boron by ion implantation, and annealed at a high temperature (between 950°C and 1100°C) for 30 min. After interconnecting the gauges by metal layers (W/Ti/Au), a membrane is formed by microspark erosion and a chemical etching from the backside of the wafer.

Piezoresistors are located at the maximum stress points on a membrane, either at the very center or at the edge. However, doing so may introduce high sensitivity to process variation. In order to minimize the sensitivity to any process variation, smart design and placements of piezoresistors have also been pursued. One suggested method is to distribute piezoresistors along the perimeter of the membrane and to have differential measurements to compensate any process variation.

In many cases where polysilicon piezoresistors are used, a polysilicon diaphragm is also implemented. Polysilicon is an attractive material to form a diaphragm for pressure sensors due to many advantages including great controllability of the film thickness, availability of a dielectric film for superior isolation, and suitability for high-temperature applications. As discussed in the previous sections, polysilicon offers a higher operating temperature than does single-crystal silicon for piezoresistive sensors. Availability of an excellent dielectric film such as silicon dioxide allows polysilicon to be used as a material for the diaphragm in piezoresistive sensors.

Kalvesten *et al.* (1998) presented a piezoresistive pressure sensor for cardiovascular pressure measurement (**Figure 11**). Although capacitive pressure sensors can achieve high sensitivity and low temperature drift they need on-chip detection circuitry, which may become difficult when fitting in 0.36 mm diameter of the guide wire to measure blood pressure inside the body. This is the major motivation for them to choose a piezoresistive detection mechanism for their device. The piezoresistive sensor has a polysilicon membrane with silicon dioxide as the sacrificial layer. The sensitivity of the pressure sensor is 2 $\mu V\,V^{-1}\,mmHg^{-1}$.

Workshop Micro Electro Mechanical Systems*, January 25–9, 1998, Heidelberg, Germany, 1998, pp. 574–9.)

2.04.3.1.3 Other micromachined piezoresistive transducers

Although MEMS pressure transducers have mainly focused on the use of polysilicon and bulk silicon, there are other materials that can be integrated into transducers that enable beneficial device properties for some applications. Silicon carbide has many attractive features including excellent mechanical properties, chemical inertness, and radiation resistance, all suitable for harsh environment operation. Although polysilicon piezoresistors increase the operating temperature up to 200°C, many applications require higher operating temperature. For instance, monitoring combustion processes needs a pressure sensor operating at ~500°C. Wu *et al.* (2006) presented a bulk micromachined silicon carbide pressure sensor that is capable of operating up to 400°C. This work used poly-SiC as piezoresistors and silicon nitride as an isolation layer, as shown in **Figure 12**.

The low gauge factor of poly-SiC can be improved upon by a factor of nine by using 3C–SiC. The fabricated device was tested at 400°C, and showed the gauge factor drops by a factor of more than two, which indicates further developments are still needed to further optimize the device.

One of the drawbacks of a piezoresistive detection mechanism is smaller sensitivity compared with a capacitive detection mechanism. Pramanik and Saha (2006) introduced a porous silicon membrane to increase sensitivity by a factor of three over that of

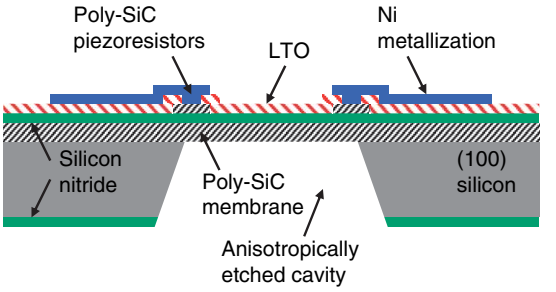

Figure 12 Fabrication process flow of a silicon carbide piezoresistors pressure sensor. (Source: Wu C, Zorman C, Mehregany M 2006 Fabrication and testing of bulk micromachined silicon carbide piezoresistive pressure sensors for high temperature applications. *IEEE Sens. J.* **6**, 316–24.)

a conventional bulk silicon membrane. **Figure 13** shows scanning electron microscope (SEM) images of the porous silicon. The porous silicon is formed by an anodic etching method in a two-pond cell, compatible with conventional micromachining techniques. The fabricated porous silicon (63% porosity) has piezoresistivity coefficient 50% higher than for single-crystal silicon, which is believed to be due to quantum confinement in the porous silicon nanostructure.

French *et al.* (1992) presented a silicon-on-oxide pressure sensor using a unique fabrication process to isolate piezoresistors by thermal oxide. **Figure 14** illustrates a cross section of the isolated piezoresistors. Instead of using a conventional silicon-on-insulator (SOI) substrate such as separation by implantation of oxygen (SIMOX), they have developed a unique fabrication process to completely isolate piezoresistors by thermal oxide and filled with polysilicon. The diamond-shaped cavity is first etched by hydrazine at 55°C and uses the <111> planes as the etch stop. Then, an oxide film is thermally grown to form silicon islands. This thermal oxide completely isolates silicon islands from the substrate. Finally, the rest of the cavities are filled with polysilicon to finish the fabrication. The fabricated device shows very linear fractional change in resistance ($\Delta R/R$) up to 300°C.

2.04.3.2 Capacitive Sensors

The implementation of silicon-based capacitive pressure sensors has been explored since the 1970s (Clark and Wise 1979, Frobenius *et al.* 1973, Fryer 1975). Overall, the use of capacitive transduction has many

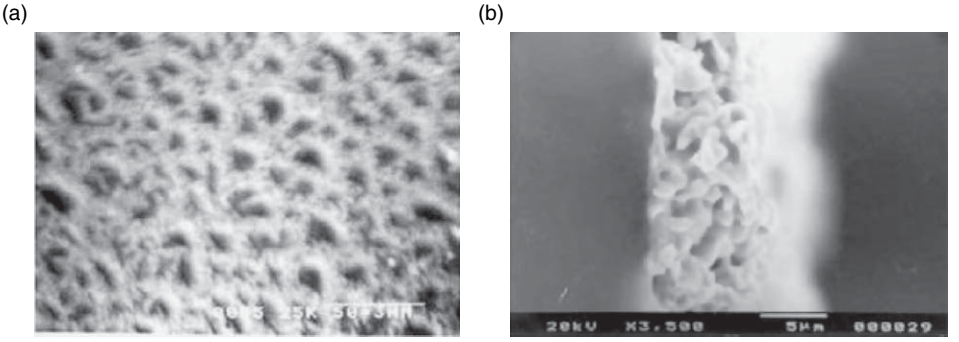

Figure 13 (a) Scanning electron micrograph (SEM) of porous silicon fabricated and (b) SEM of cross-sectional view of the porous silicon sample developed by Pramanik and Saha in 2006. (Source: Pramanik C, Saha H 2006 Piezoresistive pressure sensing by porous silicon membrane. *IEEE Sens. J.* **6**, 301–9.)

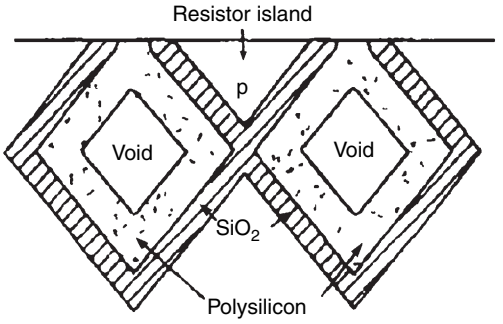

Figure 14 Silicon-on-oxide piezoresistors developed by French *et al.* in 1992. (Source: French P J, Muro H, Shinohara T, Nojiri H, Kaneko H 1992 SOI pressure sensor. *Sens. Actuators A Phys.* **A35**, 17–22.)

benefits from both a fabrication and a system design perspective. Capacitive sensors enable lower-power systems over their piezoresistive counterparts since the transducer itself consumes no active power. They also benefit from lower cross-domain sensitivity to temperature since their dependence is purely due to mechanical effects in the transducer structure. In general, capacitive transducers are diaphragm based and utilize the deflectable diaphragm as one of the electrodes of the sensors. There have been many perturbations of the transducer structure that optimize various aspects of its performance. An illustration of the basic transducer is shown in **Figure 15** along with configurations that utilize a bossed diaphragm and the diaphragm's operation in the touch mode.

A model for the transducer begins by defining its capacitance as:

$$C = \frac{\varepsilon_0 \varepsilon_r A}{d} \qquad [16]$$

where ε_0 is the permittivity of free space, ε_r is the relative permittivity, A is the area of the capacitor, and d is the gap between the electrodes. When configured using the deflected diaphragm as one of the electrodes, the capacitance must be integrated over the effective area of the electrodes. Integrating over the electrode then defines the capacitance as (Eaton and Smith 1997):

$$C = \int\int \frac{\varepsilon_0 \varepsilon_r}{d - \omega(r)} r \mathrm{d}r \mathrm{d}\theta \qquad [17]$$

where $\omega(r)$ is the diaphragm deflection across the diaphragm determined from the diaphragm mechanics, which is presented in eqn [5] for the circular case.

Inherent in the device structure is the trade-off between the device sensitivity and the needed dynamic range for the application. One of the main advantages of capacitive sensors is their ability to change their capacitance by 50–100% over their dynamic range (Chavan and Wise 2001), which contrasts with the typical 5% seen in piezoresistive devices (Puers *et al.* 1990). Since their early stages of development, capacitive transducers have claimed a 20-fold increase in implementation (Sander *et al.* 1980) over piezoresisitive sensors with equivalent gauge factors that are 5–10 times greater than silicon strain gauges (Frobenius *et al.* 1973). However, the benefits of the high response of capacitive transducers have to be weighed against the increased nonlinear response and dynamic range limitations. In addressing the nonlinearity of the flat diaphragm, Crescini *et al.* (1997) designed a snail shell-shaped bottom electrode in a capacitive transducer. This layout then tapers the response toward the periphery of the diaphragm and reduces the linearity error from

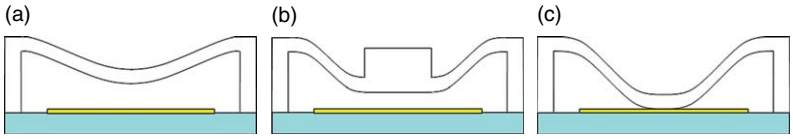

Figure 15 (a) Flat; (b) bossed; and (c) touch mode diaphragm structure and functionality for implementing capacitive transducers.

12% to 2% when compared with a standard electrode. However, this type of linearity compensation does have a trade-off with the overall sensitivity of the transducer. In optimizing these trade-offs, the device can be designed for use in the touch mode or by building in a boss in the deflectable diaphragm.

2.04.3.2.1 Bossed diaphragm sensors

The diaphragm mechanics with the implementation of a boss needs to then satisfy the boundary condition of having the angle of deflection equal to zero at $r = c$, where c is the radius of the center boss. The relationship between the pressure and the center deflection, which is then the deflection of the entire bossed area, is defined by (Giovanni 1982):

$$P = \frac{Eb^3}{A_p a^4}\omega_c + B_p \frac{Eb}{a^4}\omega_c^3 \qquad [18]$$

where:

$$A_p = \frac{3(1-v^2)}{16}\left(1 - \frac{c^4}{a^4} - \frac{4c^2}{a^2}\log\frac{a}{c}\right) \qquad [19]$$

$$B_p = \frac{\frac{7-v^2}{3}\left(1+\frac{c^2}{a^2}+\frac{c^4}{a^4}\right) + \frac{(3-v)^2 c^2}{(1+v)a^2}}{(1-v)\left(1-\frac{c^4}{a^4}\right)\left(1-\frac{c^2}{a^2}\right)} \qquad [20]$$

For a given fabrication process, the response of the bossed diaphragm can be controlled by defining both the radius of the boss and the area of the diaphragm. Chavan and Wise (2001) have implemented an array of these structures where the dynamic range of individual sensors in an array has been designed to have peak sensitivities for the various devices on the chip in a different pressure range. The transducers were realized using a dissolved-wafer, silicon-on-glass process. The diaphragms were defined using deep and shallow boron diffusions to form a concentration-dependent etch stop. The resulting deflectable part of the diaphragm is 3.5 μm and has a linear tape-open (LTO) layer that provides stress compensation as well as electrical isolation. This type of array then enables a system that maintains a resolution of 25 mtorr over the 300 torr dynamic range, with each of the segmented sensors in the array having a sensitivity of 24 fF/torr with a 50 torr dynamic range. A high level of sensitivity was achieved using a combination of pre-etching the cavity to a depth of 12 μm and then vacuum sealing the device to provide a functional gap between 300 and 800 nm. **Figure 16** shows a photograph of this device.

2.04.3.2.2 Touch mode sensors

Touch mode operation provides another option to enhance the linearity of capacitive transducers. If the distance between the diaphragm and the corresponding electrode is designed correctly and a passivation layer is used between the two, there are many benefits with operation of the device in the touch mode. The benefit of having a close to zero gap between the electrodes can be used to enhance the overall device sensitivity in the touch mode region. Ko and Wang (1999) reported the performance of circular diaphragm touch mode sensors with a sensitivity of 86 fF per psi with a sensor that has a diaphragm diameter of less than 400 μm. **Figure 17** shows the capacitive response across the various regions of operation of a capacitive transducer. The normal region is where the capacitive response is governed by the third-order equations defined in Section 2.04.2.1. The transition region is where the diaphragm first touches down. The linear region then shows the desired response of operation of the sensor in the touch mode. Guo *et al.* (2000) have reported implementing touch mode sensors with an integrated capacitance-to-frequency conversion interface circuit to measure 0.63% nonlinearity in the sensor readout across the linear touch mode region of operation. The saturation region is where the major part of the diaphragm touches the opposite electrode and only fringing effects remain. Modeling of the actual diaphragm itself then needs a more complex definition since the boundary condition defining where the angle of deflection equals zero is changes throughout the dynamic range of the sensor. This type of mechanical modeling is more suited for the use of finite element modeling or spreadsheet tools, which can provide designs that match the transducers response within 5% (Meng and Ko 1999).

2.04.3.2.3 Device noise and scaling limits

Fundamentally, the scaling of a sensor is limited by its noise floor and the sensitivity trade-offs incurred when scaling the size. Capacitive pressure sensors are exponentially dependent on the equivalent radius of the diaphragm. This then makes capacitive sensors application specific in addressing the needed signal-to-noise ratio that defines their scaling limit. Scaling limits for capacitive pressure sensors have been developed to address both device- and system-level issues. The front end of the sensing noise floor was defined by Chau and Wise (1987) as:

$$\overline{p_n^2} = \frac{kT\left(C_0 + C_p\right)}{\left(V_s C_0 S_{cap}\right)^2} \qquad [21]$$

where C_0 is the sense capacitance, C_p is the parasitic capacitance, S_{cap} is the capacitive sensitivity, V_s is the supply voltage, k is the Boltzmann's constant, and $\overline{p_n^2}$ is the mean square input pressure noise. For some applications, the transient response of the diaphragm must be considered both in the time and in the frequency domains. Diaphragm vibrations from the sampling frequency of the interface circuitry can occur if the sampling frequency is near one of the various modes of vibration for the diaphragm. The device noise does provide some detail as to the achievable resolution and accuracy of a device; however, a system-level analysis must address the noise and sensitivity coupling the device with its readout circuitry. The system-level interface circuitry can

also implement noise reduction techniques such as correlated double sampling, which lowers the $1/f$ noise of the amplifier offset and thus further optimizes the performance of the device (Chavan and Wise 2002).

2.04.3.2.4 Bulk diaphragm fabrication for capacitive sensors

Fabricating of devices from bulk silicon leverages the various isotropic and anisotropic micromachining techniques that have been developed. It also allows the use of the crystalline structure of silicon in forming the device. Various silicon-etching methods have been implemented to form micromachined pressure sensors, for many of which process simulation tools that go down to the molecular level of interaction with bulk silicon have been investigated and developed (Elwenspoek 1993, Kakinaga *et al.* 2005, Seidel *et al.* 1990). Overall, the goal is to achieve a thin, flexible, and reproducible silicon diaphragm. The three predominant methods of achieving this are the use of concentration-dependent etch stops, material- or junction-isolated etch stops, or a timed etch. Deep reactive ion etching (DRIE) is an alternative to forming for micromachining silicon structures and would fall into the category of a time-dependent etch stop.

The use of concentration-dependent etch stops enabled the silicon-on-glass structure developed by Chau and Wise (1988). The paper describes the used of sequential deep and shallow boron diffusions to define the diaphragm structure into a lightly doped silicon wafer. This silicon wafer is then anodically bonded to a patterned and metallized glass wafer. The diaphragm is then etched out using ethylene-diamine pyrocatechol (EDP) to dissolve the bulk silicon and leave only the highly boron-doped diaphragm, the metal interconnect, and the glass substrate. This method can achieve a high level of device-to-device consistency and provides a device structure that has been developed further to provide sensor circuit integration. The repeatability is mostly a factor of the EDP having an etch rate of lightly doped silicon, which is 50 times faster than the etch rate of a boron-diffused etch stop at concentration greater than $7 \times 10^{19}\,\mathrm{cm}^{-3}$.

Kloeck *et al.* (1989) utilized a reverse-biased p–n junction to define a diaphragm with an electrochemical etch stop. This device uses a <100> silicon wafer and a 40% potassium hydroxide (KOH) aqueous solution. This process has the potential to achieve a diaphragm tolerance of $\pm 0.2\,\mu\mathrm{m}$ (Kloeck *et al.* 1989). The development of an *in vivo* pressure sensor using a junction-isolated etch stop was done by El-Bahar in 1998 (El-Bahar *et al.* 1998). For this device they used TMAH to do the etching of the p-doped silicon and stop on the n-type junction. This etch then stops when the etchant reaches the biased n-type silicon, which is then passivated by an anodically formed oxide. This passivation prevents further etching of the silicon. Since an electrical setup is needed in the etch solution as well as in a sealed chamber that exposes only one side of the silicon wafer, the setup of this etch can be somewhat complicated. However, this release method does provide an opportunity to reduce intrinsic stress over methods that use a concentration-dependent etch stop, which has a high level of tensile stress in the silicon.

Timed etching of silicon has been implemented to form pressure sensors in various forms. It has been used by itself both as a dry and as a wet etch. It has been used for the pre-etch to form the recess in a silicon wafer as well as in the release step when etching all the way through the substrate and defining a sensor diaphragm. KOH has been used as the pre-etch for square diaphragms in silicon because as a timed etch its etch depth can be carefully controlled and its anisotropic etching properties provide geometrical control of the etch (Tellier and Brahim-Bounab 1994). DRIE has also been implemented as the recess etch for concentration-dependent etch processes. The use of DRIE also provides the ability to machine large corrugations in a diaphragm to further optimize the device (Chen *et al.* 2003).

2.04.3.2.4.(i) Wafer bonding It is typical to use a secondary substrate wafer for bulk micromachined devices since in most cases the majority of the silicon is removed from the primary wafer. The bonding of two wafers together provides a batch fabrication method that enables these types of structures. Since pressure sensors need the formation of a hermetically sealed cavity, inorganic materials are typically preferred over some of the polymer bonding options. Processes that bond two silicon wafers as well as bond a silicon wafer to a glass wafer have been developed (Schmidt 1998). In the case of much of the piezoresistive work, this secondary silicon wafer is used to form the sealed cavity. This bond can be formed either directly, with methods such as silicon fusion bonding, or indirectly with the use of an interstitial layer such as gold or glass that will form a eutectic or anodic bond to attach the two wafers. For direct silicon fusion bonding, there are strict

requirements needed for each of the polished silicon surfaces needing a roughness of below 10 Å and a bow of less than 5 Å (Schmidt 1998). The surface of the wafers can also be treated and cleaned to improve the quality of the bonding surface. The two silicon wafers are then elevated above 1000°C to create a bond that is comparable in strength to the silicon itself. The use of an intermediate layer when bonding two silicon wafers does relax the surface and temperature requirements to some extent. Silicon–gold eutectic bonding, when combined in the correct ratio, takes advantage of the drop in the reflow temperature to 363°C (Wolffenbuttel and Wise 1994).

Anodic bonding between a silicon and a glass wafer has been implemented for various transducer types and presents advantages both in device performance and in packaging and manufacturability of the device. Many of these are built into devices that have been implemented with the dissolved wafer process, which basically merges anodic bonding and a concentration-dependent etch in EDP. The glass substrate can then serve as a substrate for the electrical connections. These can be accessed either by wire-bonding to the routed metal traces or by more novel ways such as creating through-wafer vias in the glass substrate, which can also serve to facilitate the lead transfer to the sealed cavity (Chae *et al.* 2005a, Esashi *et al.* 1990).

2.04.3.2.4.(ii) Vacuum sealing and lead transfer The ability to form a vacuum-sealed cavity in the device enables the reference needed for absolute sensors as well as minimizes trapped gas effects on the device's performance. Various MEMS-based sensors have been developed to include a vacuum-sealed cavity and provide absolute pressure measurement. The technology that provides vacuum sealing at the wafer level also has the potential to reduce the overall device costs and provide device-to-device sameness across a batch of sensors. Chavan and Wise (2001) developed a bulk micromachined capacitive transducer that is fabricated using a silicon-on-glass dissolved wafer process. In order to enable vacuum sealing and lead transfer to the opposite electrode on the glass, a polysilicon-to-glass anodic bonding process was developed. Implementing this process needs a reduction in the surface roughness of the deposited polysilicon layer. Chemical–mechanical polishing was used to reduce the surface roughness below 50 nm and to enable a hermetic seal for the vacuum cavity. Using a polysilicon bond, the glass contact is routed in the bonded polysilicon layer, while contact to the bulk silicon is made outside the sealing ring. **Figure 18** illustrates lead transfer in the two cross sections of the device structure.

Park and Gianchandani (2003) developed a novel way to eliminate the need to provide electrical interconnect into a vacuum cavity with their implementation of the skirt electrode sensor. For this device, the fabrication process is simplified to three masks and the capacitive transduction takes place around the perimeter of the sealed cavity. **Figure 19** shows the mechanics of the structure that provide the sensor's output from a small diaphragm deflection by the touch mode operation of the device.

2.04.3.3 Resonant Sensors

Resonant structures have been implemented for pressure measurement by taking advantage of the following:

(1) Q, the quality factor, of the resonant structure changes
(2) Tension of the resonator changes over the pressure

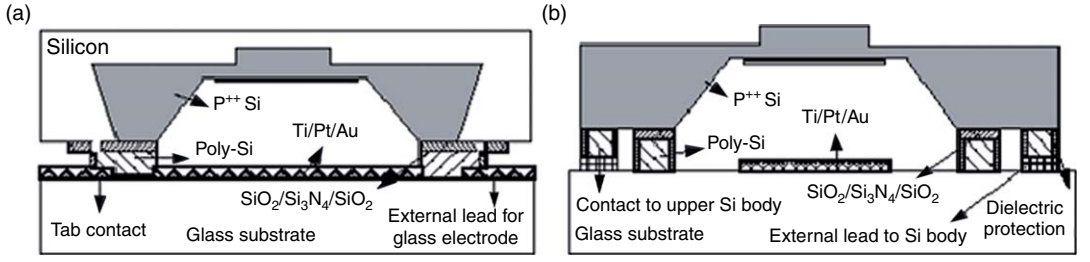

Figure 18 Cross section of the absolute sensors implemented by Chavan and Wise showing (a) the continuous polysilicon seal the perimeter of the device and (b) the isolation of the glass and silicon interconnect. (Source: Chavan A V, Wise K D 1997 A batch-processed vacuum-sealed capacitive pressure sensors. International Conference on Solid-State Sensors and Actuators. Digest of Technical Papers, Transducers 97', 1997, pt. 2, vol. 2, pp. 1449–52.)

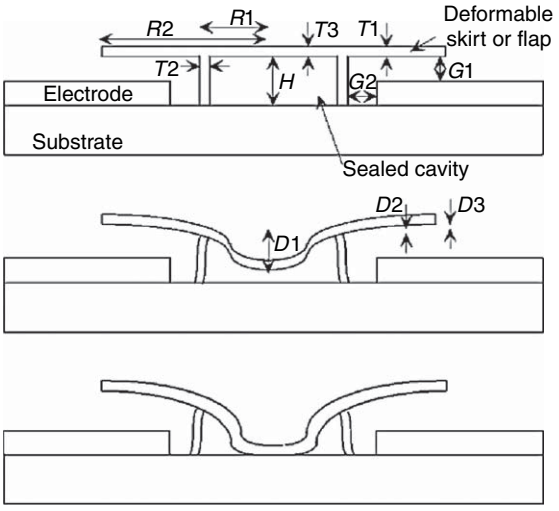

Figure 19 Capacitive skirt electrode structure implemented by Park and Gianchandani eliminates the need for electrical interconnect in a vacuum-sealed capacitive transducer structure. (Source: Park J-S, Gianchandani Y B 2000 A capacitive absolute-pressure sensor with external pick-off electrodes. *J. Micromech. Microeng.* **10**, 528–33.)

Resonant pressure sensors provide higher sensitivity than do piezoresistive sensors, and also offer better accuracy and stability, especially temperature stability. In this section, we first discuss the resonant pressure sensor using the Q factor and then a sensor utilizing the tension change over the applied pressure.

The quality factor (Q) of a resonant structure is highly dependent on its surrounding air pressure. The quality factor remains constant at a very low pressure as an intrinsic Q based on the device structure. The quality factor, Q, then begins to roll off at a certain pressure as shown in **Figure 20** (Newell 1968). The dependence Q has on air damping is due to individual air molecules exchanging their momentum with the resonant structure and inducing energy dissipation, which then results in a reduction of Q. The Q reduction stops when the molecules behave more as a viscous film, which is independent of pressure. Of course, one may want to use resonant structures as a pressure sensor at the momentum-damping region.

In the region, where Q is dependent on the momentum damping the air molecules with a temperature of 300 K, Q can be approximated by (Newell 1968):

$$Q \approx 93\left(\frac{d}{L}\right)^2 \frac{\sqrt{Y\rho}}{P} \qquad [22]$$

where d and L are the thickness and the length, respectively, of a resonator; Y is the Young's modulus; and ρ is the mass density.

By using the pressure sensitivity of microresonators, devices have been developed to include pressure measurements of enclosed cavities. Chang-Chien and Wise have demonstrated comb-drive resonators to monitor pressure integrity of micropackages (Chang-Chien 2002). The Q of the resonator versus the pressure characterization curve is shown in **Figure 21**. Using the characteristic curve, they evaluated micropackage vacuum integrity to maintain vacuum pressures below 50 mtorr.

Instead of utilizing fluidic damping effects (determining Q of a resonator), many micromachined resonators have been used as pressure sensors by taking advantage of the structural tension coupled with a diaphragm (Burns *et al.* 1995, Ikeda *et al.* 1990, Petersen *et al.* 1991, Stemme and Stemme 1990). One of the earliest examples used single-crystal silicon resonators etched by anisotropic etchants for absolute pressure sensors (Greenwood 1984).

Figure 22 shows the resonator and the response of the resonator over the pressure ranging from 0 to 60 kPa. The resonant frequency of a stretched string changes with the square root of the tension, and tension is proportional to the applied pressure; thus, the resonant frequency of the resonator varies with the square root of the pressure. The resonator is excited electrostatically on one side, with a bias voltage of 50 V and a drive signal of less than 1 V, and sensed by field effect transistor (FET) on the other side.

In order to minimize Q reduction due to damping by surrounding fluids, vacuum-sealed integrated resonators with differential measurements have been introduced (Ikeda *et al.* 1990). Ikeda *et al.* have developed a magnetically excited vacuum-sealed integrated resonant pressure sensor as shown in **Figure 23**.

The resonant beams are integrated in a diaphragm, one at the center and the other at the corner. Since these resonant beams are sealed at the vacuum, the pressure sensor has no Q reduction and no need to optimize the amplitude response of the resonator over the pressure measurement. The resonant frequency of integrated resonant beams can be described as:

$$f = \frac{4.73^2 h}{2\pi l^2}\left(\frac{E}{12\rho}\left(1 + 0.2366(l/h)^2\varepsilon\right)\right)^{1/2} \qquad [23]$$

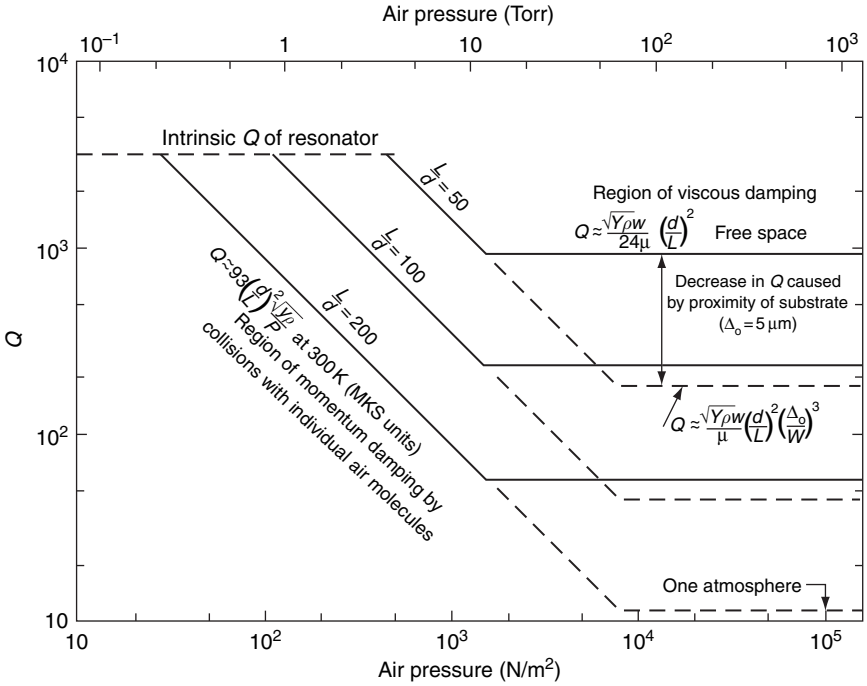

Figure 20 Quality factor (*Q*) of a resonator and its dependence on air pressure. (Source: Newell W 1968 Miniaturization of tuning forks. *Science* **161**, 1320–6.)

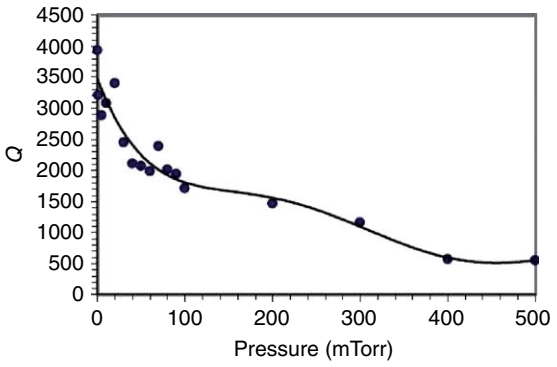

Figure 21 Quality factor (*Q*) versus pressure for a polysilicon comb-drive resonator. (Source: Chang-Chien P P L, Wise K D 2001 Wafer-level packaging using localized mass deposition. *Proc. 11th Int. Conf. Solid State Sensors and Actuators Transducers '01/Eurosensors XV.* Digest of Technical Papers. Springer-Verlag, Munich, Germany, June 10–14, 2001, Vol. 1, pp. 182–5, BN – 3 540 42150 5.)

where f is the natural frequency of a fundamental oscillating mode, l is the resonator length, h is the resonator thickness, E is the Young's modulus, ρ is the density, and ε is the strain.

The strain caused by pressure changes the resonant frequency of the resonant beams, and by differential measurement between center and corner gauges the maximum fitting error is only about 0.05% of the full-scale range. The temperature coefficient is also measured using the integrated resonators as approximately $-40\,\text{ppm}\,\text{K}^{-1}$, which is nearly equal to the theoretical value that is half the sum of the thermal expansion coefficient and the temperature coefficient of elasticity.

Kim *et al.* (2005) demonstrated the stability of microresonators over time and thermal hysteresis. Their microresonators are encapsulated by a thick ($\sim$20 μm) epitaxial polysilicon film in a very controlled environment, and were monitored for performance change over time and thermal hysteresis. Over 8000 h of operation, the resonant frequency was maintained with less than $0.5\,\text{ppm}\,\text{year}^{-1}$ drift, which is equivalent to that of a temperature compensated crystal oscillator (TCXO). For thermal cycling between $-50°\text{C}$ and 80°C for more than 400 cycles, the frequency stability is below 0.77 ppm.

2.04.3.4 Pirani Sensors

Pressure sensors typically involve physical movement of a thin diaphragm or minute structures. They generate very accurate and sensitive signals; however, moving structures are sometimes not

Solid-State Sensors and Actuators and Eurosensors III*, *Sens. Actuators A, Phys. (Switzerland).* Montreux, Switzerland, Vol. A21, pp. 146–50.)

preferred for certain applications where structural moving causes undesired effects; e.g., cross-over distortion, harmonics. A Pirani sensor has no moving parts to transduce pressure and instead measures thermal conductance changes of the ambient. Since Pirani sensors were invented in 1906 (Pirani 1906), many miniaturized Pirani sensors that take advantage of micromachining technology have been introduced.

The operation of a Pirani gauge is based on heat transfer from a suspended heater to a heat sink through a gas. The thermal conductance through the gas is a function of its pressure. Depending on the Knudsen number, K_n, the gas can be modeled in the continuum regime ($K_n << 1$) at high pressure or in the molecular regime ($K_n >> 1$) at low pressure. An illustration showing these regimes of operation is shown in **Figure 24(a)**.

With reasonable assumptions and approximations, heat flux, which is a function of ambient pressure for all K_n, can be modeled as (Mastrangelo 1991):

$$\dot{Q}(P) \approx \dot{Q}(\infty)\left(\frac{P/P_o}{1+P/P_o}\right) \qquad [24]$$

where P_o is an empirical transition pressure. This $\dot{Q}(P)$ has a linear dependence on P at low pressure and is limited to a constant P_o at high pressure, which determines the upper limit of the dynamic range. Assuming that the heater is a lossless thermal conductor, the total thermal conductance of the heater is the sum combining solid conduction, gaseous conduction, gaseous convection, and radiation. The dependence of these forms of conduction on pressure is illustrated in **Figure 24(b)**. Radiation can be ignored at low temperature, and gaseous convection can be neglected because the Pirani gauge is usually placed inside a package where no external forced gas convection exists.

The sensitivity of the Pirani gauge is then the slope of the total thermal conduction (G_{Total}) versus pressure as shown in **Figure 24(b)**. The sensitivity can be obtained as:

$$\frac{\partial G_{gas}(P)}{\partial P} \approx \frac{G_{gas}(\infty)}{P_o}\frac{1}{(1+P/P_o)^2} \cong \frac{G_{gas}(\infty)}{P_o} \text{ for } (P/P_o) << 1 \qquad [25]$$

This configuration of fabricated micro Pirani gauges is shown in **Figure 25**. These gauges have two heat sinks instead of the conventional one heat sink configuration. The dual heat sink Pirani gauge is to improve sensitivity and dynamic range. Vertical configuration has a thin-film metal heater underneath of p++ silicon and glass substrate and p++ silicon as heat sinks whereas p++ silicon itself serves as a heater and as dual heat sinks for lateral configuration. The vertical sensor performs better than the lateral one as shown in **Figure 26**, but with added fabrication complexity of a six-mask process for the vertical structure over a two-mask process for lateral sensors.

These Pirani gauges are integrated inside a micropackage, size of 2 mm × 2 mm × 0.6 mm, to monitor package integrity over the time. The base pressure is ~33 torr without a getter inside the package, and the

pressure is maintained relatively constant for more than 4 months (Chae *et al.* 2005a).

2.04.3.5 Optical Sensors

The development of technology for the telecom industry has also been leveraged in various sensor applications. The use of fiber-optic technology has led to the advance of sensors systems that benefit from off-site interface electronics. Capacitive- and piezoresistive-based devices run into problems at higher-temperature applications ($T > 250°C$). These temperatures cause problems with the on-site circuitry for capacitive sensors and increase the leakage currents in bulk silicon piezoresistive sensors. Sensors that are interfaced through an optical fiber eliminate these issues since the electronics can be placed off-site and the sensor is independent of the electrical characteristics of the diaphragm. Pulliam *et al.* (2002) have developed a diaphragm-based device mounted on an optical fiber, which uses extrinsic Fabry–Perot interferometry. This device is designed to work in temperatures up to 600°C for applications within a turbine engine. As shown in **Figure 27**, this transducer detects deflection of the diaphragm by measuring the distance between the diaphragm and the end of the optical fiber.

The readout for this type of device can use either a single- or a dual-wavelength system for interrogation. Optical readout of the diaphragm deflection can be interrogated using a single wavelength of light; however, this interface suffers from nonlinearity issues when the diaphragm displacement needs a dynamic range of $\lambda/2$ due to the sinusoidal interference pattern. Pulliam *et al.* (2002) have implemented a readout for this device that uses a dual-wavelength

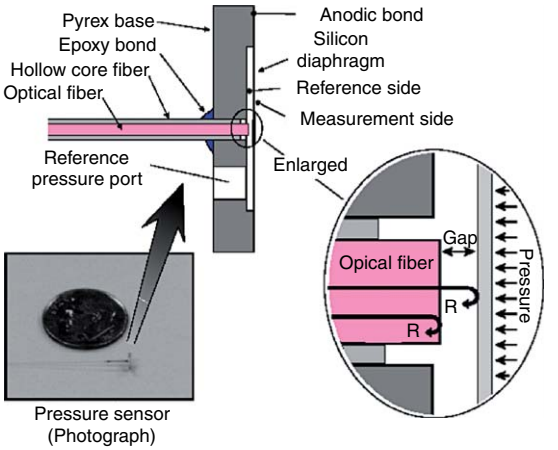

Figure 27 Illustration of the functionality of an optical transduction scheme that implemented a silicon diaphragm along with a fiber optic-based optical interface converting diaphragm deflection into a Fabry–Perot interference pattern. (Source: Pulliam W, Russler P, Fielder R 2002 High-temperature, high-bandwidth, fiber optic, MEMS pressure sensor technology for turbine engine component testing. *Proc. SPIE – The International Society for Optical Engineering: Fiber Optic Sensor Technology and Applications 2001*, Newton, MA, USA, October 30–November 1, 2001, pp. 229–38.)

interferometric output that overlaps the wavelengths to avoid the nonlinearities of the single wavelength readout.

Even though the circuitry has been removed from the environment in which the diaphragm is located, there is still a need to provide temperature compensation in some applications due to the temperature dependence of the diaphragm. In addressing this issue, Wolthuis *et al.* (1993) developed a dual-function sensor that measures both pressure and temperature and can be optically interrogated through a single optical fiber. This is done by using light emitting diodes (LEDs) of two different wavelengths to interrogate each sensor type at the readout end of the optical fiber. At the transduction end of the fiber, a dichroic mirror is placed after the temperature sensor that serially separates it from the pressure sensor. To implement this architecture, the temperature sensor has to respond to one LED for transduction as well as for passively transmitting light from the LED that is interrogating the pressure sensor. For temperature transduction, Wolthuis *et al.* utilized an absorptive long pass filter that has a temperature-dependent cutoff wavelength. The temperature signal is transduced using a 674 nm LED, whose reflection is marked by the temperature-dependent absorptive

filter. With the pressure sensors working with light in the infrared (IR) region, it is unaffected by the filters that interact with the smaller wavelength and just passes through to the pressure-sensitive diaphragm at the tip of the device. Displacements in the cavity below the diaphragm alter the reflectivity of each LED wavelength, which can be detected at the opposite end of the fiber.

2.04.4 Applications

Some of the major bottlenecks for successful commercialization are the efforts in packaging, testing, and calibration, which are all needed for final use of the devices in their intended application. Almost all MEMS packaging, testing, and calibration need to be completely redesigned for individual devices. Unlike in integrated circuits, the lack of standard/automated packaging, calibration, and testing capability strongly impedes yield improvement and cost reduction. This section first addresses packaging for one of the first commercialized pressure sensors in the case study of the manifold absolute pressure (MAP) sensor. Rough structures of the MAP sensor package and issues are described. This section is then followed by a section that addresses the advantages and disadvantages of sensor circuit integration. Interface circuitry is presented to discuss various readout schemes for the different transducer types that then convert the transduced parameter into an electrical signal. This is followed by a subsection that discusses calibration and temperature compensation techniques, which are essential issues in addressing the system-level transducer operation. This section is then concluded with a discussion on merging MEMS-based pressure sensors within a wireless system.

2.04.4.1 Packaging Technology

Packaging is considered to be the single most critical element in successful commercialization of microsystem products. The cost of packaging ranges between 20% and 95% of the total production cost depending upon packaging requirements. There are many factors related to the high costs including the following:

(1) No (or very little) standard automated assembly tools are available.
(2) High diversity of products, which demands different requirements of packaging from one to another.
(3) Packaging processes being used for integrated circuits often cause undesirable effects on microsystems including stiction, geometry distortion, and delamination of the packaged devices.

Packaging of micromachined pressure sensors is not an exception to these aforementioned issues. In this section, we introduce an example of packaging techniques for pressure sensors.

Packaging of pressure sensors needs to provide access for an external pressure source unlike for other more conventional hermetic packaging requirements. This attribute specification often makes pressure sensor packaging complicated and costly. Nevertheless, developments of pressure sensors have matured to penetrate markets, and one package that has been successfully commercialized is the pressure sensor described in this section (Monk 2002).

Figure 28 illustrates the Freescale MAP sensor package (Freescale 2005, 2007a). The MAP sensor needs a reference pressure to measure absolute pressure, which is provided by a backplate to form a vacuum cavity (Freescale 2007b in press). The sensor is bonded to the backplate by wafer-level, glass frit bonding. Due to on-chip conditioning electronics, the bond temperature needs to be low to maintain the thermal budget. Unlike anodic bonding, glass frit bonding can tolerate nonperfectly flat bond interface while the bond is performed at low temperature (400–500°C). The bonded die is then placed inside the premolded thermoplastic case, attached to the

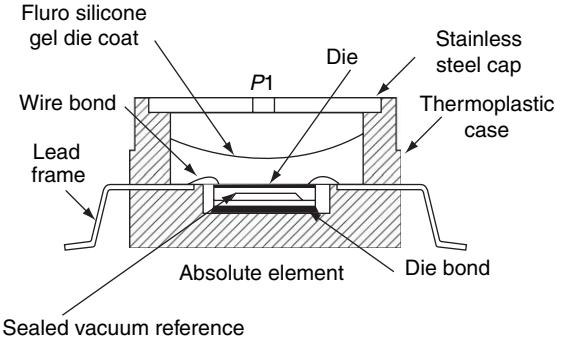

Figure 28 Freescale manifold absolute pressure (MAP) sensor package. (Source: Freescale 2007 Data sheet, MPXA6115A, High temperature accuracy integrated silicon pressure sensor for measuring absolute pressure, on-chip signal conditioned, temperature compensated, calibrated).

bottom of the case by an adhesive wire bonded to a lead frame, and covered with a low-stress (fluoro) silicone gel. The die is attached to a square pad of adhesive (silicone gel), which needs a 150°C oven cure. The adhesive was chosen not to transfer a large stress to the die. The low-stress (fluoro) silicone is to protect the sensor from environments while allowing pressure measurements at the same time. It has a low modulus and provides passivation against corrosion. A stainless-steel cap with a pressure access hole covers the plastic case. The sensor has a mechanical diaphragm and signal-conditioning electronics monolithically integrated with the MEMS device. The monolithic integration can achieve a smaller overall device size and improved interconnect reliability.

2.04.4.2 Monolithic Integration

Sensor circuit integration is one of the main benefits in micromachined transducers made out of silicon. This attribute has been sought after since the early days of micromachining pressure sensors in silicon. As discussed earlier, the first monolithically integrated sensor and circuit was developed by Borky and Wise in 1979 (Borky and Wise 1979). Compatibility with the current circuit fabrication processes has been difficult to maintain for this level of integration, since many of the sensor and circuit processes need some level of compromise. For example, concentration-dependent etch stops cannot be used in the circuit areas so a certain level of care must be taken to ensure that the circuit areas are protected in other ways. Chavan and Wise (2002) successfully developed a monolithic device that merges the bulk micromachined silicon-on-glass sensor array with a 3 μm bipolar complementary metal oxide semiconductor (BiCMOS) process. This then provides the needed on-site electronics for the capacitive transducers as well as enables the first-level encapsulation of the system. A cross section of this device is shown in **Figure 29**.

Surface micromachined versions of monolithic devices have implemented a combination of polysilicon diaphragm and silicon dioxide or phosphosilicate glass (PSG) film as a sacrificial layer. Guo *et al.* (2000) presented a capacitive pressure sensor that uses polysilicon as a membrane and PSG as a sacrificial layer as shown in **Figure 30**. The PSG sacrificial layer is deposited between n-/p-channel source/drain implantation and polysilicon deposition. The sacrificial layer is etched using hydrofluoric acid (HF) to release the polysilicon membrane, and the cavity is sealed by LTO to form a reference pressure.

Success in monolithic integration has now come to the point where it is offered as a foundry service utilizing bulk devices fabricated using a electrochemical-dependent etch stop and surface micromachined structures (Foundries 2005a, b).

2.04.4.3 Interface Circuits

Interface circuits are an essential part of a sensing system providing the signal conversion to an analog or digital signal. There have been very extensive developments on the readout/feedback circuitry for micromachined pressure sensors. In this section,

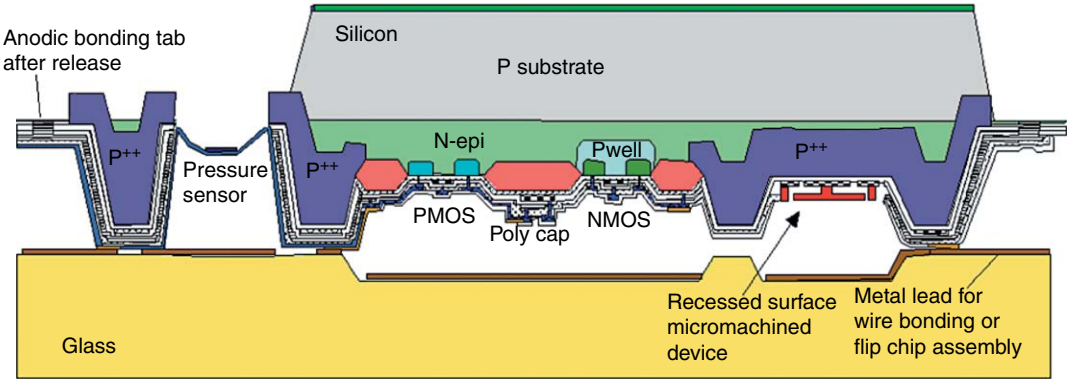

Figure 29 Cross section of the integrated device developed by Chavan and Wise merging pressure sensors formed with the silicon-on-glass dissolved wafer process with a bipolar complementary metal-oxide semiconductor (BiCMOS) fabrication process. (Source: Chavan A V, Wise K D 2002 A monolithic fully-integrated vacuum-sealed CMOS pressure sensor. *IEEE Trans. Electron Devices* **49**, 164–9.)

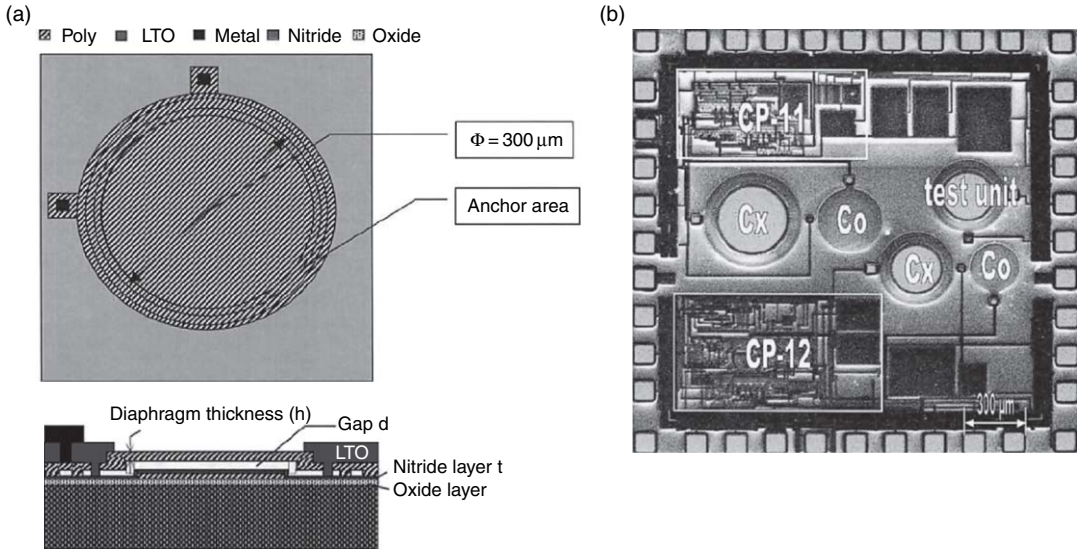

Figure 30 Integrated polysilicon diaphragm-based pressure sensors. (a) Layout of cross section and (b) integrated chip shot. (Source: Guo S, Guo J, Ko W H 2000 A monolithically integrated surface micromachined touch mode capacitive pressure sensor. *Sens. Actuators A Phys.* **A80**, 224–32.)

interface electronics for pressure sensors are briefly introduced. The interface electronics described in this section are separated into piezoresistive, capacitive, resonant, and thermal detection for readout of their respective transducer types.

2.04.4.3.1 Piezoresistive interface

Building interface circuitry into the output of the Wheatstone bridge provides the first stage of signal conversion. The output of Wheatstone bridge is analog, which is not immune to changes in the signal path and noises as a time-domain signal; thus converting an analog signal to a digital form is highly desirable. Spencer *et al.* introduced a voltage-controlled duty-cycle oscillator (VCDCO). This straightforward approach to digital signal conversion is shown in **Figure 31** (Spencer and Angell 1990). This oscillator generates a pulse-width-modulated digital output using simple bipolar junction transistor (BJT) circuits. The oscillation cycle and the voltages of notable nodes are shown **Figure 31(b)**.

Analysis of this circuit enables defining the voltage charge on one side of the capacitor as:

$$\Delta V_C = V_{E2} - V_{E1} = (V_{CC} - 0.7V) - (V_{CC} - RI_{EE} - 0.7V) = RI_{EE} \quad [26]$$

where V_{E1} and V_{E2} are the voltages at the emitters of Q_1 and Q_2, respectively, and V_C is the voltage across the capacitor. The output of the oscillator is then taken at the collector of Q_2 and is shown in the V_{C2} waveform. The positive feedback transistors then create a multivibrator with the time for each phase of the charging cycle defined as:

$$t_2 \approx C\frac{\Delta V}{I} = C\frac{2RI_{EE}}{I_{C3}} \quad [27]$$

and

$$t_1 \approx C\frac{2RI_{EE}}{I_{C4}} \quad [28]$$

If Q_1 and Q_2 transistor pairs are matched and switch abruptly, then the current ratio can be defined as:

$$\frac{I_{C3}}{I_{C4}} = \exp(v_{in}/V_T) \quad [29]$$

This then enables the dependence of the oscillator timing on the input voltage from the Wheatstone bridge as:

$$v_{in} = V_T \ln\left(\frac{t_1}{t_2}\right). \quad [30]$$

2.04.4.3.2 Capacitive interface

Capacitive sensor readout provides a number of advantages that build on the simple transducer structure such as low noise and low power consumption. There are three main implementations of capacitive readout: capacitance–frequency (C–F) converter, AC

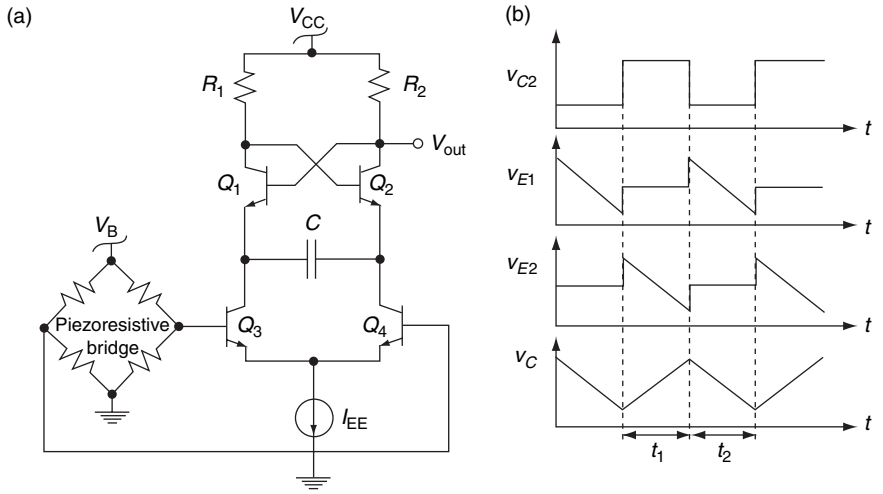

Figure 31 (a) Voltage-controlled duty-cycle oscillator (VCDCO) and (b) waveforms of VCDCO. (Source: Spencer R R, Angell J B 1990 A voltage-controlled duty-cycle oscillator. *IEEE J. Solid-State Circuits* **25**, 274–81.)

bridge, and switched-capacitor (SC) interface. C–F converter is simple, but generally suffers from parasitics and temperature effects. AC-bridge-type interface utilizes complementary excitation pulses to charge capacitors and to convert to voltage signal. This type of interface is relatively easy to implement; however, synchronizing the phase between the modulated signal and the reference is challenging. Also, AC bridge generally suffers from parasitics. Switched-cap interface is the most sophisticated circuit architecture of all, but offers extremely low noise and robust architecture against parasitics.

Like the oscillator described in the resistive readout, a capacitive version of this oscillator then implements the charging capacitor as the varying parameter. Matsumoto and coworkers developed the C–F interface circuit shown in **Figure 32** (Matsumoto and Esashi 1993). The sensor capacitor is represented as C_X. Using the input hysteresis of a Schmitt trigger inverter, the voltages across the reference capacitor (C_r) and the sense capacitor (C_X) are converted to frequency signal and the slope of the output curve represents C_r and C_X. When charging C_r, the output of Schmitt trigger forms a line, and the slope of the line is I_o/C_r, and when discharging C_X the slope becomes I_o/C_X. Assuming I_o and C_r are known, C_X is modulated to frequency signal at the output. The period and frequency can be defined as:

$$t = t_r + t_f = \frac{V_b C_r}{I_o} + \frac{V_b C_X}{I_o} = \frac{V_b}{I_o}(C_r + C_X) \qquad [31]$$

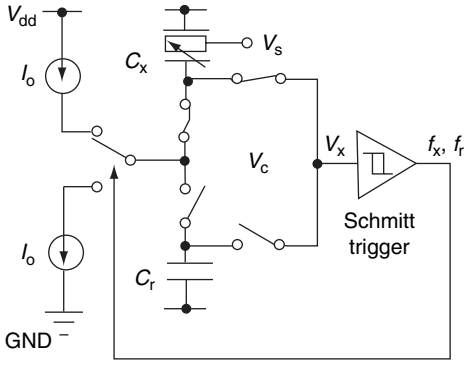

Figure 32 Schematic of a capacitance-to-frequency converter circuit implemented by Matsumoto *et al.* (Source: Matsumoto Y, Esashi M 1993 Integrated silicon capacitive accelerometer with PLL servo technique. *Sens. Actuators A Phys.* **A39**, 209–17.)

and:

$$f = \frac{I_o}{V_b(C_r + C_X)} \qquad [32]$$

where V_b is the difference in the trip points for the Schmitt trigger.

2.04.4.3.2.(i) AC bridge The AC bridge configuration has been widely used since the early 1990s, especially for microaccelerometers. Again, almost the same architecture can be used for capacitive pressure sensors. The AC bridge configuration utilizes complementary AC carriers, preferably exactly out-of-phase carriers. **Figure 33** shows a simplified system block diagram of AC bridge interface circuits (Yun *et al.* 1992).

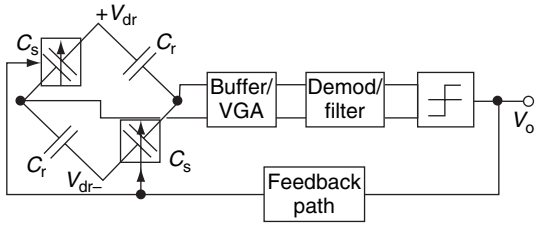

Figure 33 System block diagram for AC bridge interface circuit developed by Yun *et al.* in 1992. (Source: Yun W, Howe R T, Gray P R 1992 Surface micromachined digitally force-balanced accelerometer with integrated CMOS detection circuitry. *Solid-State Sensor and Actuator Workshop*, Hilton Head, SC, pp. 126–31.)

The sense capacitors (C_s) and reference capacitors (C_r) form the capacitive bridge. The bridge is excited by a high-frequency (in this case, 1 MHz) complementary square wave ($+V_{dr}$ and $-V_{dr}$). The output of the bridge is a linear function of capacitance change, which is amplified, demodulated, filtered, and quantized to produce a pulse-width-modulated (PWM) digital output (V_o) (Chau *et al.* 1996). Due to the vulnerable architecture for parasitics and input capacitance of electronics, the output of the bridge is fed to a unity gain buffer with low input capacitance to bootstrap the ground plane. This is necessary if the sense capacitors are small so that they are not overwhelmed by stray capacitances. The buffered signal goes to a variable gain amplifier (VGA) to amplify the signal controlled externally. The amplified signal is demodulated and filtered before being quantized. This functionality is expressed analytically as follows:

$$[A(t)\cos(\omega t)][B\cos(\omega t+\theta)] = \frac{A(t)B}{2}[\cos(\theta)+\cos(2\omega t+\theta)] \quad [33]$$

Here, $A(t)\cos(\omega t)$ is the output from the VGA ($A(t) \propto \Delta C$) and $B\cos(\omega t+\theta)$ is the reference (B is known, and θ is the phase difference between the reference and the output from VGA).

After the filter, the demodulated signal can be approximated by $A(t)\mathrm{B}\cos(\theta)$. Since B is known and $A(t)$ is proportional to capacitance change, the incident pressure that is deflecting the diaphragm can be extracted. The demodulated and filtered signal is quantized by a quantizer (in this case 1-bit quantizer) to produce a PWM signal. Zero or one of PWM corresponds to polarity of pressure input, and the width indicates the magnitude of the input. The demodulated and filtered signal is proportional to ΔC as well as $\cos(\theta)$. This indicates the phase difference between the reference and the output from the bridge significantly affect the sensing capability. This inherent sensitivity of the phase makes the AC bridge interface less attractive than the SC configuration despite the relatively simple circuit implementation architecture.

SC interfaces are the most frequently used interface configurations for capacitive detection. One example of an SC interface is shown in **Figure 34** as implemented by Chavan and Wise (2002). This SC interface circuits consist of three stages: a front-end integrator, a VGA, and sample and hold stages. The front-end integrator is the heart of the SC interface, the fully differential charge integrator with a self-biased folded-cascode amplifier. The charge integrator implements a correlated double-sampling (CDS) technique to reduce $1/f$ noise and amplifier offset. The user-configurable parameters, including feedback capacitor (C_f), reference capacitor (C_r), and on-chip gain capacitors (C_{g2}), allows adjusting output (V_{DC}), is shown as:

$$V_{DC} = \frac{C_{g2}}{C_{f2}}\left(\frac{C_s}{C_f}V_{in+} - \frac{C_R}{C_f}V_{in-}\right) + 2.5 \quad [34]$$

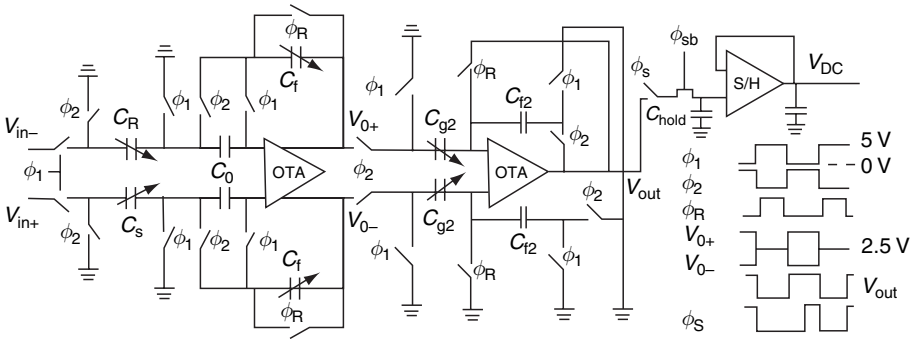

Figure 34 Switched-capacitor (SC) interface implemented for capacitive readout by Chavan and Wise. (Source: Chavan A V, Wise K D 2002 A monolithic fully-integrated vacuum-sealed CMOS pressure sensor. *IEEE Trans. Electron Devices* **49**, 164–9.)

The SC interface circuitry does not need a demodulation stage where the exact phase match is required to produce a precise output. Also, the output is independent of parasitics to the first order. These robust features make an SC interface very attractive because they allow for off-chip electronics when needed. On the other hand, SC interfaces are more complicated than other circuit implementation architectures.

2.04.4.3.3 Resonant sensor interface

Interface circuitry for micromachined resonators is based on a transimpedance amplifier (TIA). A simplified resonant interface implemented by Nguyen is shown in **Figure 35** (Nguyen 1995). Excitation is provided at the input as a voltage source ($V_I + v_i$) and the resonant device is biased by bias voltage (V_P). Due to electromechanical transduction, the output of the resonator is current (i_o), which is fed to TIA to produce voltage output. The amplitude of the output is scanned over the frequency and generates a Q factor versus pressure plot. As pressure changes, the detected Q factor changes due to the sensitivity of the resonator to air damping.

2.04.4.3.4 Pirani gauge thermal interface

A Pirani gauge measures pressure by detecting the heat flux change from a heater to a heat sink as discussed in Section 2.04.3.4. The interface for this device is straightforward yet offers high resolution and accuracy. **Figure 36** shows a benchtop measurement diagram for the device (Stark *et al.* 2003).

A current source forces a constant current through the gauge, and the voltage drop across the gauge is measured using a standard four-point probe configuration. Temperature can then be determined from the measured resistance of the gauge with the given temperature coefficient of resistance (TCR) while power is measured from the current and voltage product. Current is increased until the gauge reaches a preset temperature, typically ~30°C, and then a linear curve fit is applied to the power versus the temperature data to extract thermal impedance that is a slope of the linear curve. As pressure decreases, the slope of the curve, which corresponds to the thermal impedance, then increases as shown in **Figure 37** (Chae *et al.* 2005b).

According to Chae *et al.*, micro Pirani gauge has an uncertainty of 50 μtorr and can be used for hermeticity testing to detect a leak rate of 3.1×10^{-16} $cm^3\,s^{-1}$, assuming a common micropackage volume of 1.6×10^{-5} cm^3. This exceeds the resolution by at least four orders of magnitude over traditional leak testing.

2.04.4.4 Calibration and Temperature Compensation

Assessment of the true performance of a pressure sensor system is done by analyzing the accuracy that can be achieved when the sensing device and its interface circuitry are combined. For a given measurement, the resolution of the sensor system will then be set by device and interface circuitry noise. Spanning the dynamic range of the sensor, the system-level measurements will also be impacted by the sensor's nonlinearity. In addition, the device also needs to work over a range of temperatures. These issues can be addressed at either the device or the system level. Device-to-device tolerance must also

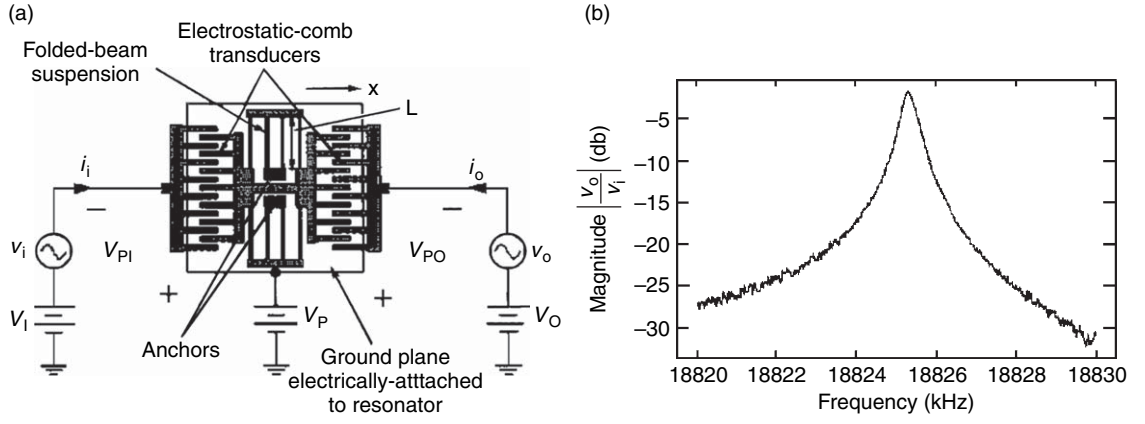

Figure 35 Resonant device interface technique. (a) The measurement configuration for a microresonator; and (b) the output amplitude plot over frequency. (Source: Nguyen C 1995 Micromechanical resonators for oscillators and filters. IEEE Ultrasonics Symposium, pp. 489–99.)

Int. Conf. Micro Electro Mechanical Systems*, Kyoto, Japan, pp. 506–9.)

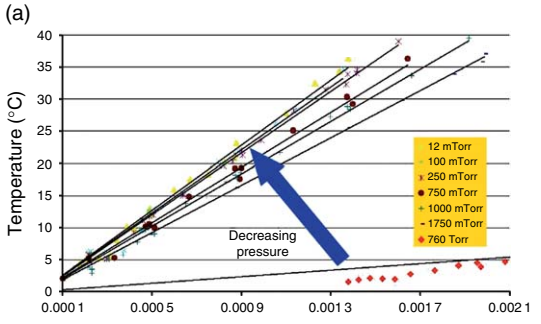

Figure 37 Micro Pirani gauge characterization showing the thermal impedance (slope) of a Pirani device versus ambient pressure. (Source: Chae J, Stark B, Najafi K 2005 A micromachined Pirani gauge with dual heat sinks. *IEEE-CPMT Adv. Packaging Micro/Nano-Scale Syst.* **28**, 619–25.)

be addressed in a manufacturing environment. To facilitate this, some level of individual device modifications can be utilized to compensate for variations. Lee *et al.* (1999) implemented a laser trimming scheme that enables calibration for offset voltage, full-scale span, and TCO voltage and full-scale span. This design used ion-implanted resistors in the interface circuit that are implanted in the same step that the diaphragm piezoresistors are implanted. This technique was able to produce devices with a temperature coefficient of 46 ppm $°C^{-1}$.

These issues can be addressed at the system level by using smart sensor systems that are microcontroller based and allow for device customization within the firmware of the device. The two predominant ways of implementing calibration at this stage are to use a lookup table or to perform a polynomial approximation (Crary *et al.* 1990). A lookup table has the potential to provide a high level of accuracy in calibration. However, there is a high demand made on device memory and there is an inherent trade-off between the level of complexity built into the lookup table and the amount of memory available to the device. Polynomial approximation has also shown potential to enable accurate calibration showing a fivefold improvement in the linearization of the sensor's data (Crary *et al.* 1990). Although the polynomial approximation method does relax the memory requirements, it does utilize more processing power. This then presents an inherent trade-off between the bandwidth of the device and the optimization of device accuracy through compensation. Calibration of the device is also a practical matter since the resolution of the sensor then needs to be maintained over the lifetime of the device. This then needs a high level of characterization of the reliability of the seal for the reference cavity.

2.04.4.5 Wireless Devices

There are two levels of merging wireless technology and wireless sensors: at the system level and at the device level. Merging these at the system level involves microcontroller-based systems, which provide the sensor interface and can be configured to transmit and receive. However, merging these technologies at the device level opens up MEMS-based pressure sensors to a wide variety of applications that

need a moderate amount of telemetry distance combined with a small device footprint. The merging of wireless technology with micromachined pressure sensors at the device level has enabled highly scalable devices that can be designed for applications spanning biomedical, environmental, and industrial monitoring. The most straightforward implementation of merging wireless technology and pressure sensors is the integration of an antenna with a capacitive sensor. When connected to form a parallel inductor and capacitor (LC) tank, this device can be queried remotely through a loosely coupled passive telemetry system. A nearby coupled inductor can then detect the resonant frequency of the LC tank by a dip in the phase of its own measured impedance. This type of system was demonstrated by Collins who, in 1967, implemented a system for the remote monitoring of a resonant LC tank to provide long-term ocular pressure measurements (Collins 1967). Readout of a capacitive sensor in this configuration defines the resonant frequency of the LC tank as:

$$\omega_o = \frac{1}{\sqrt{L_s C_s}} \quad [35]$$

At the resonant frequency of this secondary LC tank, the received peak phase dip signal can be defined by:

$$\Delta\phi_{peak} = \tan^{-1}\left(k^2 Q_{tank}^{series}\right) \quad [36]$$

where the quality factor of the secondary LC tank is defined by:

$$Q_{tank}^{series} = \frac{1}{R_s}\sqrt{\frac{L_s}{C_s}} \quad [37]$$

and k is the coupling coefficient of the loosely coupled inductors. Although this type of wireless interface provides a relatively straightforward device implementation, attention must be paid to any parasitic capacitances and resistances in the device as they directly impact the sensitivity, telemetry range, and resolution of the coupled system.

Recent work by Akar and Akin presents a monolithic version of a passive telemetry-based pressure sensor (Akar *et al.* 2001). **Figure 38** shows a cross section of the device as well as its equivalent circuit model. This device measures only 2.6 mm × 1.6 mm. This type of device is designed for an intracranial or intraocular application. The integrated inductor measures 1.2 μH and enables a wireless pressure

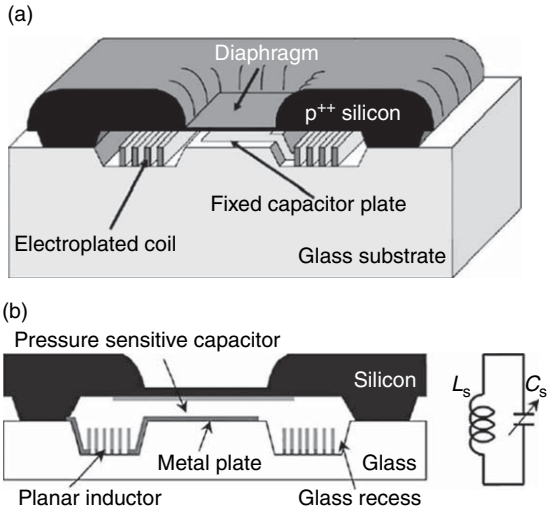

Figure 38 (a) Device structure and (b) cross section and equivalent circuit for an LC tank sensor enabling a passive, monolithic wireless pressure sensor. (Source: Akar O, Akin T, Najafi K 2001 A wireless batch sealed absolute capacitive pressure sensor. *Sens. Actuators A Phys.* **95**, 29–38.)

sensitivity of 1553 ppm $mmHg^{-1}$ with a self-resonant frequency between 95 and 103 MHz when operating between 0 and 50 mmHg.

Moving to a higher level of integration to include monolithically fabricated active circuitry then leads to the implementation of multiple sensors within the device that can be read out using backscatter telemetry. This level of integration was used to implement a dual-site pressure sensor for use in characterizing the pressure differential and flow rates within the arterial system (DeHennis and Wise 2006). The schematics for this system and device photograph are shown in **Figure 39**.

This device was developed for use within the carotid artery and has a volume of 2 mm^3 integrating a 3 μm BiCMOS process with a sputtered antenna and two bulk micromachined capacitive pressure sensors. The entire device is released using a series of dicing steps along with dissolving both the excess glass and the silicon substrates using wet etching techniques. The wireless sensor interface consumes 340 μW and uses capacitance-to-frequency conversion for readout of the vacuum-sealed pressure transducers. The integrated device has a 200 μm profile and a volume of 2 mm^3. The system can sense a reduction in flow of 13%, which corresponds to a differential pressure of 3 mmHg (**Figure 40**).

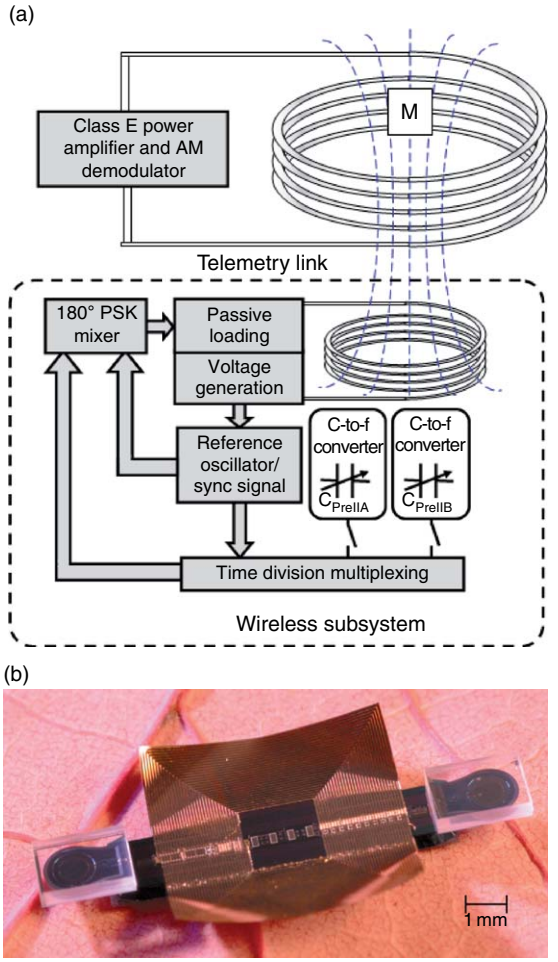

Figure 39 (a) Wireless system schematic and (b) fabricated device photograph of a two-site, wireless pressure sensor that enables intraarterial pressure and flow characterization. (Source: DeHennis A D, Wise K D 2006 A fully integrated multisite pressure sensor for wireless arterial flow characterization. *J. Microelectromech. Syst.* **15**, 678–85.)

Integration of the pressure transducer and circuitry with a hybrid attached antenna enabled the development by Stangel *et al.* (2001) of an integrated, surface micromachined sensing device that is targeted for intraocular application. This device integrates a 1.2 μm complementary metal oxide semiconductor (CMOS) interface circuit with an array of polysilicon diaphragm transducers. The on-chip temperature sensor, sensor readout, and calibration electronics are then interfaced through a 13.56 MHz backscattered modulation telemetry scheme. This device needs only the attachment of a foldable planar coil to enable remote querying of ocular pressure over long periods of time. A photograph of the integrated die is shown in **Figure 41**.

Solid-State Circuits* **36**, 1094–100.)

2.04.5 Conclusions

This chapter has presented an overview of MEMS-based pressure sensors spanning their device-level design and their system-level application. The material presented in this chapter provides a basis for understanding the basic transducer functionality as well as

the high-level intricacies that are needed to realize a functional sensing system. Process development has enabled the ability to form the transducer on a monolithic substrate in a variety of forms. This chapter has also covered various transduction mechanisms that enable measurement of pressures from vacuum to ambient, even in applications with elevated temperatures. The presentation of interface electronics, which provides the second level of transduction, then builds to a system-level perspective of MEMS-based sensors. To date, pressure sensors have been the most successfully commercialized MEMS device. The continued technological improvements in device performance and system level of integration provide platforms for silicon-based pressure sensors to continue to reach the forefront of industrial, biomedical, and environmental applications.

Biographies

Andrew D. DeHennis received the BS degree in physics from Millersville University in 1997 and the MS and Ph.D. degrees in electrical engineering from the University of Michigan in 2001 and 2004, respectively. From 1997 to 1999 he worked at Metrologic Instruments, Inc where his effort focused on the development of highly automated dimensioning and tracking systems. His research interests are in remotely powered wireless microsystems for biomedical and environmental monitoring applications. After graduating with his doctorate, he joined Sensors for Medicine and Science, Inc. and is currently working on the development of a fully-implantable glucose monitoring system.

Junseok Chae received the B.S. degree in metallurgical engineering from the Korea University, Seoul, Korea, in 1998, and the M.S. and Ph.D. degrees in EECS (Electrical Engineering and Computer Science) from the University of Michigan, Ann Arbor, in 2000 and 2003, respectively. After a couple of years of being research fellow at Michigan, he is now at Arizona State University as an assistant professor in electrical engineering. His areas of interests are MEMS sensors/actuators, MEMS integration with electronics, micro-packaging, micro/nano-fluidics, and bio-MEMS.

He has published over 20 journal and conference articles and a book chapter, "Monolithically Integrated Inertial Sensors" in the 2nd volume of Advanced Micro and Nanosystems (AMN), CMOS-based MEMS and NEMS, Wiley-VCH series. He holds two US patents.

2.05.1 Introduction

The first micromachined accelerometer was demonstrated in the late 1970s by using the piezoresistive effect based on a bulk micromachining process (Roylance and Angell 1978, 1979). It was not until the late 1980s that interest in micromachined accelerometers became more intense. Various sensing mechanisms, including piezoresistive, piezoelectric, capacitive, and tunneling, and thermal and optical sensors were extensively investigated using both bulk and surface micromachining techniques. The main driving force behind micromachined accelerometers was the automotive airbag deployment application due to the demand for lower cost and improved reliability and performance over traditional mechanical accelerometers (MacDonald 1990, Sulouff 1991). In the mid-1990s, many commercial micromachined accelerometers were brought into the market mainly for automotive uses. Starting from the beginning of this new century, the use of micromachined accelerometers has rapidly expanded in different fields such as portable electronics, video games, and medical applications. The following discussion attempts to give a historical perspective of the accelerometer development over the past few decades.

Before micromachined accelerometers, mechanisms consisting of pendulums and strain gauges were typically used to measure acceleration (IEEE-Std-337 1972, Sawyer and Ishii 1969). For example, one of the early Bosch accelerometers used a beryllium copper spring and a strain gauge with the mass suspended in oil for damping. This accelerometer, shown in **Figure 1**, was used in early automotive applications to measure negative acceleration and judge the impact for airbag safety systems.

Strain gauges with high gauge factors (GFs) that occur with doped single-crystal silicon (SCS) are a transduction mechanism that has found its way into various accelerometer designs in the past 30 years. Because SCS is a readily available material for the integrated circuit (IC) electronics industry, it has been exploited as the building block for accelerometers. Kulite used this approach in some of the earliest piezoresistive accelerometers (Kurtz 1976). The cantilever beam mechanical shape with additional mass added on the free end and a strain gauge at the mount or clamped end have been used in different sizes and shapes to build accelerometers. The SensoNor design as shown in **Figure 2** created a diffused strain gauge on the top and bottom of a silicon beam and achieved an electrical connection with a gold–tin alloy. The beam was clamped in the

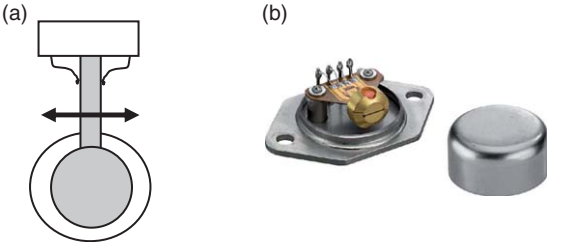

Figure 1 Schematic and photo of Bosch pendulum accelerometer. (Photo courtesy: Wilhelm Frey.)

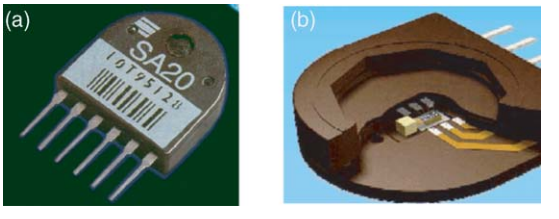

Figure 2 Photos of SensoNor SA 20 Crash Sensor.

housing base and additional mass was added to the end of the cantilever. Improvements to the design and packaging resulted in an etched structure and a plastic package with oil fill that went into large volume production in the early 1990s.

The cantilever beam accelerometer reported by Roylance and Angell (1979) used the mass of silicon created by anisotropic etching from the underside of a wafer along with boron diffusion and gold metallization from the front side to create a monolithic wafer approach. The monolithic microelectromechanical systems (MEMS) approach was further developed into a commercial product by Insouth Microsystems, Auburn, AL, in 1979, using aluminum metallization and a full piezoresistive bridge that was known as the G-Chip. The silicon accelerometer, double side processed and anisotropically etched, was mounted in a leadless chip carrier (LCC) package and combined with electrical amplification and compensation, as shown in **Figure 3**.

Anisotropically etched piezoresistive accelerometers by Delphi, IC Sensors, Nova Sensors, Denso, Bosch, and Endevco, among others, were also developed for instrumentation and automotive applications in the early 1990s. Due to the demand for automotive applications, especially airbag safety systems, many organizations entered the accelerometer field with innovative designs.

In the late 1980s and early 1990s, the use of polysilicon as an accelerometer mechanical spring and mass structure was investigated by numerous university groups, such as the University of California at Berkeley (UC-Berkeley) (Boser and Howe 1995, Lu *et al.* 1995), the University of Wisconsin (Guckel *et al.* 1992), and the University of Berlin (Fricke and Obermeier 1993). Polysilicon is a common material used in silicon gate complementary metal oxide semiconductor (CMOS) transistors and therefore is compatible with IC processing. Early work on this approach by Analog Devices Inc. (ADI) in 1989 resulted in the ADXL50, which was the first integrated surface micromachined accelerometer. An ADXL50 is shown in **Figure 4**. The ADI accelerometer used interdigitated comb fingers to sense a differential capacitance change when the mass supported by the polysilicon springs was accelerated and displaced. By integrating the electronics with the mechanical structure, a single small die was possible. This approach made it possible to add additional circuit functions and multiple axes of sensing by changing the layout while maintaining a common process.

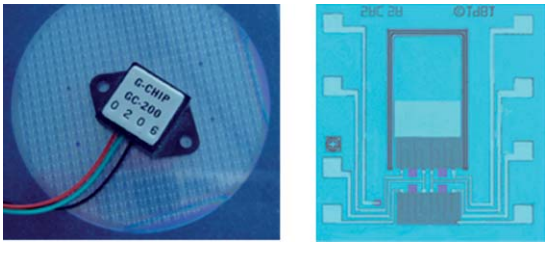

Figure 3 Photo of Insouth Microsystems G-Chip.

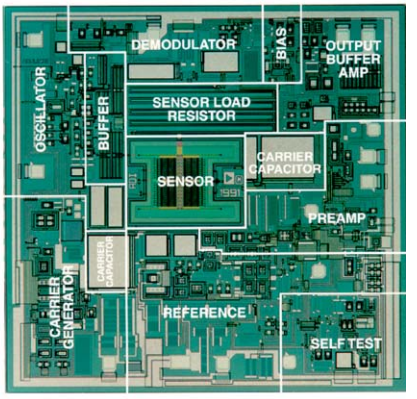
Capacitive sensing of displacement of a polysilicon structure was developed and introduced by Motorola in the early 1990s (Ristic *et al.* 1992). The Motorola structure used a multilayer polysilicon and a silicon-capped G-Cell (**Figure 5**) that was then packaged with electronics. Bulk micromachined capacitive accelerometers were also developed in the early 1990s by Centre Suisse d'Electronique et de Microtechnique SA (CSEM, Rudolf and Bergqvist 1991), Litton (Warren 1996), Applied MEMS in late 1990s, and the University of Michigan (Najafi *et al.* 2003), among many others.

The metal-plated accelerometer design created by Silicon Designs Inc. in the early 1980s used an off-center mechanical mass and a torsion spring to sense differential capacitance and therefore acceleration (Cole 1991). This design was then converted to a polysilicon mechanical structure by Ford and manufactured for a limited time in automotive airbag applications (Kemp and Spangler 1995). Capacitive designs have been a popular approach to accelerometers due to the low-temperature coefficient of the measurement as compared to piezoresistive designs and because of the opportunity to use an electrostatic voltage on the capacitive plates to perform a self-test.

Automotive airbag applications have fueled the demand for very large volumes of low-cost and high-reliability accelerometers. The initial application replaced a mechanical switch that could detect a negative acceleration and inflate an airbag. The accelerometer provided more information at a significantly reduced price and could be used in all systems and vehicles by a software change in the electronics. With the addition of airbags throughout the car, such as variable inflate passenger and side impact airbags, additional accelerometers per vehicle have been required. This has continued to fuel the demand for accelerometers with growth rates of over 20% per year for over a decade. In recent years, the use of accelerometers to control vehicle stability and



Analog Devices' ADXL-50, the industry's first surface micromachined accelerometer, includes on-chip signal conditioning.

Figure 4 Photo of ADXL50.

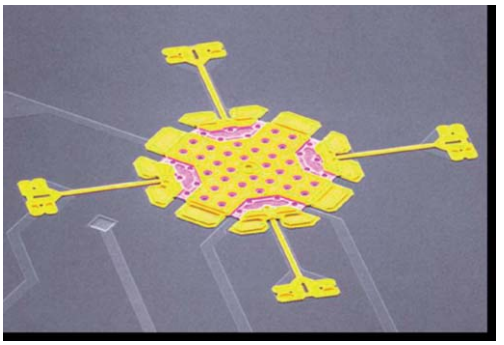


Figure 5 Die photo of a Motorola G-Cell.

rollover has added to the demand, especially in the low-gee range of 1–2 gees (also *g*). Companies such as VTI, LETI, Bosch, Denso, and ADI have supplied low-range accelerometers in adaptive braking and vehicle stability applications.

With the introduction of low-gee accelerometers for automotive applications, a wide range of applications in the consumer field have emerged. Accelerometers that can measure tilt and motion have been used in wireless mouse applications for interface to computers and video games. Sports applications such as golfing, tennis, or baseball have used accelerometers to analyze and coach players. A popular application for laptop computers has been to protect the data and disk drive due to mechanical shock. With the availability of three-axis accelerometers and prices less than $2, the feasibility of adding motion sensing to a wide range of hand-held devices has occurred. Cell phones, with the ability to recognize gestures and perform situation analysis for improved display orientation and battery life, promise to provide a market demand in excess of 700 million devices per year. When combined with automotive and other applications, the world market for accelerometers is expected to grow to over 1 billion devices.

In the remaining part of this chapter, we will introduce basic accelerometer concepts in Section 2.05.2 and examine various acceleration sensing mechanisms in Section 2.05.3. Some representative examples of accelerometer fabrication are presented in Section 2.05.4. Then the design considerations, packaging issues, and application considerations are discussed in Section 2.05.5, 2.05.6, and 2.05.7, respectively. Summary and future trends are given in Section 2.05.8.

2.05.2 Basic Accelerometer Concepts

Acceleration is the change in velocity for a given time period. If we confine our discussions to rectilinear motion, then a mass moving in a straight line has increasing acceleration with increasing velocity, described as scalar with a positive sign, and if the velocity is decreasing, the acceleration value is negative. Acceleration can be positive in either direction along the straight line of travel as it is dependent on the change in velocity. The most common error in acceleration measurement is sign. To ensure a good transferable convention, the earth's gravitational field is used and direction is then applied to give a positive acceleration when a reference arrow on the accelerometer or outline drawing is noted in relation to the

earth and the electrical output is referenced to ground.

To understand accelerometer operation, we first start with some of the basic building blocks of mechanics. Newton's second law of motion describes a relationship between force, mass, and acceleration. Specifically, this is $F = ma$, where F is the force, m is the mass, and a is the acceleration. This makes it possible to determine acceleration by measurement of the force on a given mass. A mass at the earth's surface has an acceleration of 9.8 m s^{-2} or 1 g if left to free fall. The change in velocity as a function of time of a mass is acceleration and as per Newton's second law would require a force to create such a velocity change. MEMS accelerometers are devices that determine the force required to create a velocity change. By keeping the mass constant and accelerating the frame, as illustrated in **Figure 6**, the spring, which connects the frame to the mass, is acted upon by the force due to acceleration and changes length. The mass is often called proof mass or seismic mass. The spring can either extend or contract as a result of positive or negative acceleration.

To measure force, it is common to use a spring that has a linear displacement with the force, or $F = kx$, where k is the ratio of force to displacement and is called the spring constant. The measurement of the proof mass displacement in relation to the frame thus becomes a direct indication of acceleration. Because we are referring to changes as a function of time, the dynamic or time-dependent aspects of the force measurement are also important considerations. When there is no drag force to oppose the acceleration force, displacement occurs in direct proportion to the acceleration. When the velocity and the direction are reversed, inertia creates an overtravel in the displacement and adds force to the spring in opposition to the force due to acceleration. If this motion continues in a harmonic fashion with an oscillation frequency that adds force in opposition to the acceleration and no damping or drag forces occur, displacement in excess of the acceleration force will result around the natural resonant frequency of the spring–mass system. The displacement at the natural frequency is maximized 90° out of phase with the frame acceleration. However, spring–mass systems in most accelerometer configurations have drag and viscous forces that act upon the moving mass and therefore dampen the oscillations. These damping forces can create nonlinear displacements with frequency and make it imperative that bandwidth and usable frequency ranges be considered.

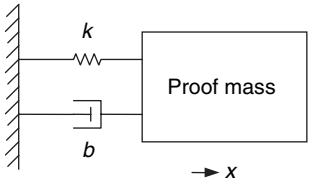

Figure 6 Spring–mass system.

The governing equation for the spring–mass system is readily given by

$$m\frac{d^2x}{dt^2} + b\frac{dx}{dt} + kx = ma \qquad [1]$$

which results in the transfer function of the system,

$$H(s) = \frac{X(s)}{A(s)} = \frac{1}{s^2 + (b/m)s + (k/m)} = \frac{1}{s^2 + (\omega_0/Q)s + \omega_0^2} \qquad [2]$$

where b is the damping coefficient of the proof mass, ω_0 is the resonant frequency defined by $\omega_0 = \sqrt{k/m}$, and Q is the quality factor defined by $Q = (m\omega_0/b)$. For accelerometers working at a frequency much lower than the resonant frequency, the mechanical sensitivity can be obtained by setting $s = 0$ in the denominator in eqn [2], which yields

$$\frac{x}{a} = \frac{m}{k} = \frac{1}{\omega_0^2} \qquad [3]$$

It is interesting to note that the mechanical sensitivity is inversely proportional to the square of the resonant frequency. This represents a fundamental design trade-off between sensitivity and bandwidth. Thermomechanical (Brownian) noise limits the ultimate achievable resolution. The Brownian noise spectral density, referred to the input acceleration, is given by

$$\sqrt{\frac{a_n^2}{\Delta f}} = \frac{\sqrt{4k_B Tb}}{m} \qquad [4]$$

where a_n is the Brownian equivalent acceleration noise, Δf is the bandwidth of the system, which is usually set by the interface circuit, k_B is the Boltzmann's constant, and T is the absolute temperature in Kelvin. The unit is m s^{-2} Hz$^{-1/2}$ or g Hz$^{-1/2}$.

The natural resonances of MEMS accelerometers are in the range of 100 Hz to 20 kHz, and can vary from underdamped with Qs of 100 or more to overdamped with Qs below 1. **Figure 7** shows the schematic of a system for testing accelerometers. The accelerometer housing is connected through a

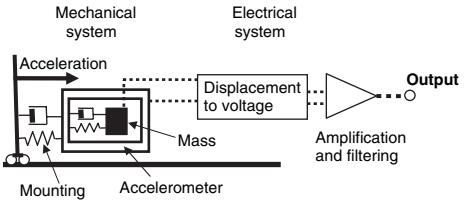

Figure 7 Schematic of an acceleration measuring system.

mounting structure to the module or assembly. As this mounting can create a spring–mass system with additional resonance and damping characteristics, the mechanical input and the accelerometer's indicated acceleration can be different. The accelerometer has a mechanical spring–mass and damper configuration, which also establishes a transfer function from the case or package to the moving mass. The displacement of the mass in relation to the accelerometer frame or housing is detected and converted to an electrical signal in several different ways, the most common being a piezoresistive bridge, a capacitive measurement, or a piezoelectric charge across a capacitor. There are advantages and error terms associated with each method, as will be discussed in Section 2.05.3. The voltage derived from the displacement transduction is then signal conditioned through amplification and filtering and perhaps digital conversion. The electrical signal transfer function is influenced by temperature, power supply changes, electrical noise, frequency, and load characteristics.

2.05.3 Acceleration Sensing Mechanisms

2.05.3.1 Piezoresistive Accelerometers

The resistance R of certain kinds of resistors changes with an applied mechanical load. This behavior is called the piezoresistive effect and can be expressed as

$$\frac{\mathrm{d}R}{R} = (1 + 2\nu)\varepsilon + \frac{\mathrm{d}\rho}{\rho} \qquad [5]$$

where ν is the Poisson's ratio, ε is the strain, and ρ is the resistivity. Note that there are two terms on the right-hand side of eqn [5]. The first term represents the resistance change due to geometry, while the second term is due to stress-induced resistivity change. The stress-induced resistivity is negligible for metals but is very large in semiconductors such as silicon. For a more convenient comparison of different materials, normalized resistance change, or GF, is normally used and it is readily obtained from eqn [5] as

$$\mathrm{GF} = \frac{\mathrm{d}R/R}{\varepsilon} = (1 + 2\upsilon) + \frac{\mathrm{d}\rho/\rho}{\varepsilon} \qquad [6]$$

GF is about 2 for metals as the Poisson's ratio of most metals is about 0.35. Semiconductors have much higher GF as the second term in eqn [6] for semiconductors is on the order of 100. Silicon is the main material for making piezoresistive accelerometers. The GF of silicon is strongly dependent on the doping level. Lower doping concentration yields higher sensitivity. However, devices with higher doping concentration are less sensitive to temperature change. Thus, the doping concentration must be carefully chosen. Detailed discussion can be found in Madou (2002).

In its simplest form, a piezoresistive accelerometer comprises a cantilever beam with a proof mass attached to it, as shown in **Figure 8(a)**. Because the resistance change of a piezoresistor increases with increasing stress, the piezoresistor is typically placed at the anchor edge of the cantilever beam where the stress is maximum. Both in-plane (lateral-axis) and out-of-plane (z-axis) acceleration sensing can be realized. Differential bridges can be formed for lateral-axis sensing either by using a T-shaped cantilever beam (**Figure 8(b)**) (Chen *et al.* 1997) or by forming piezoresistors on the sidewalls of a cantilever beam using a sidewall ion implantation (**Figure 8(c)**) (Partridge *et al.* 2000). When the beam bends laterally, the two piezoresistors on the sidewalls will experience stresses with opposite signs, and thus one piezoresistor's resistance decreases while the other's increases. Lateral acceleration sensing was also demonstrated by using a (110) wafer for obtaining wet-etched vertical sidewalls (Suminto 1991). z-Axis acceleration sensing typically requires a reference resistor fixed on the substrate because it is difficult to form a symmetric diffusion layer on the underside of cantilever beams.

Due to the vector nature of acceleration, measuring acceleration in all the three axes is often required. To assemble three single-axis accelerometers will drastically increase the packaging size and cost. Therefore, many efforts have been devoted to developing monolithic three-axis (or triaxial) piezoresistive accelerometers (Amarasinghe *et al.* 2007, Chaehoi *et al.* 2005, Kruglick *et al.* 1998, Kwon and Park 1997, Kyung Il *et al.* 2003, Plaza *et al.*

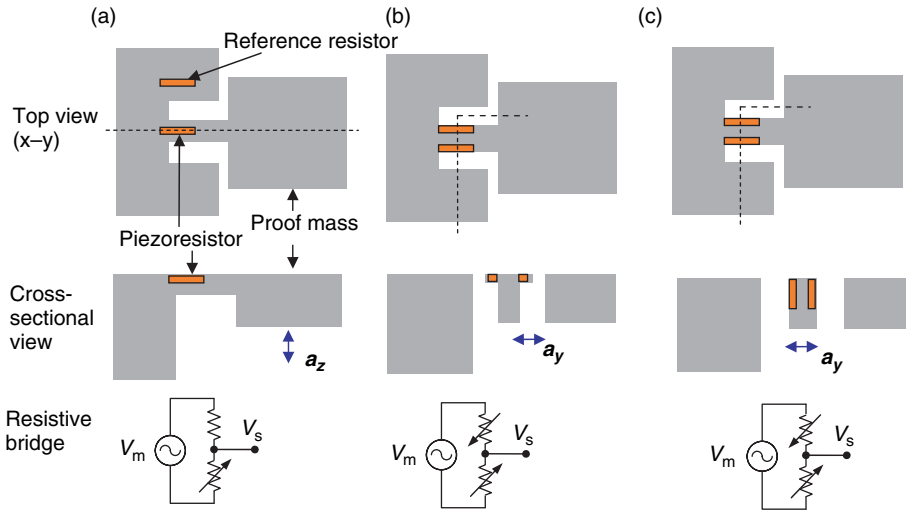

Figure 8 Schematics of piezoresistive sensing. (a) Out-of-plane (*z*-axis) sensing with a quarter bridge. (b) In-plane (lateral-axis) sensing with a half-bridge where the piezoresistors are formed from the frontside diffusion. (c) In-plane (lateral-axis) sensing with a half-bridge where the piezoresistors are formed on the sidewalls by inclined ion implantation.

1998, Rdjegrd *et al.* 2005, Takao *et al.* 1995). The challenge to fabricate three-axis piezoresistive accelerometers has been the lateral-axis sensing. A commonly used three-axis piezoresistive accelerometer design employs a frame mass suspended by four symmetric beams, which are connected to the center anchor, as shown in **Figure 9**. The five piezoresistors are connected in series and driven by a constant current source. The center piezoresistor (R5) is used as a reference resistor to eliminate the thermal drift of the piezoresistors. For an *x*-axis acceleration, R1 and R3 change their values oppositely while R2 and R4 change with the same value and sign. Thus, the *x*-axis acceleration can be detected by the differential output of R1 and R3. Similarly the *y*-axis acceleration can be obtained by the differential of R2 and R4. The sum of all four piezoresistors results in the *z*-axis acceleration. This design employs a simple structure and a straightforward fabrication process. However, the lateral-axis sensitivity is much lower than the *z*-axis sensitivity, and DC offsets are also large.

Another solution to the lateral-axis sensing is to make piezoresistive structures aligned vertically with respect to the substrate. Kruglick *et al.* (1998) reported a three-axis piezoresistive accelerometer with thin-film structures that were bent up out of plane. As shown in **Figure 10**, the out-of-plane structures are used to detect *x*- and *y*-axis acceleration. The piezoresistors are located at the hinges of the bent-up

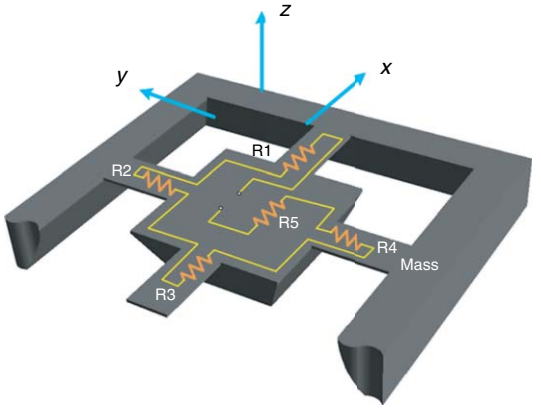

Figure 9 Schematic view of a bulk micromachined piezoresistive three-axis accelerometer.

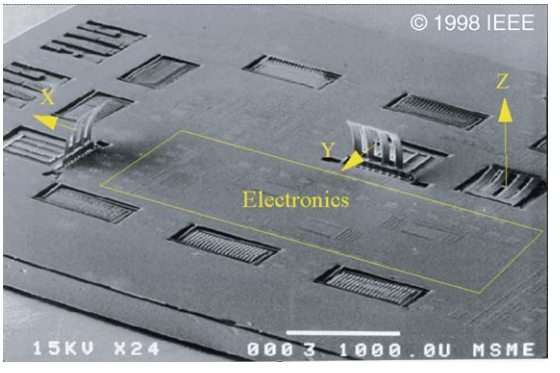

Figure 10 Scanning electron micrograph (SEM) of a surface-micromachined piezoresistive three-axis complementary metal oxide semiconductor (CMOS) accelerometer.

structures. This accelerometer was integrated with CMOS circuits. However, the extra assembly step, low GF of polysilicon, robustness, and temperature stability are still concerns.

The advantages of piezoresistive accelerometers include the simplicity of structural design and readout circuitry due to the low impedance at the sensor output. Their fabrication processes are also relatively simple. A bulk micromachined accelerometer can be made in two steps: one backside aqueous KOH etch to form thin sensing beams and then a frontside KOH etch to release the proof mass. After that, a top cover and a bottom cover are bonded to seal the accelerometer. The covers provide overload stops and damping control. The packaging process can also be simplified by using an integrated overload stop (Barth *et al.* 1988).

One of the key process issues for bulk micromachined piezoresistive accelerometers is the etch stop that controls the thickness of the sensing beam. A simple timed etch often yields poor thickness control. Electrochemical stop and p+ doping provide automatic etch stop but require extra steps. Another possible etch stop is a buried oxide (BOX) layer. Plaza *et al.* (2002) used silicon-on-insulator (SOI) wafers to achieve automatic etch stop and overrange protection as well. The cross-sectional view of the device is shown in **Figure 11**.

Because the main process step for making bulk piezoresistive accelerometers is wet silicon etching, the major obstacle to integrate piezoresistive accelerometers is the protection of ICs during this step. Many researchers have demonstrated integrated piezoresistive accelerometers, and most of them are foundry CMOS compatible (Chaehoi *et al.* 2003, 2005, Kruglick *et al.* 1998, Riethmuller *et al.* 1991, Seidel *et al.* 1995, Shi *et al.* 2004). Furthermore, deep reactive ion etch (DRIE) of silicon has also been used to fabricate piezoresistive accelerometers (Huang *et al.* 2003). This dry etch technique is more expensive than wet etching, but it greatly simplifies the integration process. A desirable attribute of piezoresistive accelerometers is that the output impedance of a piezoresistive sensor node is low ($\sim$kΩ) compared to that in capacitive sensing approaches. Thus, chip-to-chip wire bonding does not attenuate the sensing signal significantly. Therefore, two-chip or hybrid packaging is a more viable approach for micromachined piezoresistive accelerometers.

2.05.3.2 Piezoelectric Accelerometers

Piezoelectricity is the ability of some materials to create an internal polarization in response to strain. In other words, when a force or stress is applied to a piezoelectric material, a voltage is generated, which is a measure of the force or stress. The piezoelectric effect is reversible in that piezoelectric crystals, when subjected to an externally applied voltage, will produce a strain, i.e., can be used as actuators. This is extremely useful in the case of resonant accelerometers where both actuation and sensing are required in a single device. There are three basic classes of piezoelectric materials used in microfabrication: piezoelectric crystals such as quartz, lithium niobate, and gallium phosphate; thin-film piezoelectrics, such as zinc oxide, aluminum nitride, and lead zirconate titanate (PZT); and polymer-film piezoelectrics, such as polyvinylidene fluoride (PVDF). Note that piezoelectrics in general are not suitable for quasi-static sensing of strain because of the parasitic effects of small DC leakage currents, but they are highly effective for sensing of vibratory or resonant motions.

A basic piezoelectric cell is sketched in **Figure 12**. The piezoelectric effect can be expressed as

$$q = d_{33}F \qquad [7]$$

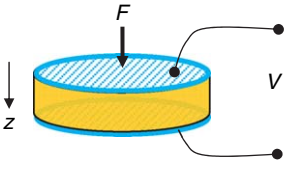

Figure 12 Piezoelectric effect.

where q is the total charge, d_{33} is the piezoelectric charge constant in units of $C\,N^{-1}$ (d_{33} refers to the case where both induced polarization and applied stress are in direction 3 or z), and F is the external force. The output voltage is then given by

$$V = \frac{q}{C} = \frac{d_{33}F}{C} \qquad [8]$$

where C is the sensing capacitance formed by the piezoelectric layer. According to this equation, a small capacitance will yield high sensitivity. However, small sensing capacitance also has a large impedance, which in turn reduces the signal in the presence of parasitic interconnect capacitance. Thus the placement of the electrodes and the piezoelectric material must be carefully considered. The design goal is to maximize C and q/C at the same time. One good practice is to place the electrodes around the maximum stress region(s).

A basic piezoelectric accelerometer design is illustrated in **Figure 13**. It is essentially a sandwiched structure with the piezoelectric layer in the middle and two conducting layers on the top and bottom, respectively. As discussed above, the upper electrode only covers the near-anchor portion of the cantilever beam where the stress is maximal. The piezoelectric layer can be either surrounded by dielectrics (**Figure 13(b)**) or directly in contact with the electrodes (**Figure 13(c)**). The dielectric isolation can significantly reduce the leakage current and improve the quasi-static response performance (Chen *et al.* 1982). However, adding the isolation layer also increases process complexity and reduces the sensitivity.

Similar to three-axis piezoresistive accelerometers, monolithic three-axis piezoelectric accelerometers can also be realized using a single microstructure (Okada 1995, Zou *et al.* 2004). One of the many possible designs is shown in **Figure 14**. The center proof mass is connected to the substrate via four symmetric beams. When there is a z-axis acceleration, the proof mass produces tensile stresses in the top halves of the bimorph beams (i.e., x_1, x_2, y_1, and y_2), and compressive stresses in z_1–z_4. Thus, the sum of z_1 to $-z_4$ measures the z-axis acceleration. The differential components x_1-x_2 and y_1-y_2 are zero. When there is an x-axis acceleration, the proof mass rotates around the y-axis (**Figure 14(b)**) and produces tensile stresses in x_1 and z_3 and compressive stresses in z_1 and x_2. It also produces shear stresses in y_1, y_2, z_2, and z_4, which can be neglected. Thus, an x-axis acceleration produces a signal from the differential of x_1 and x_2. The differential of y_1 and y_2 and the sum of z_1 to z_4 are both zero because the stresses in y_1 and y_2 have the same amplitude and sign while z_1 and z_3 have the same amplitude but opposite signs. The same principle applies to the y-direction.

Among various piezoelectric materials, quartz is preferred because of its high-temperature stability and high quality factor. High-performance, wide-bandwidth quartz piezoelectric accelerometer products are manufactured by many companies such as Kistler, Endevco, and Honeywell. Resonating beams are typically used for quartz accelerometers due to the high quality factor, which will be further discussed in Section 2.05.3.7.

ZnO and PZT are two other main materials for piezoelectric accelerometers. Because these materials can be deposited as thin films, surface micromachining as well as bulk micromachining can be used. **Figure 15** shows two surface micromachining processes that use oxide and silicon substrate,

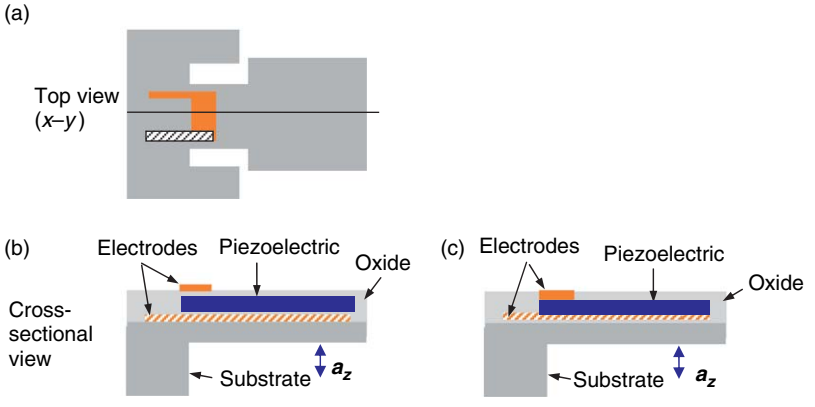

Figure 13 A typical z-axis piezoelectric accelerometer structure.

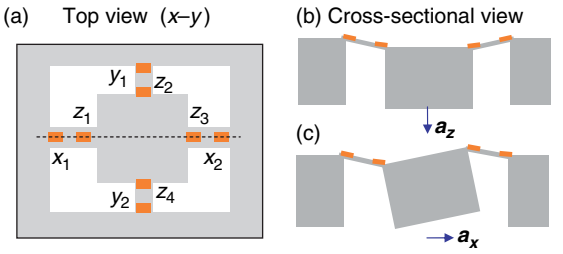

Figure 14 Schematic of three-axis piezoelectric accelerometer made with a single proof mass.

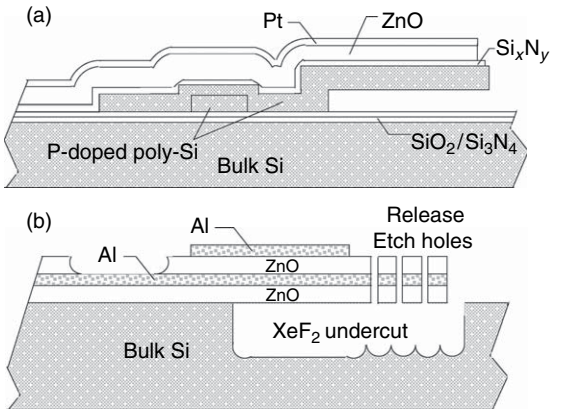

Figure 15 Cross-sections of cantilever structures formed in two processes based on (a) sacrificial oxide and (b) sacrificial silicon fabrication. (Source: Devoe D L, Pisano A P 2001 Surface micromachined piezoelectric accelerometers (PiXLs). *J. Microelectromech. Syst.* **10**, 180–6.)

respectively, as the sacrificial layer (Devoe and Pisano 2001). A sensitivity of 45 fC g^{-1} was demonstrated. Wang *et al.* (2002) used bulk micromachining to suspend a bulk silicon proof mass on a thick-film PZT annular diaphragm. The sensitivity was about 1–7 pC g^{-1}. In addition, ZnO can be deposited using magnetron sputtering at low temperature, so ZnO-based piezoelectric accelerometers can be made CMOS compatible (Chen *et al.* 1982). Furthermore, PVDF has also been used to make piezoelectric accelerometers (Benech *et al.* 1996, Marcal *et al.* 1997, Toda and Thompson 2006).

2.05.3.3 Capacitive Accelerometers

Capacitive accelerometers are dominating the automotive and consumer electronics markets due to their high sensitivity, good temperature performance, low fabrication cost, small size, and easy integration with CMOS. Capacitive displacement sensing structures are very simple. They basically are a pair of electrodes with one of them movable. The two most commonly used electrodes are parallel plates and interdigitated comb fingers. In microfabrication, the lateral (in-plane) dimensions can be easily made large (up to a few tens of millimeters), but the vertical (out-of-plane) dimensions are typically restricted to a few microns. Thus, parallel plate electrodes are normally used for vertical acceleration sensing while comb-finger electrodes are suitable for lateral acceleration sensing.

Figure 16 shows the basic configurations for capacitive displacement sensing with horizontal plates. The suspended plate can move either vertically (**Figure 16(a)** and **16(b)**) or laterally (**Figure 16(c)**). The configuration with a fully differential bridge (**Figure 16(b)**) is always preferred for DC offset and temperature variation cancellation. However, the configuration with a fixed reference capacitance is much easier to implement.

Figure 17 shows the configurations for capacitive displacement sensing with comb fingers. The configuration in **Figure 17(a)** is typically used for lateral displacement sensing. The three comb fingers form two capacitors C_1 and C_2. Each capacitance includes a sidewall parallel plate capacitance and a fringing capacitance. The middle finger is movable and often called a rotor. When the rotor moves along the x-direction, C_1 decreases while C_2 increases, resulting in a fully differential capacitive half-bridge, as shown in **Figure 17(b)**.

$$V_s = \frac{C_1 - C_2}{C_1 + C_2 + C_P} V_m \qquad [9]$$

where C_P is the parasitic capacitance. The parasitic capacitance attenuates the signal and should be minimized.

The configuration illustrated in **Figure 17(c)** is used for z-axis displacement sensing. The comb fingers consist of multiple conductor layers. When all the conductor layers are electrically connected, it becomes similar to what is shown in **Figure 17(a)**. Note that the conductor layers are separated by dielectrics and thus can be connected in many ways. **Figure 17(c)** is one of the wiring configurations, where the middle finger (rotor) has two electrodes and the stationary fingers (stators) have a single electrode each. With this wiring, similar to that shown in **Figure 17(a)**, two capacitors C_1 and C_2 are formed. The difference is that the capacitors in **Figure 17(c)** add up the capacitances on both sides of the rotor. Thus, a small gap variation in the lateral direction

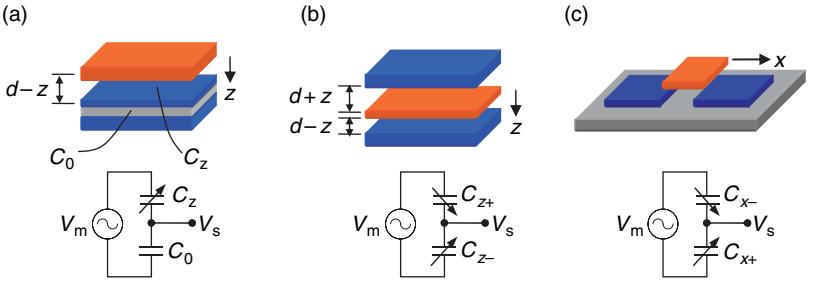

Figure 16 Basic capacitive displacement sensing configurations with horizontal plates. (a) Half differential capacitive bridge where a reference capacitor is embedded on the substrate. (b) Fully differential capacitive bridge where the movable plate is suspended in between two fixed plates. (c) A movable plate is suspended over two separate electrodes.

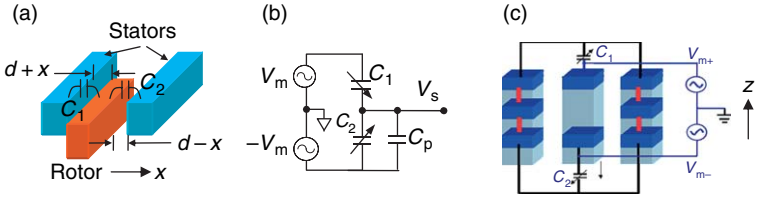

Figure 17 Basic capacitive displacement sensing configurations based on the sidewall capacitance of comb fingers.

will not change C_1 and C_2, which means that the device is insensitive to lateral acceleration. However, C_1 and C_2 are formed by splitting the sidewall capacitance into two parts vertically. When the rotor moves in the z-direction, as shown in Figure 17(c), C_1 decreases while C_2 increases, resulting in a differential output. One may notice that C_1 and C_2 are not equal at the original position. This initial capacitance difference will generate a large DC offset. This problem can be solved by using two sets of comb fingers and swapping the rotor and stator of the second set (Xie and Fedder 2002).

MEMS capacitive accelerometers can be categorized into three types: thin-film accelerometers fabricated using surface micromachining; bulk accelerometers fabricated using bulk micromachining and/or wafer bonding technology; and other accelerometers fabricated using combined surface and bulk micromachining processes. Surface micromachined accelerometers have been commercialized for more than 10 years (Cournar *et al.* 2004). Due to its good mechanical properties and mature deposition process, polysilicon has been the major structural material for surface micromachined accelerometers. Researchers from UC-Berkeley have demonstrated several generations of single- and three-axis capacitive accelerometers with noise floors on the order of 1 milli-$g\,\mathrm{Hz}^{-1/2}$ (Boser and Howe 1996, Lemkin and Boser 1999, Lemkin *et al.* 1997, Lu *et al.* 1995). The commercial accelerometers from ADI, Bosch, Motorola, Freescale, and ST Microelectronics (ST) are all based on thin-film or thick-film polysilicon. An alternative material is multilayer aluminum/oxide composite. Carnegie Mellon University developed a maskless, post-CMOS micromachining process that is foundry CMOS compatible (Fedder *et al.* 1996). This process has been used to demonstrate both lateral- and vertical-axis accelerometers (Luo *et al.* 2000, Xie and Fedder 2000, Zhang *et al.* 1999). One of the advantages of the multilayer composite is its capability to realize differential capacitive comb-finger displacement sensing in both lateral and vertical directions (Xie and Fedder 2002). The main drawbacks include the curling and poor temperature performance. Due to their thickness and size limitations, surface micromachined accelerometers normally can only achieve noise floors of 0.1–1 milli-$g\,\mathrm{Hz}^{-1/2}$. Another promising material is polycrystalline silicon germanium (poly-SiGe). Due to its low deposition temperature, poly-SiGe can be integrated with CMOS (Franke *et al.* 2003).

In contrast, most bulk micromachined capacitive accelerometers can reach micro-g or even submicro-g resolutions. For example, researchers from the University of Michigan have developed several innovative bulk micromachining processes and demonstrated many high-performance capacitive accelerometers (Chae *et al.* 2002, 2004, Selvakumar

et al. 1996, Yazdi and Najafi 1997, Yazdi *et al.* 1999). There are numerous other bulk micromachined capacitive accelerometers. Some of them are listed in **Table 1**. Most of the device fabrications employ wafer bonding and wet etching for obtaining large proof mass. SOI substrate is also becoming more popular, but the fabrication cost especially for CMOS integration is still high.

Other interesting capacitive accelerometers such as electrostatically elevated spherical accelerometers were also reported (Qu 1999, Takeda 2000, Toda *et al.* 2002). These technologies require special processes and equipment, which are currently too expensive for commercialization. To take the advantages of the large proof mass of bulk silicon structures and the readout circuitry integration of surface micromachining processes, a DRIE CMOS-MEMS process has been developed at Carnegie Mellon University (Xie *et al.* 2002). It is a maskless post-CMOS process that can create thick SCS structures using only dry etch steps. The process was further improved at the University of Florida and a three-axis capacitive accelerometer with a lateral-axis noise floor of 12 micro-$g\,\mathrm{Hz}^{-1/2}$ was demonstrated (Qu *et al.* 2006).

The resolution versus device size of capacitive accelerometers for different technological approaches is illustrated in **Figure 18**. The thin-film surface micromachined devices will continue dominating the low- to medium-end markets while the higher-resolution but more expensive bulk micromachined devices will find niche applications in high-end markets such as defense, space, security, and harsh environment. The DRIE CMOS-MEMS technology has the potential to achieve high resolutions at small form factors.

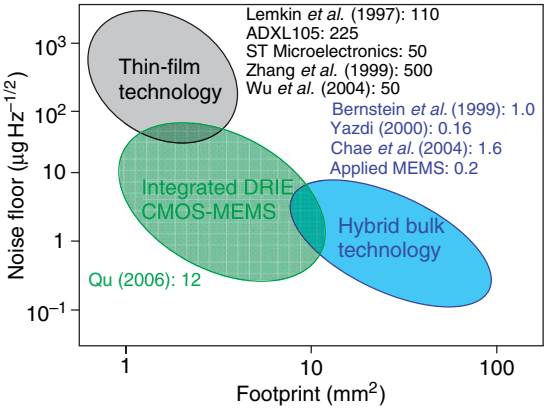

Figure 18 Capacitive accelerometers: resolution performance versus device size with different technological approaches. Noise values associated with representative references are given in units of μg $\mathrm{Hz}^{-1/2}$. (Source: Qu H 2006 Development of DRIE CMOS-MEMS process and integrated accelerometers. University of Florida.)

2.05.3.4 Thermal Accelerometers

Thermal equilibrium of a system will be disturbed if there exists a forced fluidic flow or a moving part due

to an external acceleration. The temperature change at a fixed point of the disturbed system is a measure of the acceleration. There are basically two ways to measure acceleration thermally:

(1) To utilize a moving mass to change the heat transfer due to conduction and
(2) To use the natural convection of gas or mixed liquid/gas in a sealed chamber

We discuss each of the approaches below.

2.05.3.4.1 Thermal accelerometers based on conduction heat transfer

Hiratsuka *et al.* (1991) proposed the first micromachined thermal accelerometer and demonstrated the concept of using a thermopile and an integrated heater to measure small displacements of a proof mass. One of the advantages of thermal accelerometers is their immunity to electromagnetic interferences (EMIs). The working principle is illustrated in **Figure 19**. The device consists of a heated plate sandwiched by two heat sinks. The heat of the hot plate can be transferred through radiation, convection, and conduction. However, the gap between the hot plate and the heat sink is very small (in a few microns or less), so the convection can be neglected. In addition, as the temperature change is small, radiation is also negligible. Therefore, the conduction dominates. In this case, the heat flux transferred from the hot plate to the heat sinks is inversely proportional to the gap. In other words, the temperature change is proportional to the gap change. Hence, if one of the plates is connected to a proof mass, then the acceleration will be linearly proportional to the temperature change of the hot plate, which is typically measured by a thermopile. This type of thermal accelerometers has two possible implementations: one is to use the hot plate as the proof mass and the other is to use the sink as the proof mass.

Dauderstadt *et al.* demonstrated a thermal accelerometer using the top heat sink as the proof mass.

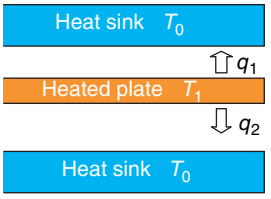

Figure 19 Cross section of a thermal accelerometer showing the concept of using conductive heat transfer to measure small displacements.

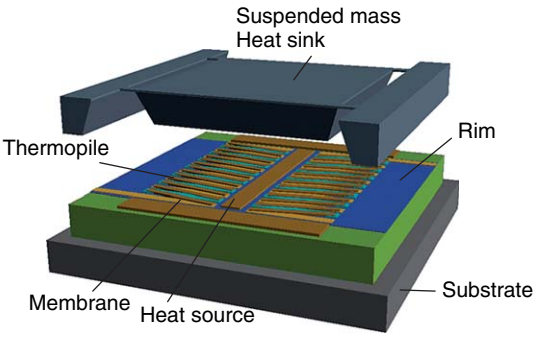

Figure 20 A conduction-based thermal accelerometer. (Source: Dauderstadt U A, de Vries P H S, Hiratsuka R, Sarro P M 1995 Silicon accelerometer based on thermopiles. *Sens. Actuators A Phys* **46**, 201–4.)

The device design is illustrated in **Figure 20**. It consists of two chips that are bonded together. The proof mass is formed in the top chip by KOH etching and p–n junction electrochemical etch stop. The suspension beams of the proof mass are etched using a reactive ion etching (RIE) step from the frontside of the wafer. Polysilicon–aluminum thermopiles are used to measure the temperature. The thermopiles are fabricated on the lower chip with a silicon nitride layer for thermal isolation. A KOH etch step is used to remove the silicon below the silicon nitride. In this way the heat conduction from the heat source to the substrate can be minimized. The polysilicon is also used to form the heater. The polysilicon–aluminum thermocouples have a relatively large Seebeck coefficient of about 0.2–0.4 mV K^{-1}. The tested sensitivity of the accelerometer is 20 mV g^{-1}. The accelerometer works at frequencies up to 300 Hz and has a temperature coefficient of -0.12% K^{-1} (Dauderstadt *et al.* 1998).

2.05.3.4.2 Thermal accelerometers based on convective heat transfer

Different from the conduction-based thermal accelerometers, convection-based thermal accelerometers do not need a solid proof mass and they have no moving mechanical structures. So convective thermal accelerometers are robust and can stand high shock. Convective thermal accelerometers come in two types: one uses only gas while the other has a liquid-filled chamber. We discuss the gas type first.

Dao *et al.* (1996) proposed an idea in which the temperature change due to convective heat transfer of gas in a sealed chamber is used to measure acceleration. Leung *et al.* (1998) demonstrated the first micromachined convective thermal accelerometer

in 1998. The device structure is illustrated in **Figure 21(a)**. It consists of three resistor strips on a silicon substrate. The silicon under the resistors is removed to provide good thermal isolation. The resistor on the center strip is used as a heater. When the heater is on, the density of the air surrounding it becomes smaller and there is a temperature gradient from the heater to either of the side strips. The resistors embedded in the two side strips are used as temperature sensors and form a half-bridge to output a differential voltage. When there is no acceleration, the heater produces a symmetrical temperature distribution (the solid lines in **Figure 21(b)**). Thus the differential output is zero. When an external acceleration is applied, the symmetry is disturbed as illustrated by the dashed lines in the same figure. The resulting temperature difference is picked up by the differential resistor bridge, which produces an output corresponding to the applied acceleration.

The device fabrication is straightforward. The heater and temperature sensors are made of a polysilicon layer, which is sandwiched by two oxide layers. The bonding pads are formed by electroplating gold. The final step is to etch the cavity using ethylene diamine pyrocatechol (EDP). After the microfabrication is finished, the device is packaged in a sealed chamber to prevent external air flow from disturbing the device operation.

The prototype reported in Leung *et al.* (1998) had a chip size of 3 mm × 5 mm. The temperature coefficient of resistivity of the polysilicon was measured as $\sim 0.2\%\ ^{\circ}C^{-1}$. The measured noise level was 0.5 milli-*g* rms at a heater power of 20 mW. It was found that the sensitivity was linearly proportional to the heater power. It was also found that the sensitivity was proportional to the square of the chamber pressure. This implies that the same device can be made 100 times more sensitive simply by packaging it into a chamber with a 10 times higher pressure. But it also puts stringent requirements on the packaging for long-term pressure control. The frequency range for the prototype device was from DC to 20 Hz.

The fabrication of convective thermal accelerometers can be made IC compatible. Milanovic *et al.* (2000) successfully fabricated such accelerometers in a 2 μm CMOS process plus one additional maskless post-CMOS micromachining process. There are some new developments in the past few years. For example, non-polysilicon heater/temperature sensing materials such as platinum have been investigated (Mailly *et al.* 2003). Porous silicon instead of a cavity has also been used to achieve good thermal isolation (Goustouridis *et al.* 2004). Furthermore, a liquid-filled thermal accelerometer with a thermally generated bubble was reported (Liao *et al.* 2006). The noise equivalent acceleration was found to be 1 mg rms. The measured response time was approximately 60 ms. This liquid-filled type has the potential to achieve faster response time but may consume more power.

The commercialization of convective thermal accelerometers is very successful. MEMSIC Inc. licensed the convective thermal accelerometer technology and has developed a series of monolithically

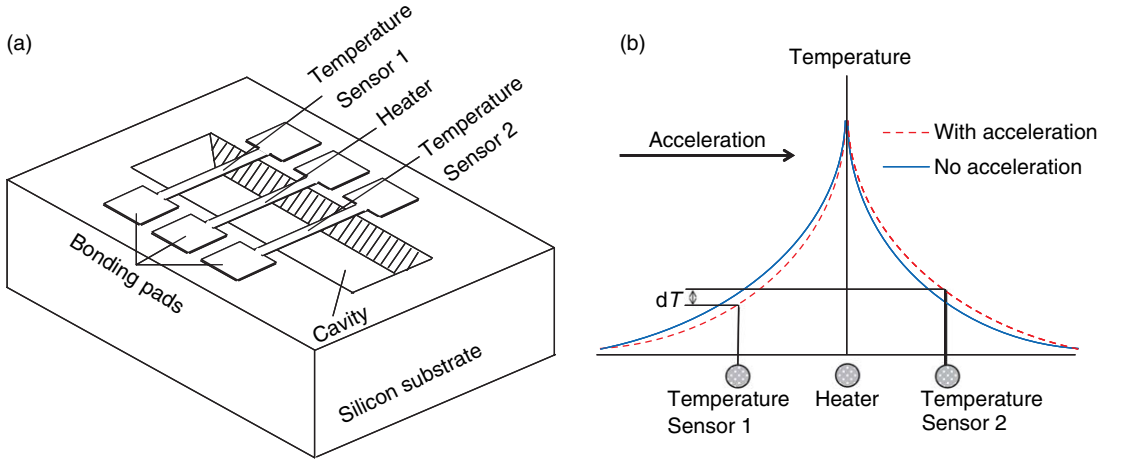

Figure 21 Device structure of the thermal accelerometer. (Source: Leung A M, Jones J, Czyzewska E, Chen J, Woods B 1998 Micromachined accelerometer based on convection heat transfer. *Proc. 11th IEEE Int. Workshop Micro Electro Mechanical Systems (MEMS '98)*.)

integrated accelerometers based on a standard IC process. **Figure 22** is a die photo of a MEMSIC's two-axis accelerometer. The high integration, small form factor, and low cost have made these products very competitive in consumer and electronics markets for low-bandwidth applications.

2.05.3.5 Optical Accelerometers

Optical sensors are known for their immunity to EMI, safety, and low cost. If optical fiber based, they also have low transmission loss, inherent multiplexing capability, and potential high resolution. Fiberoptic accelerometers have been demonstrated in the 1980s without using MEMS technology (Rines 1981, Spillman 1982). Resolutions of about 1 μg were achieved using a tilting mirror (Soref and McMahon 1984) or fiber microbending effect (Freal *et al.* 1987). However, these devices are bulky. It was not until the mid-1990s when research activities on micromachined optical accelerometers started to grow (e.g., Marty *et al.* 1995). Just like other optical sensors, optical accelerometers can be divided into two categories: one is intensity based and the other is interferometry based. We discuss micromachined optical accelerometers separately in each category.

2.05.3.5.1 Optical accelerometers with intensity modulation

Intensity modulation-based optical sensors have simple structures and good linearity, and they are also inexpensive. **Figure 23** shows various configurations

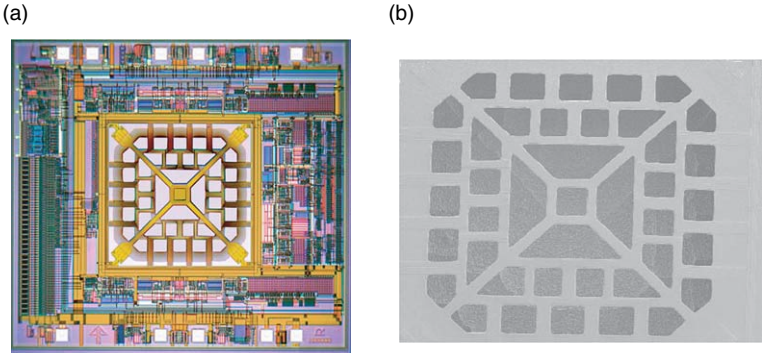

Figure 22 (a) Die photo of a MEMIC thermal accelerometer. (b) Scanning electron micrograph (SEM) of the thermal sensing element. (Photo courtesy: Y Cai of MEMSIC.)

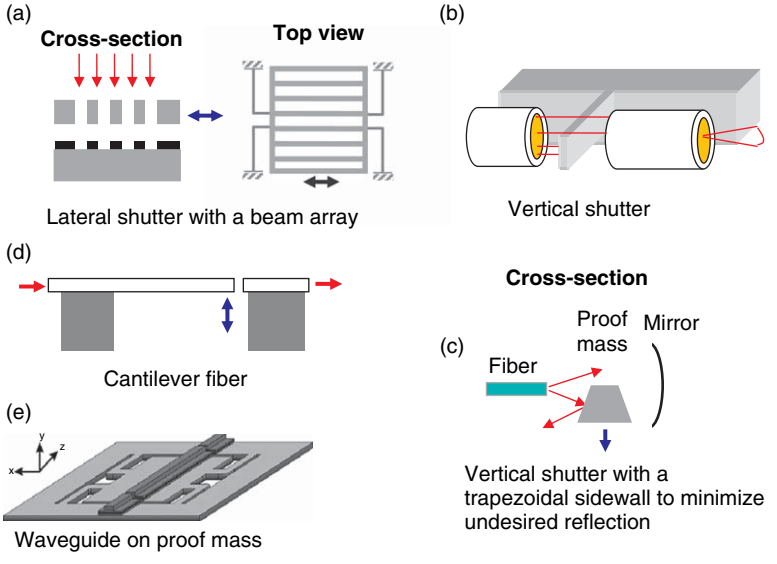

Figure 23 Schematic views of various intensity modulation optical accelerometers.

of optical intensity modulation micromachined accelerometers.

(a) This is a lateral-axis accelerometer. The shutter is placed between the light source and the photodetector. The shutter consists of alternating opaque/transparent regions. Note that the transparent regions are not necessarily through-holes. For instance, silicon is transparent to infrared light ($\lambda > 1\,\mu m$). This type of optical accelerometer has been implemented both in a bulk micromachining process using (110) silicon wafers (Abbaspour-Sani *et al.* 1995) and in a surface micromachining process (Tien 1998).
(b) This is a vertical (z-axis) optical accelerometer. The shutter can be obtained either by silicon DRIE or by anisotropic etch of (110) silicon substrate. An accelerometer with a 2-mg resolution and a 1-kHz bandwidth was demonstrated (Guldimann *et al.* 2000).
(c) This is also a z-axis optical accelerometer, but the shutter does not have vertical sidewalls. Instead, its cross section is a trapezoid. The slope reflects undesired light away from the fiber to minimize back reflection (Marty *et al.* 1995).
(d) This is a very simple structure. The fiber does it all, providing spring force, proof mass, and sensing element. However, cleaving and polishing the fiber are challenging (Kalenik and Pajak 1998).
(e) In this method, the waveguide is integrated on the proof mass (Llobera *et al.* 2004).

2.05.3.5.2 Interferometric optical accelerometers

Acceleration generates through a proof mass a displacement or stress, which can be measured by optical interferometers. The commonly used interferometers include the Michelson interferometer, the Mach–Zehnder interferometer (MZI), and the Fabry–Perot interferometer (FPI). For micromachined accelerometers, FPIs are often used due to their compactness and high resolution. The working principle of FPIs is based on multiple beam interference. A simplified Fabry–Perot (FP) etalon is sketched in **Figure 24**. Interference fringes will be generated due to multiple reflections when a light beam is incident on the etalon. The condition for a fringe maximum is given by

$$\frac{4\pi}{\lambda_0} nd\cos\theta = 2N\pi - \delta_r \qquad [10]$$

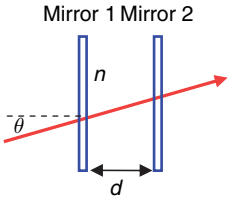

Figure 24 Schematic view of a Fabry–Perot interferometer.

where λ_0 is the vacuum wavelength, n is the refractive index of the medium between the two mirrors, d is the separation of the reflecting surfaces, θ is the incident angle, N is the order of interference, and $\delta_r/2$ is the phase change for one reflection, which is equal to 0 or π for dielectrics.

There are four variables in eqn [10], i.e., λ_0 , n, d, and θ. The transmission of a FPI can change with any of the variables. For acceleration sensing, d and θ can be used. However, $\cos\theta$ is approximately equal to 1 and is not sensitive to the change of θ when θ is small. Thus, for accelerometers, the change of the gap d is used to measure acceleration. There are two configurations for FPI accelerometers depending on the light source employed.

(1) The light source is a collimated monochromatic laser. In this case, the transmitted optical power is a measure of the gap change, which is proportional to the acceleration.
(2) The light source is broadband.

In this case, the shift of the transmission peak wavelength will be measured. This configuration is typically preferred as the measurement is independent of the absolute intensity reading. But cautions must be taken when designing an FPI accelerometer. The wavelength resolution is greatly affected by the reflectance of the mirrors, as shown in the following equation:

$$\Delta\lambda_{min} = N\pi\left(\frac{R^{1/2}}{1-R}\right)\lambda_0 \qquad [11]$$

where $R = (R_1R_2)^{1/2}$ with R_1 and R_2 being the reflectances of the two mirrors. For example, the resolving power is reduced by a factor of 2 when R is just slightly changed from 99% to 98%.

The FP cavity can be formed either vertically or horizontally. As shown in **Figure 25(a)**, a vertical FP cavity is formed between a vertical sidewall and the end face of an optical fiber. The vertical sidewall is

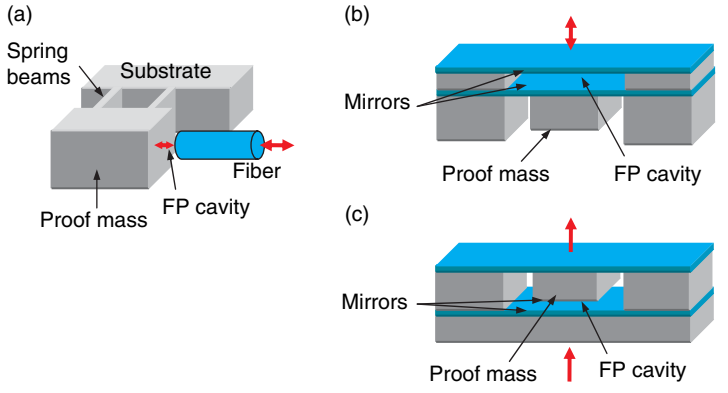

Figure 25 Schematic views of Fabry–Perot interferometer (FPI)-based accelerometers. (a) Lateral-axis sensing with a vertical FP cavity. (b) and (c) Vertical-axis sensing a horizontal cavity.

part of a proof mass. So the gap changes when there is an external acceleration. The optical fiber brings the light in and collects the reflected light back to a photodetector via a beam splitter (not shown). The wavelength shift of the reflection spectrum can be used to deduce the acceleration. Both (110) silicon substrate (Uenishi *et al.* 1994) and (100) silicon substrate (Schropfer *et al.* 1998) have been used to obtain vertical sidewalls. Smooth sidewall surfaces are always desired. Several approaches have been used to reduce the sidewall roughness such as deep etch shallow diffusion process (Juan and Pang 1998) and oxidation (Sparacin *et al.* 2005). Smooth sidewalls can also be achieved by optimizing the processing parameters of the Bosch ASE process (Donohue *et al.* 2004). Due to the low reflectance of the bare silicon sidewall (~30%), the resolution of this type of accelerometers is only on the order of 1 mg (Schropfer *et al.* 1998).

Horizontal cavities can be realized using wafer bonding as shown in **Figure 25(b)** and **25(c)**. If the proof mass is opaque to the incident light (**Figure 25(b)**), the reflected light from the FPI will be picked up by a photodetector (Baglio *et al.* 2004). If the proof mass is transparent to the source light (**Figure 25(c)**), the transmitted light will be collected to calculate the acceleration (Perez *et al.* 2005). The horizontal surfaces can be made extremely flat, and multilayer antireflection and high-reflection coatings can also be easily applied. Thus, the horizontal FPI accelerometers can achieve much higher resolutions (~1 micro-$g\text{Hz}^{-1/2}$) than their vertical FPI counterpart.

A Bragg grating is a transparent device with a periodically modulated refractive index, as shown in **Figure 26**. The wavelength that satisfies the

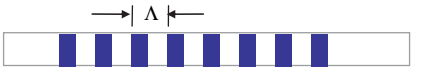

Figure 26 Schematic view of a Bragg grating.

Bragg condition is called the Bragg wavelength. The Bragg's law can be expressed as

$$\lambda_B = n\Lambda/2 \qquad [12]$$

where n is the refractive index of the grating material and Λ is the period of the grating. Only the Bragg wavelength is reflected and other wavelengths are transmitted. So a Bragg grating can be used as a filter or as a reflector. Note that a small index modulation is sufficient to achieve nearly total reflection for λ_B.

Bragg gratings can be made in a planar waveguide or in an optical fiber. Planar Bragg gratings are widely used in laser diodes and integrated optics while fiber Bragg gratings (FBGs) find extensive applications in optical communications. Bragg gratings can be created using femtosecond laser pulses or UV writing where the periodic pattern can be generated holographically or by a phase mask.

Package sizes of FBG-based accelerometers are relatively large due to the need of assembling circular optical fibers (Berkoff and Kersey 1996, Todd *et al.* 1998, Zhu *et al.* 2003). The demonstrated resolution is just around 1 micro-$g\text{Hz}^{-1/2}$, but there is a plenty of room to improve. To make optical sensors more compact, planar Bragg gratings are preferred. One such device is illustrated in **Figure 27**, where a Bragg grating is embedded in a planar waveguide (Storgaard-Larsen *et al.* 1996). A (110) silicon substrate and KOH etching can be used to obtain vertical thin beams. The Bragg grating is formed on

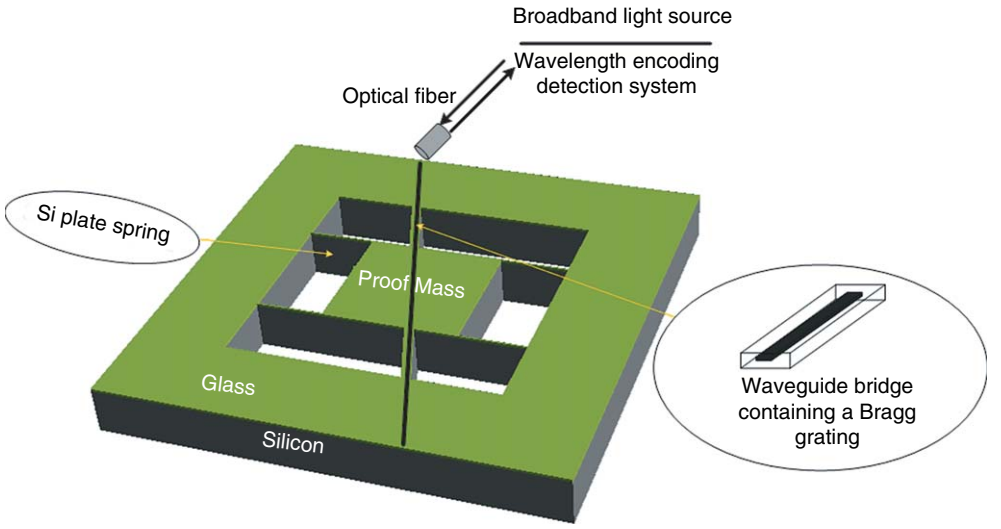

Figure 27 Schematic view of a planar Bragg grating-based lateral-axis accelerometer.

top of the thin beams using UV writing. When the proof mass moves due to external acceleration, the thin beams deform and in turn induce a stress in the Bragg grating. The strain of the Bragg grating then shifts the reflection spectrum, which is picked up by a photodetector.

There are also interferometric accelerometers based on diffraction gratings. Loh *et al.* (2002) demonstrated a high-resolution accelerometer with a bulk micromachined silicon proof mass and an interferometric position sensor. The interferometer consists of interdigitated fingers that are alternately attached to the proof mass and support substrate. Illuminating the fingers with coherent light generates a series of optical beams corresponding to different diffraction orders, as shown in **Figure 28(a)**. The intensity of a given beam depends on the out-of-plane separation between the proof mass fingers and support fingers. Proof masses with mechanical resonances ranging from 80 Hz to 1 kHz were fabricated with a two-mask process involving two DRIEs, an oxide etch stop, and a polyimide protective layer. The structures were packaged with a laser diode and photodiode into 8.6-cm^3 acrylic housings, as illustrated in **Figure 28(b)**. The 80-Hz resonant proof mass has a noise equivalent acceleration of 40 nano-$g\,Hz^{-1/2}$ and a dynamic range of 85 dB at 40 Hz.

Figure 29 shows another configuration for position sensing based on a diffraction grating, in which a sensing diaphragm rests above a rigid diffraction grating back electrode (Hall *et al.* 2006). In contrast, the design shown in **Figure 28** has all the grating fingers suspended. When illuminated from the backside with a coherent light source, such as a vertical

cavity surface-emitting laser (VCSEL), as shown in Figure 29, a series of diffraction beams are generated. The angles of the diffraction orders remain fixed, and their intensities are modulated by the diaphragm deflection. The zero-order beam intensity is complementary to all higher-order beams, which enables a differential detection scheme for sensitivity doubling and laser intensity noise cancellation without any additional optical components. This design is robust, and the light source and photodiodes can be integrated. It is very suitable for microphones and pressure sensors, but additional steps or wafer bonding are needed to make the proof mass for accelerometers.

As can be seen from the various micromachined optical accelerometers discussed above, the sensitivity and resolution of optical accelerometers are normally not dependent on the gap size. This greatly eases the fabrication as compared to that for tunneling or capacitive accelerometers. However, optical accelerometers have much more stringent requirements in terms of surface flatness and roughness. In addition, optical accelerometers generally have large sizes mainly because many discrete optical components such as lenses, fibers, mirrors, beam splitters, laser diodes, and photodetectors are needed. With the progress of integrated optics, more and more optical components will be integratable and overall packaging size will be reduced.

In summary, optical accelerometers have unique features such as immunity to EMI, fire safety, low transmission loss, and multiplexing capability, so they are the better candidates for applications in harsh environments (high voltage or high temperature), underwater and underground. Although optical micromachined accelerometers are still in the early development stage, some demonstrated results such as a $40\,ng\,Hz^{-1/2}$ resolution from an interdigitated diffraction-based accelerometer are very promising. There is no doubt that we will continuously see increasing research activities in this area.

2.05.3.6 Tunneling Accelerometers

Scanning tunneling microscopy (STM) has been a powerful tool to study the atomic scale structure of surfaces since it was invented in 1981 by Binning and Rohrer. Electron tunneling occurs between two conductors separated by a sufficiently thin insulating layer or vacuum. The tunneling current I is a function of the gap $d(\text{Å})$ and has the following dependence:

$$I \propto V \exp\left(-\alpha\sqrt{\phi}d\right) \qquad [13]$$

where ϕ is the effective height of the tunneling barrier in electron-volt, V is the bias voltage in volts, and $\alpha = 2.05(\text{eV})^{-1/2}\text{Å}^{-1}$. This exponential relation makes the tunneling current extremely sensitive to even a tiny gap change. For example, with typical values of ϕ and d, the current varies by an order of magnitude for each angstrom change of the gap. This high position sensitivity creates an opportunity for making accelerometers with much higher resolutions than other types of accelerometers. A scanning tunneling probe is illustrated in Figure 30. At constant current mode, the feedback loop maintains the tunneling current constant by adjusting the gap between the tip and the sample surface. The tip height is typically adjusted by a piezoelectric actuator. Thus, the voltage applied to the actuator is a measure of the tip height. By scanning the tip over the surface and recording the actuator voltage, the surface structure of the sample can be reconstructed. STMs can reach sufficient resolution to show single atoms and are widely used in both industrial and fundamental research.

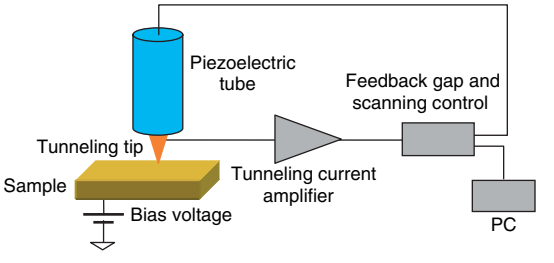

Figure 30 Schematic view of a scanning tunneling probe.

Electron tunneling was used in accelerometer designs in the late 1980s (Baski *et al.* 1988, Waltman and Kaiser 1989). In 1991, Kenny *et al.* reported the first micromachined tunneling accelerometer, and a gap change resolution of 2×10^{-4} Å $\mathrm{Hz}^{-1/2}$ and an acceleration resolution of 10 n$g\,\mathrm{Hz}^{-1/2}$ were measured at 1 kHz. Electrostatic actuation was employed in this design, eliminating the need for piezoelectric actuators. Compared with piezoelectric actuation, electrostatic actuation is much less sensitive to temperature drift and is immune to creep and hysteresis. The basic structure of a micromachined tunneling accelerometer consists of a proof mass, a tunneling tip, and an electrostatic actuator. The tunneling tip can be made either on the proof mass or on the substrate, as shown in **Figure 31(a)** and **31(b)**. According to eqn [3], the mechanical sensitivity is inversely proportional to the square of the resonance frequency of the spring–mass system. Therefore the early tunneling accelerometers have bandwidths up to only about 100 Hz. In order to increase the bandwidth, a cantilever is placed above the tunneling tip as shown in **Figure 31(c)** (Kenny *et al.* 1994). The resonance frequency of the cantilever is much higher than that of the proof mass. So, the cantilever can follow closely the motion of the proof mass at much higher frequencies than the proof mass resonance. A bandwidth of 1 kHz was reported by using this approach (Rockstad *et al.* 1996). Note that the responsivity of the device decreases rapidly after 100 Hz (the resonance frequency of the proof mass). The soft, lightweight cantilever can also reduce the crush failure of the tip. Another way to protect the tip is to use a pull-back electrode as shown in **Figure 31(d)** and **31(e)** (Yeh and Najafi 1995, Zavracky *et al.* 1996).

Tunneling accelerometers have been demonstrated using surface, bulk, and mixed micromachining processes. The microfabrication challenges include the tip fabrication and the tip gap control during wafer bonding. Numerous tip fabrication methods have been developed and some of them are illustrated in **Figure 32**. The method in **Figure 32(a)** has been widely used (Dong *et al.* 2005, Kenny *et al.* 1991, Yeh and Najafi 1997, Zavracky *et al.* 1996). In this method, the tip is fabricated by etching silicon anisotropically (e.g., EDP or KOH) or isotropically (e.g., hydrofluoric acid–nitric acid–acetic acid (HNA)) with a square oxide mask. The silicon undercutting forms a sharp silicon tip. After that the wafer is passivated (e.g., plasma-enhanced chemical vapor deposition (PECVD) oxide). Then a Ti (or Cr)/Pt/Au layer is coated on the tip by either lift-off or sputtering with a shadow mask. The method in **Figure 32(b)** follows the same steps as those in **Figure 32(a)** and then uses one backside and one front-side anisotropic wet tech (Liu *et al.* 1998). The tip is formed on a thin-film cantilever, which prevents the tip from crash damage. The method in **Figure 32(c)** employs focused ion beam (FIB) lithography to obtain small patterns (<100 nm). Followed by an ion milling step, a Ti/Pt/Au tip is formed. Using this process, a surface micromachined tunneling accelerometer was demonstrated with a noise floor of 85 µ$g\,\mathrm{Hz}^{-1/2}$ (Kubena *et al.* 1996). The method in **Figure 32(d)** uses hot embossing to create a polymethylmethacrylate (PMMA) tip from a silicon pyramid etched by KOH (Cui and Wang 2005). The last method is quite different from other methods. In this method (see **Figure 32(e)**), the tip moves laterally, while all other methods use vertically moving tips. The lateral tip can be fabricated using the single-crystal reactive etching and metallization (SCREAM) process (Shaw *et al.* 1993).

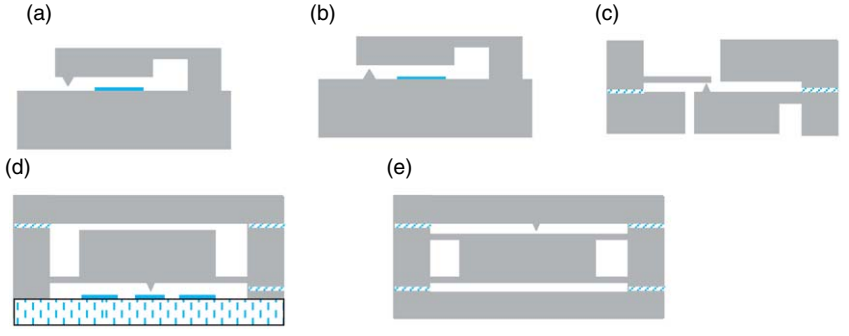

Figure 31 Schematic cross-sectional views of micromachined tunneling accelerometers. (a) Tunneling tip is on the proof mass. (b) Tunneling tip is on the substrate. (c) Wide-bandwidth design. (d) and (e) Dual-plate designs with tip protection and overrange protection.

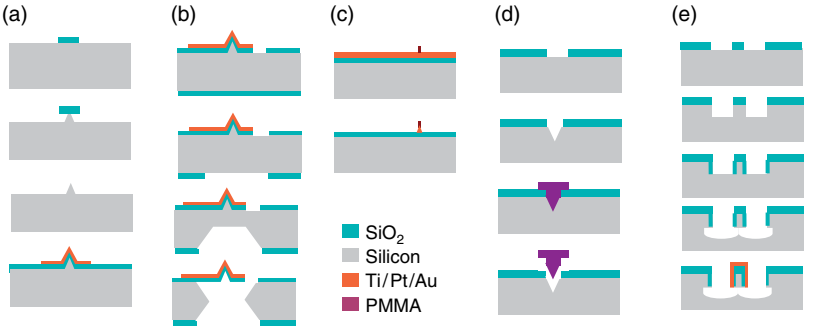

Figure 32 Schematic views of various tip fabrication methods. (a) A tip fabricated on a proof mass or substrate using a square oxide mask with anisotropic or isotropic wet etching. (b) A tip on a thin-film cantilever. (c) A small tip by focused ion beam (FIB) lithography plus ion milling. (d) A polymer tip by hot embossing. (e) A lateral tip fabricated by the SCREAM process.

A lateral tunneling accelerometer with a resolution of $20\,\mu g\mathrm{Hz}^{-1/2}$ was demonstrated using this process (Hartwell *et al.* 1998).

2.05.3.7 Resonant Accelerometers

Resonant accelerometers generate direct acceleration-to-frequency outputs. This provides not only the immunity to any amplitude measurement errors but also quasi-digital outputs to simplify the interfacing with digital systems. With the high quality factor, resonant accelerometers have high resolution and wide dynamic range. Quartz, single crystal silicon (SCS), and polysilicon are the common materials for resonators. Quartz resonant accelerometers have good performance and are commercially available especially for inertial-grade applications (Albert 1994, Kourepenis *et al.* 1991, Le Traon *et al.* 1998, Norling 1988). The high performance of quartz accelerometers is attributed to its high quality factor and inherently piezoelectric property for both actuation and sensing. SCS also has excellent mechanical properties and is the major substrate material for IC products. Various SCS resonant accelerometers have been demonstrated (Aikele *et al.* 2001, Burrer and Esteve 1995, Ferrari *et al.* 2005, Helsel *et al.* 1994, Ohlckers *et al.* 1998, Roszhart *et al.* 1995). Although polysilicon resonators show an inferior quality, the process maturity, the extensive use in IC fabrication, and the ease of IC integration make them very competitive. This is similar to the case for capacitive accelerometers. Some early micromachined resonant accelerometers are based on polysilicon (Burns *et al.* 1996, Chang *et al.* 1990, Guckel *et al.* 1992, Roessig *et al.* 1997, Seshia *et al.* 2002). Polysilicon resonators are not only used for accelerometers but also for radio frequency (RF) filters, clock generators, and biochemical sensors.

A resonant accelerometer is a device that has an element vibrating at its resonance. The resonance frequency shifts in the presence of an external acceleration. The vibrating element can be a beam, bridge, or tuning fork (Stemme 1991). The resonance frequency can be varied by a change in stress, mass, temperature, etc. For accelerometers, the most commonly used effect is the stress-induced stiffness change, which in turn changes the resonance frequency of the resonator. To excite the resonance, piezoelectric, electrostatic, and electrothermal actuations are often used. The vibration can be sensed piezoelectrically, capacitively, or piezoresistively. So there are several excitation and sensing combinations. The most commonly used pairs include piezoelectric/piezoelectric, electrostatic/capacitive, electrothermal/piezoresistive, and electrostatic/piezoresistive.

High mechanical quality factor (Q-factor) is needed for high sensitivity and high resolution. There are a few damping mechanisms, which can be expressed as a specific Q-factor for each: viscous and acoustic damping, Q_a, damping due to imbalances, Q_s, and damping resulting from internal material-related losses, Q_i. The overall Q is given by

$$\frac{1}{Q}=\frac{1}{Q_a}+\frac{1}{Q_s}+\frac{1}{Q_i} \qquad [14]$$

The first term ($1/Q_a$) dominates for any resonators in air. Air damping is negligible at a sufficiently low pressure (~0.1 mtorr). So vacuum packaging is needed for micromachined resonant accelerometers. The second term ($1/Q_s$) accounts for the

energy loss to the anchor. This energy loss can be minimized by mechanically isolating the resonator from its support(s). Thus a resonator design that minimizes the forces and torques acting on the support(s) should be used. A well-known example is the double-ended tuning fork (DETF) (Helsel *et al.* 1994). As shown in **Figure 33**, the beams oscillate 180° out of phase to cancel reaction forces at the ends of the beams. Thus, the dynamically balanced DETF resonator has a high Q. The third term $(1/Q_i)$ concerns the internal energy losses and it is dependent on the purity, dislocations, and thermoelastic losses of the resonator material. The thermoelastic losses are due to irreversible heat conduction resulting from the flexural motion. Polycrystalline materials have lower Q than single-crystal materials. If an SCS or quartz is used, the third term can be neglected (Stemme 1991).

There are mainly two types of micromachined resonant accelerometers in terms of the vibrating element design: DETF and doubly sustained beam (DSB). The basic structure of DETF is already shown in **Figure 33**. Using this DETF design and a bulk micromachining process, Helsel *et al.* (1994) reported an SCS-based resonant accelerometer with a resolution of 50 μg. In order to increase the scale factor, Roessig *et al.* (1997) proposed a novel lever structure. As shown in **Figure 34(a)**, the leverage mechanism can easily provide a force amplification of over an order of magnitude. Using the topology sketched in **Figure 34(b)**, a surface micromachined resonant accelerometer with a 2-μm-thick polysilicon structural layer demonstrated a scale factor of 2.4 Hz g^{-1} and a resolution of 1.5 mg $Hz^{-1/2}$ (Roessig *et al.* 1997). Using the same process and DETF design but a different topology as shown in **Figure 34(c)**, Seshia *et al.* (2002) improved the scale factor to 17 Hz g^{-1} and the resolution to 40 $\mu g\,Hz^{-1/2}$ with a working frequency range up to 1 kHz. Jia *et al.* (2004) implemented a similar design using an SOI substrate and achieved a scale factor of 27 Hz g^{-1} and a resolution of 160 $\mu g\,Hz^{-1/2}$.

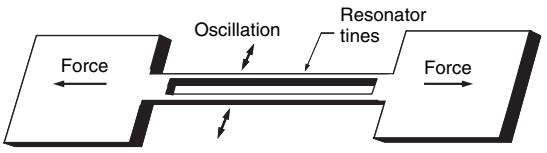

Figure 33 Schematic view of a double-ended tuning fork (DETF) resonator. The beams vibrate 180° out of phase to provide dynamic moment cancellation.

Recently, Su *et al.* (2005) reported a two-stage leverage mechanism to further increase the scale factor. A resonant accelerometer design with a two-stage leverage mechanism and a pair of DETF is illustrated in **Figure 35(a)**. The two-stage leverage was measured to have a force amplification factor of 80, and the overall scale factor was improved to 153 Hz g^{-1}.

There are a few variations for the DSB design. Three of them are illustrated in **Figure 36**. In all cases, there are a proof mass and a suspension flexure. The vibrating element is a resonant microbeam with one end anchored on the substrate and the other end attached to the proof mass or the flexure. The resonant frequency of the microbeam is much higher than that of the proof mass. The microbeam resonance is in the range of 100 kHz to 1 MHz, while the proof mass resonance is on the order of 100 Hz. An external acceleration deflects the flexure through the proof mass. The flexure deflection then stretches or compresses the microbeam, resulting in a respective decrease or increase of the resonance frequency of the microbeam. This frequency shift is a measure of the external acceleration.

In the case in **Figure 36(a)**, the doubly sustained microbeam is formed on top of the flexure with a small gap. To maximize the sensitivity, the microbeam is placed close to the substrate where the stress is maximal. Burns *et al.* (1996) developed a combined bulk and surface micromachining process to demonstrate this type of resonant accelerometer. The microbeam was fabricated from thin films of mechanical-grade polysilicon with integral polysilicon vacuum encapsulation. The microbeam was electrostatically excited and the vibration was detected piezoresistively. Resonant accelerometers with scale factors greater than 700 Hz g^{-1} and a base microbeam frequency of 524 kHz were fabricated. The Q was about 20,000.

In the case in **Figure 36(b)**, the resonant microbeam is clamped to the substrate on one end and connected to the proof mass on the other end. The proof mass is supported by some thin hinge beams. Note that the microbeam is typically thinner and longer than the hinges. Roszhart *et al.* (1995) demonstrated a 2-μg resolution resonant accelerometer using a bulk micromachining process plus wafer bonding. A scanning electron micrograph (SEM) of a fabricated device chip is shown in **Figure 37(a)**. The Q was higher than 60,000. Burrer

and coworkers also made similar devices (Burrer and Esteve 1995, Burrer *et al.* 1996). **Figure 37(b)** shows a SEM of a fabricated device. Electrothermal drive and piezoresistive sense were used. The measured scale factor was 260 Hz g^{-1}. It is also interesting to note that Ohlckers *et al.* (1997) demonstrated a vibrating beam accelerometer without using a microbeam. Instead, a high-order mode (~400 kHz) of the cantilever proof mass assembly was used. The Q of that mode is around 1000 at atmospheric pressure. So no vacuum packaging is needed. The measured scale factor is 6–7 Hz g^{-1}.

In the case in **Figure 36(c)**, the microbeam is anchored to the substrate on one end and perpendicularly connected to the suspension beam of the proof mass. Both the suspension beam and the microbeam are narrow and thick, so that the lateral strain or acceleration can be detected. **Figure 38** shows such an accelerometer developed by Aikele *et al.* (2001) using a bulk micromachining process. The thickness of the sensor structure is 30 μm. The microbeam is thermally excited to a lateral vibration by an implanted resistor. The vibration is sensed by an implanted piezoresistor. Both resistors are located on a U-shaped structure. The resonant frequency of the microbeam is 400 kHz, which can be easily excited by the U-shaped structure. The Q is about 60,000 at 0.01 mbar. The measured scale factor is 70 Hz g^{-1}. The resonant frequency of the proof mass is also as high as 17 kHz, making the sensor insensitive to any vehicle vibrations.

All the resonant accelerometers discussed so far are based on stress-induced resonance shift. There also exist other effects, which can be used to detect acceleration by a resonator. For example, Lee *et al.* (2000) proposed to use a gap-sensitive electrostatic stiffness changing effect to detect external acceleration. In this case, electrostatic actuation is used to excite the resonance. The idea is based on the fact that the effective stiffness of an electrostatic actuator changes with a varying gap. An imbalance proof mass with a torsional spring was used to create a differential output in a differential z-axis accelerometer (Seok *et al.* 2002). The same group extended the design to lateral-axis accelerometers and achieved a 5.2-μg resolution and 128 Hz g^{-1} scale factor (Seok and Chun 2006).

2.05.4 Accelerometer Processing

There are a large number of different micromachining processes. Here we only select a few representative processes to address fabrication issues such as temperature, stress, size, cost, stiction, circuit integration, and packaging. Because of their dominance in the commercial products market, piezoresistive and capacitive accelerometers have been given more attention.

2.05.4.1 First Bulk Micromachined Piezoresistive Accelerometer

The first micromachined accelerometer was developed at Stanford University in 1978 (Roylance and Angell 1978). It was a bulk silicon micromachining process plus silicon-to-glass bonding. The process flow is shown in **Figure 39**. It starts with n-type (100) silicon. The first step was to etch some holes completely through the wafer. These through-holes were used as two-side alignment markers. Next, thermal oxide and p^+ diffusion were used to form p-type piezoresistors (**Figure 39(a)**). After that, a KOH etch was performed on the backside (**Figure 39(b)**) and stopped at twice the desired silicon thickness. Next, the frontside oxide on the trench region was removed, followed by another KOH etch (**Figure 39(c)**). This second KOH etch was stopped when the trench region was etched through, yielding the desired thickness for the piezoresistive sensing region (**Figure 39(d)**). Next, the remaining oxide was stripped (**Figure 39(e)**). Finally, the silicon wafer was anodically bonded to a top and bottom glass plate for hermetic sealing (**Figure 39(f)**). Both plates had wells for microstructure clearance. The top glass plate also had sputtered aluminum for contacts. A SEM of a fabricated device before glass bonding is shown in **Figure 39(g)**. This device was capable of measuring accelerations from 1 mg to 50 *g* over a 100-Hz bandwidth.

2.05.4.2 Motorola's Surface Micromachined *z*-Axis Capacitive Accelerometer (G-Cell)

The basic idea of this process is to create a fully differential capacitive output by sandwiching a movable plate in between a fixed top and bottom plate. This process was developed in the early 1990s (Ristic *et al.* 1992, Shemansky *et al.* 1995), and surface micromachining was used. The process flow is shown in **Figure 40**. It starts with a 2.4-μm-thick thermal oxide for isolation and a thin silicon nitride layer for protection during the sacrificial etching step (**Figure 40(a)**). Then the first polysilicon layer (poly-1) is deposited and patterned, followed by the deposition and patterning of the first polysilicate glass (PSG) spacer layer (PSG-1) (**Figure 40(b)**). After that, the second polysilicon layer (poly-2) is deposited and patterned to define the proof mass (**Figure 40(c)**). Then a second PSG spacer layer (PSG-2) is deposited and patterned (**Figure 40(d)**), followed by the deposition and patterning of a third polysilicon layer (poly-3) (**Figure 40(e)**). Finally the PSG layers are etched to release the microstructure (**Figure 40(f)**). A released accelerometer is shown in **Figure 40(g)**, where the middle electrode (poly-2) is suspended via four long beams. The top electrode (poly-3) is anchored rigidly to the substrate, and the bottom electrode (poly-1) is directly deposited on the substrate and isolated by a thick oxide layer. Thus, a

(Source: Roylance L M, Angell J B 1979 A batch-fabricated silicon accelerometer. *IEEE Trans. Electron Devices* **26**, 1911–17; reproduced with permission from IEEE.)

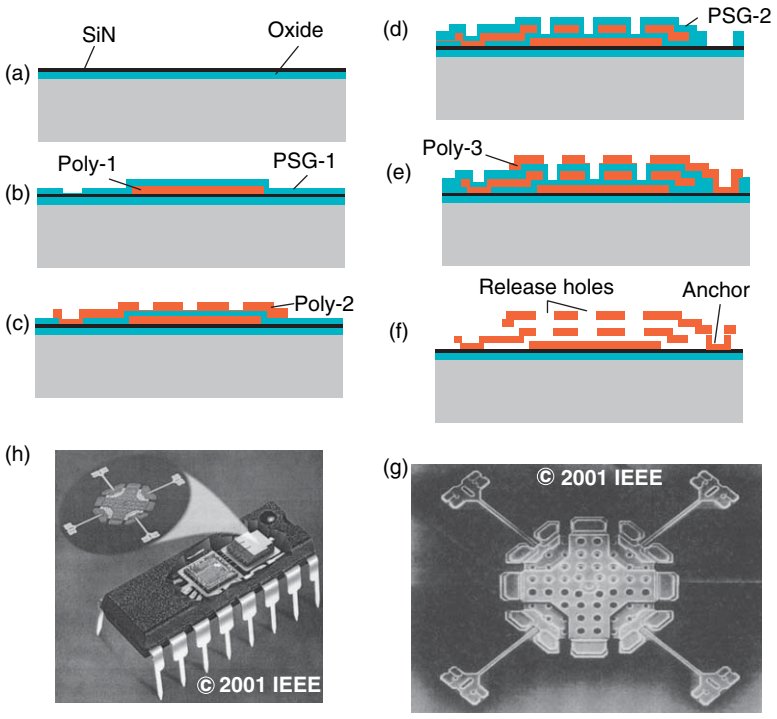

Figure 40 (a)–(f) Cross-sectional process flow of Motorola's G-cell accelerometer. (g) Scanning electron micrograph (SEM) of a released device. (h) Two-chip packaging. (Source: Li G, Tseng A A 2001 Low stress packaging of a micromachined accelerometer. *IEEE Trans. Electron. Packaging Manuf.* **24**, 18–25; reproduced with permission from IEEE.)

z-axis accelerometer with differential capacitive sensing is obtained. This configuration has several advantages including low cross-axis sensitivity, overrange protection, and self-test capability. A two-chip package (a sensor chip and an application-specific integrated circuit (ASIC) chip are wire bonded in a dual inline package (DIP)) is shown in **Figure 40(h)** (Li and Tseng 2001). These accelerometers are targeted at airbag applications. They have a 50-g full-scale output and can withstand over 5000-g impact.

2.05.4.3 ADI's iMEMS Process

ADI, teaming up with UC-Berkeley, started to develop integrated MEMS process in the late 1980s and brought up its first production of accelerometers in 1993 (Lewis *et al.* 2003, Payne *et al.* 1995, Sherman *et al.* 1992). The process flow is shown in **Figure 41**. This is an intermediate CMOS micromachining process, i.e., the MEMS structural layer is formed in between the CMOS process steps. In this process, standard IC process steps are performed until a gate is formed (**Figure 41(a)**). The remaining steps for circuits are just passivation and metallization. Polysilicon and oxide, respectively, are used as the structural and sacrificial layer (**Figure 41(b)**). After oxide deposition, low-pressure chemical vapor deposition (LPCVD) polysilicon is deposited at about 650 °C. In order to minimize residual stresses, a high-temperature annealing is followed. Due to the high deposition and annealing temperature, the aluminum layer must be deposited after the structural polysilicon layer is formed (**Figure 41(c)**). Then the metal layer and the circuit area are covered by an oxide/Si_3N_4 layer. For the final release step, instead of using vapor HF or critical point drying, a very inexpensive buffered HF etch is employed (**Figure 41(d)**). To prevent stiction, photoresist ties are patterned to hold the MEMS structures in place during buffered HF etching. After that, photoresist is stripped in oxygen plasma. Single-axis, dual-axis, and three-axis accelerometers with resolutions on the order of 100 $\mu g\,Hz^{-1/2}$ are commercially available.

2.05.4.4 Bosch Epipoly Capacitive Accelerometer

Thicker structural layers yields larger sensing capacitance and smaller thermomechanical noise with a given size. Bosch developed a thick structural layer process based on epitaxial polysilicon and used it for

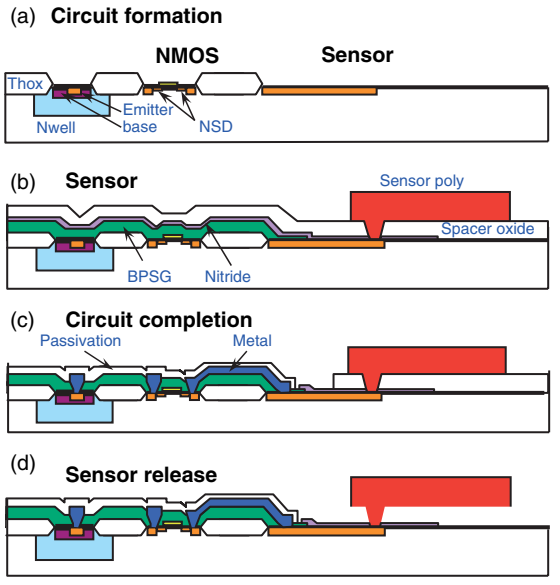

Figure 41 Cross-sectional view of Analog Devices Inc. (ADI's) iMEMS process (NMOS: N-type MOSFET; NSD; N-type source drain; and BPSG: borophosphosilicate glass).

fabricating inertial sensors (Lutz *et al.* 1997, Offenberg *et al.* 1995, Reichenbach *et al.* 2003). Several processes have been developed by Bosch. The process presented here is modified to enable three-axis sensing by using an interconnect polysilicon layer to form *z*-axis displacement sensing (Reichenbach *et al.* 2003).

The cross-sectional view of the process is shown in **Figure 42**. First, a 2.5-μm-thick passivation oxide is thermally grown on a silicon substrate, followed by a 0.45-μm-thick LPCVD polysilicon (**Figure 42(a)**). This thin polysilicon layer serves as an interconnection layer and the bottom electrode of *z*-axis sensing capacitors as well. This approach also provides better isolation and smaller parasitic capacitance compared to the diffusion wiring and p–n junction isolation in an early process (Offenberg *et al.* 1995). Then a 1.6-μm-thick sacrificial oxide layer is deposited and patterned (**Figure 42(b)**). The most critical step of the process is the epitaxial growth of an 11-μm-thick polysilicon layer (epipoly). After that, the epipoly is planarized, doped, and annealed to minimize residual stresses (**Figure 42(c)**). Next, aluminum bond pads are formed and covered by patterned photoresist, and then DRIE is performed to anisotropically etch the epipoly (**Figure 42(d)**). Finally, a vapor HF technique is used to remove the sacrificial oxide and release the microstructure (**Figure 42(e)**). A release structure is shown in **Figure 42(f)**. After the fabrication, each sensor chip is encapsulated by a silicon cap and wire bonded to an ASIC chip in a package, as shown in **Figure 42(g)**. This process can be used to make low-gee, airbag, and three-axis accelerometers. The resolution of the low-gee accelerometers is on the order of 1 mg.

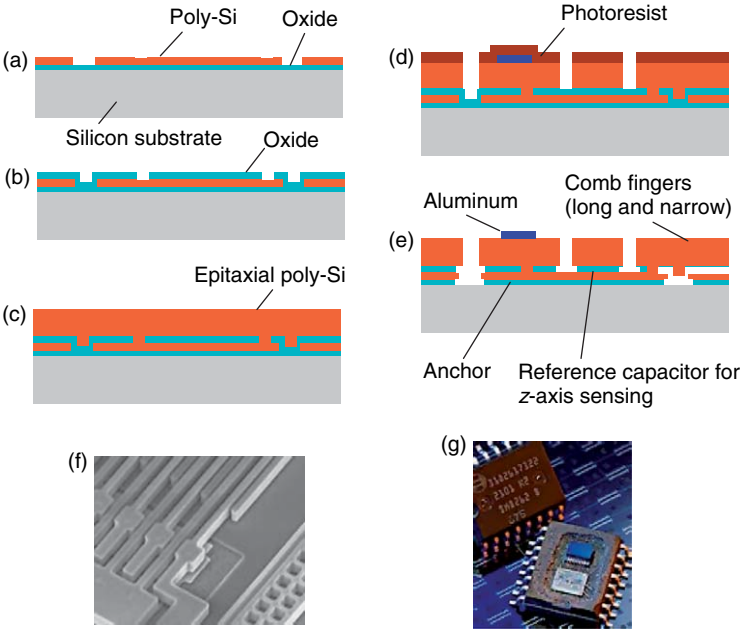

Figure 42 (a)–(e) Cross-sectional process flow of Bosch capacitive accelerometers. (f) Scanning electron micrograph (SEM) of a released microstructure. (g) Two-chip packaging.

2.05.4.5 ST's Capacitive Accelerometer

Similar to Bosch's approach, ST also uses low-stress, large-thickness epitaxially grown polysilicon as structural layers. The process developed by ST is called THELMA (thick epipoly layer for microactuators and accelerometers). ST has been developing MEMS accelerometers since 1996. The process flow is shown in **Figure 43(a)–(e)**. Deep silicon etching is used to obtain high aspect ratio vertical sidewalls. The stiction problem is overcome by using vapor HF dry etching. The sensor microstructure is capped by using wafer-to-wafer bonding. A SEM of a sensor structure and a packaged accelerometer are shown in **Figure 43(f)** and **43(h)**, respectively.

2.05.4.6 ADI's SOI iMEMS Process

This newly developed iMEMS process based on an SOI substrate is CMOS compatible and provides trench isolation and robust SCS microstructures (Chen *et al.* 2005). The top silicon layer (about 10 μm thick) is used as the MEMS structural layer, and the BOX layer (about 1 μm thick) is used as the sacrificial layer. The process flow is shown in **Figure 44**. It consists of three stages:

(1) Pre-CMOS-MEMS definition. In this stage, electrically isolated silicon islands are formed using isolation trenches. The isolation trenches are obtained by DRIE trench etch, silicon nitride passivation of trench sidewalls, and trench refilling by polysilicon; and the wafer is planarized using chemical–mechanical planarization (CMP) (**Figure 44(a)**). An oxide layer protects the trenches and MEMS sensor area during CMOS processing.

(2) Standard CMOS fabrication (**Figure 44(b)**). The planarized wafer can be directly sent to a CMOS foundry. The only extra effort is to align the first CMOS photomask to the prefabricated markers on the wafer. Because no high-temperature processing is necessary for MEMS after stage (1), metallization is much

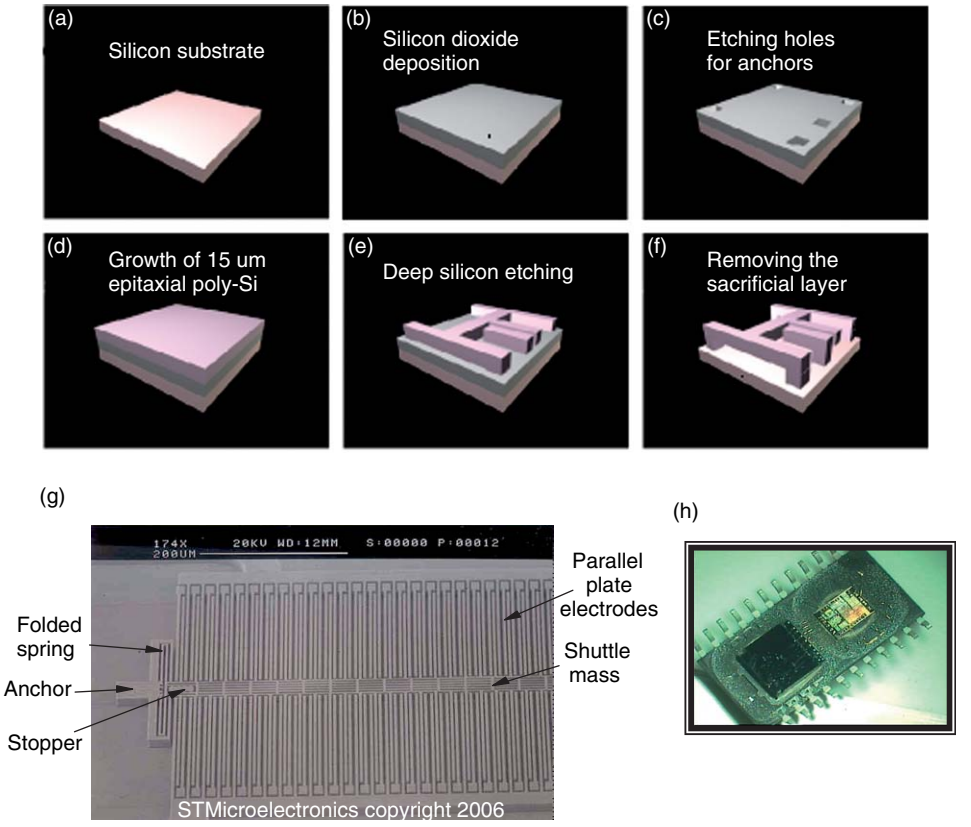

Figure 43 (a)–(f) Cross-sectional process flow of ST Microelectronics (ST) capacitive accelerometers. (g) Scanning electron micrograph (SEM) of a released microstructure. (h) Two-chip packaging. CMOS, complementary metal oxide semiconductor; DRIE, deep reactive ion etch; BOX, buried oxide.

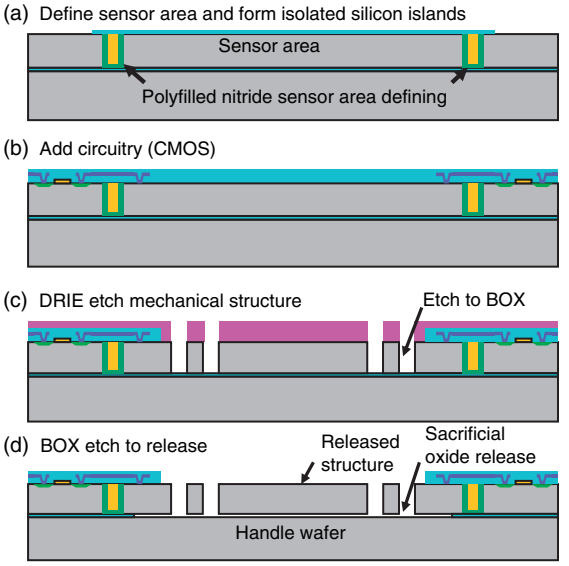

Figure 44 Cross-sectional view of Analog Devices Inc. (ADI's) silicon on insulator (SOI) iMEMS process.

more flexible and multiple interconnect metal layers can be used to decrease the circuit area. The CMOS metal layers also interconnect the silicon islands to form capacitive displacement sensors.

(3) Post-CMOS-MEMS release. There are two steps involved in this stage. First, silicon DRIE is used to form narrow-gap, interdigitated comb fingers, and define the suspension flexure and the proof mass (**Figure 44(c)**). Photoresist can be used as the etching mask. For the final release step, instead of using vapor HF or critical point drying, a very inexpensive buffered HF etch is employed. To prevent stiction, photoresist ties are patterned to hold the MEMS structures in place during buffered HF etching. The photoresist is later stripped in oxygen plasma to release the moving structure (**Figure 44(d)**). The working of a high-*g* accelerometer has been demonstrated with this process (Davis *et al.* 2004).

2.05.4.7 SensoNor's Resonant Piezoresistive Accelerometer – SA30

SensoNor's crash sensor SA30 is a resonant accelerometer with electrothermal excitation and piezoresistive sensing (Jakobsen 1996, Kvisteroy and Jakobsen 1998, Ohlckers *et al.* 1998). A die photograph of the sensor is shown in **Figure 45(g)**, where a center proof mass is suspended in two flexible beams to form a resonator structure. The resonator shifts its frequency corresponding to the external acceleration.

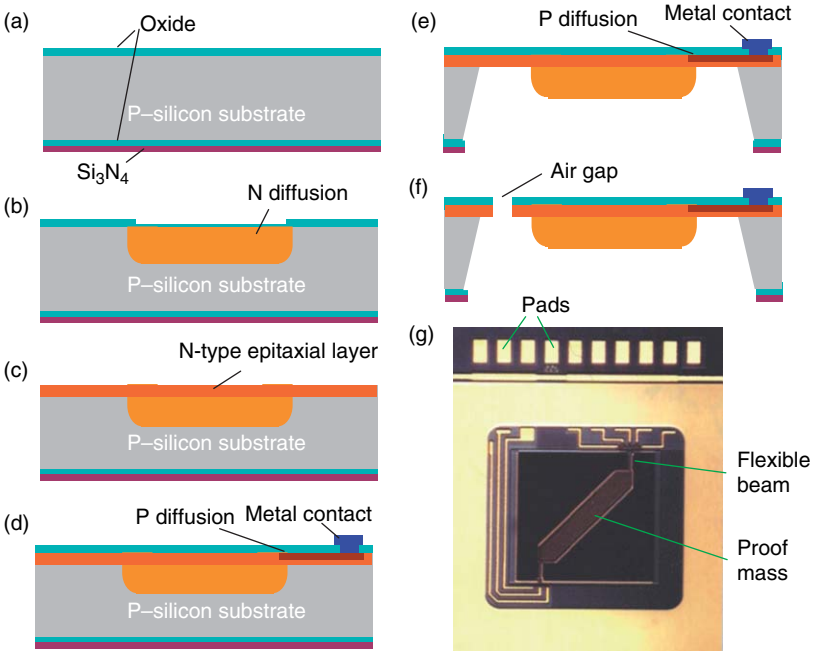

Figure 45 (a)–(f) Cross-sectional process flow of SensoNor's SA30 crash sensor. (g) Photograph of the sensor chip of a SA30 sensor.

The thickness of the proof mass is 20 μm and the thickness of the flexible beams is 3 μm. A basic fabrication process flow is shown in **Figure 45(a)–(f)**. The actual process might be different. The process starts with a double-side polished p-type (100) silicon substrate. First a ~1-μm-thick oxide is thermally grown on both sides of the wafer, followed by a 0.3-μm-thick LPCVD Si_3N_4 (**Figure 45(a)**). Then, phosphorus ions are implanted and driven 17 μm deep into the substrate (**Figure 45(b)**). Next, a 3-μm-thick n-type epitaxial layer is grown on the frontside (**Figure 45(c)**). After that, boron ions are implanted to form thermal resistors and p-type piezoresistors, followed by the formation of metal contacts to the diffusion resistors (**Figure 45(d)**). Then the process is turned to the backside. An aqueous KOH etch is applied and the Si_3N_4 layer is the etching mask. An electrochemical technique can be used to automatically stop the etching at the p–n junction. Because there are different p–n junction depths in the wafer, different silicon thicknesses are obtained (**Figure 45(e)**). Finally, the flexible beams and proof mass are released by RIE etching (**Figure 45(f)**).

Anodic bonding is used to hermetically seal the silicon die between two glass plates. The structure thickness can be controlled within 1%. A Q-factor higher than 2000 is obtained at atmospheric pressure. The resonance frequency for the micromachined device is approximately 700 kHz. The sensitivity is in the range 60–70 Hz g^{-1} (Ohlckers *et al.* 1998).

2.05.4.8 MEMSIC Thermal Accelerometer – Surface Micromachining

The fabrication process is foundry CMOS compatible (Zhao and Hua 2004). The process flow is shown in **Figure 46**. It starts with a CMOS wafer. The first step is to define the MEMS structure and protect on-chip CMOS circuits. The mask layer can be photoresist, polyimide, or metals (**Figure 46(a)**). Then an anisotropic oxide etch is performed to expose the silicon substrate (**Figure 46(b)**), followed by a DRIE silicon etch (**Figure 46(c)**). Finally an isotropic silicon etch is used to undercut the silicon beneath the microstructure (**Figure 46(d)**). A microstructure created by this process is shown in **Figure 46(e)**, and a SEM of a release sensor die in **Figure 46(f)**. This process involves very low cost due to its standard CMOS compatibility and simple process steps. The resultant accelerometers are robust because they have no moving parts. The resolution and bandwidth of these accelerometers are about 1 mg and 30 Hz.

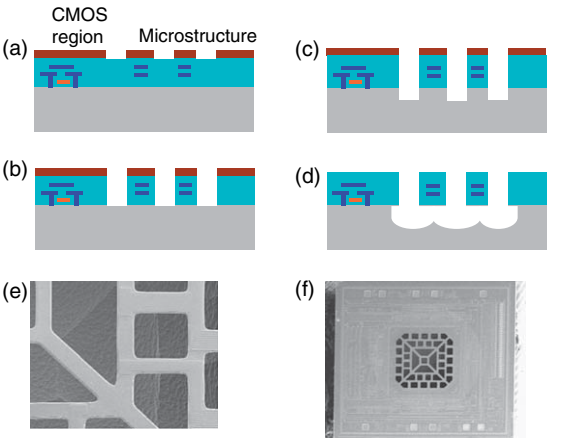

Figure 46 (a)–(d) Cross-sectional process flow of MEMSIC's complementary metal oxide semiconductor (CMOS) microelectromechanical systems (MEMS) process. (e) A released microstructure showing the undercut silicon pit and suspended oxide/metal beams. (f) Scanning electron micrograph (SEM) of a whole sensor die.

2.05.4.9 A DRIE CMOS-MEMS Three-axis Accelerometer

DRIE CMOS-MEMS processes provide large proof mass and integrated interface circuits. One of the key challenges is to obtain reliable electrical isolation of silicon. Because electrical isolation structures often have poor thermal conductivity, overheating problems occur during the DRIE silicon etch. Overheating in DRIE results in large silicon undercut, which increases the gaps of capacitive sensing comb fingers. The DRIE CMOS-MEMS process introduced here uses two silicon etch steps to obtain electrical isolation and narrow comb-finger gaps, and solves the overheating problem by using a temporary thermal path.

The process flow is illustrated in **Figure 47**. It starts with a backside etch that produces a silicon membrane and defines the structure thickness (**Figure 47(a)**). Then an anisotropic oxide etch is performed, followed by applying a thick sacrificial polymer layer (~50 μm) to the back of the silicon membrane (**Figure 47(b)**). This polymer layer may simply be the photoresist and will be used as a temporary heat path. Next, the top Al layer is etched (**Figure 47(c)**), and then a deep silicon etch and undercut is used to form electrical isolation structures for silicon (**Figure 47(d)**). After that, a second anisotropic SiO_2 etch and DRIE silicon etch is performed to define comb fingers and mechanical springs (**Figure 47(e)**). Finally the photoresist is removed in oxygen plasma for final device release.

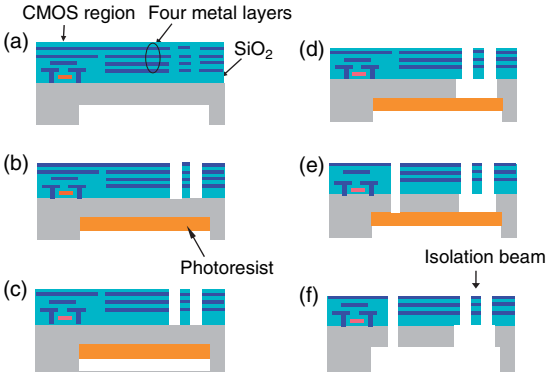

Figure 47 A deep reactive ion etch (DRIE) complementary metal oxide semiconductor (CMOS)-microelectromechanical systems (MEMS) process flow. (a) Backside etch. (b) Backside photoresist coating followed by front side anisotropic SiO_2 etch. (c) Top Al etch. (d) Deep Si etch and undercut to form isolation structures. (e) Anisotropic SiO2 etch and DRIE Si etch for comb fingers and mechanical springs. (f) Photoresist ashing for final release.

Figure 48 shows a SEM of a three-axis accelerometer fabricated using this process. One inset in the figure shows the backside of a group comb fingers with trench isolation. The thickness of the structural silicon layer is about 50 μm. The measured noise floor of the accelerometer is about 12 $\mu g\ Hz^{-1/2}$ (Qu *et al.* 2006).

2.05.5 Design Considerations

As we have seen in the above sections, there are various acceleration sensing mechanisms and each of them can then be applied to accelerometers by using different fabrication technologies. Which way to go may often largely depend on the available facilities and expertise. The following provides some general guidelines for decision making.

2.05.5.1 Single Axis or Three Axis

Acceleration is a vector. In many cases, acceleration in all three axes must be monitored. Assembling two or three devices to form three-axis sensing will drastically increase the packaging size compared with a monolithic three-axis accelerometer. Although several companies including ADI, Bosch, and ST have already launched monolithic three-axis accelerometers in the market, the fabrication complexity and compromised performance in one or two of the axes are still concerns. Therefore, the size constraint must be carefully evaluated to determine whether three-axis accelerometers should be used. Table 2 lists the three-axis readiness of all the sensing mechanisms.

As shown in Table 2, each sensing mechanism has its favorable sensing axis. Capacitive sensing (surface) is suitable for lateral-axis sensing using comb fingers. Its *z*-axis implementation is more challenging due to the substrate parasitic capacitance and/or the difficulty for forming fully differential capacitive bridges. Both capacitive sensing (bulk) and piezoresistive sensing (bulk) are typically used for *z*-axis sensing, but the twisting modes of a proof mass can be used for lateral-axis sensing. Tunneling sensing in a lateral axis is not easy to implement because of the difficulty to fabricate a sharp tip oriented in the wafer plane, while thermal sensing is suitable for lateral axes. Resonant accelerometers can depend either way on

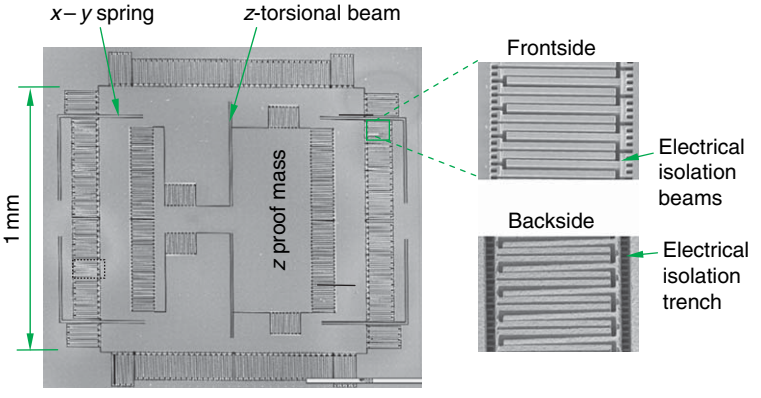

Figure 48 Scanning electron micrograph (SEM) of a deep reactive ion etch (DRIE) complementary metal oxide semiconductor CMOS-microelectromechanical systems (MEMS) three-axis accelerometer.

Table 2 Comparison of the readiness of various acceleration sensing mechanisms

Type	*Primary*	*Secondary*	*Triaxial readiness*[a]
Piezoresistive	Vertical	Lateral	2
Piezoelectric	Vertical	Lateral	2
Capacitive			
Surface (poly-Si or poly-SiGe)	Lateral	Vertical	2
Surface (multiconductor layer)	Lateral	Vertical	3
Bulk micromachining	Vertical	Lateral	2
Thermal	Lateral	Vertical	1
Tunneling	Vertical	Lateral	1
Optical	Vertical	Lateral	1
Resonant	Either	Either	2

[a]1 – possible but difficult, 2 – easy but with performance degradation, 3 – good.

the actual actuation and sensing mechanism employed. There are many three-axis accelerometer designs reported from both academia and industry. These designs are mainly based on piezoresistive, capacitive, and piezoelectric sensing.

2.05.5.1.1 Three-axis piezoresistive accelerometers

Takao *et al.* (1995) fabricated a three-axis piezoresistive accelerometer for high-temperature applications using an SOI substrate. Andersson (1995) fabricated inclined beams using anisotropic etching of silicon to achieve three-axis sensing. Kwon and Park (1997) reported a three-axis piezoresistive accelerometer using polysilicon on top of SOI substrate, but the cross-axis sensitivities were about 10%. Plaza *et al.* (1998) reduced the cross-axis sensitivities of a three-axis piezoresistive accelerometer to less than 1.6% using a BESOI substrate and a combined bulk and surface micromachining process. Takao *et al.* (1997, 2001) utilized piezoresistive effects of p-MOSFETs (metal oxide semiconductor field effect transistors) and made a CMOS-integrated three-axis piezoresistive accelerometer. Kruglick *et al.* (1998) demonstrated a CMOS three-axis piezoresistive accelerometer by using assembled vertical plates for lateral-axis sensing. Chaehoi *et al.* (2005) combined piezoresistive *z*-axis sensing and heat-transfer lateral-axis sensing on a single chip to make a CMOS three-axis accelerometer using anisotropic wet silicon etching.

2.05.5.1.2 Three-axis capacitive accelerometers

Mineta *et al.* (1996) used a proof mass whose center of gravity is raised above its suspension beams so that vertical and lateral accelerations can be detected by a parallel shift and tilt of the proof mass, respectively. Lemkin *et al.* (1997) demonstrated a force-balanced CMOS three-axis accelerometer using a surface micromachining process. Lotters *et al.* 1998 used a highly symmetric cubic structure and a polydimethylsiloxane (PDMS) spring flexure. Matsumoto *et al.* (1999) achieved three-axis acceleration sensing using an SOI substrate. Li *et al.* (2001) used a SiO_2/Si_3N_4 flexure to suspend a bulk micromachined proof mass. Reichenbach *et al.* (2003) demonstrated a three-axis accelerometer using a single proof mass. Szaniawski *et al.* (2004) designed a three-axis accelerometer using multiuser MEMS processes (MUMPs). Rodjegard *et al.* (2005) created unique slanted beams for both in-plane and out-of-plane acceleration sensing. Chae *et al.* (2005) achieved about 1 $\mu g Hz^{-1/2}$ noise floors for both in-plane and out-of-plane acceleration by using a combined surface and bulk micromachining process. Qu *et al.* (2006) demonstrated an integrated three-axis accelerometer with a noise floor of 12 $\mu g Hz^{-1/2}$ using a DRIE CMOS-MEMS process.

There are also three-axis piezoelectric accelerometers based on either ZnO or PZT (Kunz *et al.* 2001, Okada 1995, de Reus *et al.* 1999, Scheeper *et al.* 1996). All the above-discussed three-axis accelerometers either use a single proof mass, one for in-plane sensing and one for out-of-plane sensing, or use one for each axis. Sharing a proof mass means a small chip size, but at the same time the coupling and cross-axis sensitivities will be increased.

On the commercial side, three-axis capacitive accelerometers have been released by a few companies in the past two years (Analog Devices Inc. 2005, Bosch Sensortec 2005, Colibrys Inc. 2006, ST Microelectronics 2004, Freescale 2006). Some three-axis piezoresistive accelerometers are also available as volume products (Fujitsu 2005, Hitachi Metals 2005). **Table 3** lists some of the three-axis accelerometers that currently are commercially available. Very recently, MEMSIC added *z*-axis acceleration capability to their dual lateral-axis thermal accelerometers (Zhao and Cai 2005).

Table 3 List of some commercially available three-axis accelerometers

	Model	*Size (mm)*	*Range (g)*	*Noise ($\mu g\ Hz^{-1/2}$)*	*Bandwidth (kHz)*	*Current (mA)*	*Packaging*
ADI	ADXL330	$4 \times 4 \times 1.45$	±3.6	280	1.6	0.2	Single-chip

ADI, Analog Devices Inc.; ST, ST Microelectronics.

2.05.5.2 Sensing Method

Which sensing method to choose will be determined by several factors: resolution, bandwidth, cost, available facilities, etc. **Table 4** compares various sensing methods.

2.05.5.3 Fabrication Method

For each sensing method, there are various fabrication processes and structural materials to choose from. Anisotropic wet bulk micromachining is the most cost-effective process, but it requires protection and etch stop, which greatly restricts its application range. Surface micromachining is quite mature now. Polysilicon layers with thickness greater than 10 μm have been demonstrated (Furtsch *et al.* 1997). Low-temperature deposition materials such as electroplated metals (Cole 1991) and polycrystalline silicon germanium (Franke *et al.* 2003, Rusu *et al.* 2003) have also been developed. In addition, thin-film materials such as Al/oxide composite from CMOS processing can be used for structural materials (Fedder *et al.* 1996, Xie and Fedder 2000). DRIE silicon etch is a newly added powerful tool and has been used to achieve bulk silicon equivalent performance with a foundry CMOS-compatible process (Qu *et al.* 2004, Xie *et al.* 2002).

2.05.5.4 Integrated vs. Hybrid

Integration is always desired, but the cost for the integration may be high. The majority of three-axis accelerometers in the market are hybrid, where single- or dual-axis sensing elements and signal conditioning circuits are assembled together and packaged in the same enclosure. There are some trade-offs between monolithic integration and hybrid packaging. The advantages of monolithic integration include small packaging sizes, less signal attenuation, and accurate alignment of the three orthogonal sensing axes. But fabrication processes are more complicated and most likely the yield will not be high. Readers who are interested in the integrated approach may further refer to Fedder *et al.* (2005),

Table 4 Performance comparison of various sensing methods

Type	*Resolution ($\mu g\ Hz^{-1/2}$)*	*Bandwidth (kHz)*	*Acceleration range*	*Readout circuits*	*Fabrication cost*	*Temperature performance*
Piezoresistive	100–1000	0.1–5	Low to medium	Easy	Low	Poor
Piezoelectric	1–1000	~15	Wide	Easy	Medium	Good
Capacitive	0.01–100	1–20	Wide	Difficult	Low	Very good
Thermal	~1000	<0.1	Wide	Medium	Low	Good
Tunneling	1–0.01	~0.1	Low	Medium	High	Good
Optical	0.01–1000	0.1–5	Wide	Easy	Varies	Good
Resonant	1–1000	0.1–1	Low to medium	Medium	Varies	Good

which provides a comprehensive overview of integrated accelerometers and gyroscopes. The hybrid solution, on the other hand, allows mechanical structures and readout circuits both being optimized and fabricated separately by dedicated and well-tuned processes. The higher yield and the always improving packaging techniques may make up the relatively large package sizes.

2.05.5.5 Readout Circuits

The readout circuits for piezoresistive accelerometers are simple because of the low impedance at the sensing nodes. Optical accelerometers also have a fairly simple interface circuit, which basically is a photodiode plus a transimpedance amplifier. Resonant accelerometers need more complicated circuits as both resonance excitation and strain detection are involved. Self-oscillation circuits and force feedback closed-loop control circuits are discussed in detail in Khammash *et al.* (2005), Yeh and Najafi (1998), and Partridge *et al.* (1999). The interface circuitry for capacitive accelerometers is the most challenging due to the high impedance of the capacitive sensing nodes and the parasitic capacitance. Interested readers can refer to Yun *et al.* (1992), Kemp and Spangler (1995), Boser (1997), Kulah *et al.* (2000), Kajita *et al.* (2002), Wu *et al.* (2002), Amini *et al.* (2004), Yazdi *et al.* (2004), and Fang *et al.* (2006).

2.05.5.6 Accelerometers for Applications in Harsh Environments

There are many situations where the sensors must operate in extremely high temperature, shock, vibration, or radiation. For example, for munition launching, the acceleration can easily exceed 10 kg. For underground drilling, the temperature could be as high as 500 °C or more. The strong radiation must be considered in all space missions (Brown 2003, Cass 2001). The piezoresistive method is often used for high-*g* applications. Piezoresistive accelerometers that can operate up to 20–100 kg have been reported (Ning *et al.* 1995, Wang *et al.* 2003). But piezoresistive accelerometers have poor temperature performance. Capacitive accelerometers can be used for high-*g* applications in the 1–20 kg range with better temperature stability (Beliveau *et al.* 1999, Davis *et al.* 2004, Stauffer 2006, Stewart *et al.* 2004). In order to further improve the temperature performance, more stable materials such as SiC have been used (Atwell *et al.* 2003). The radiation effects of some commercial accelerometers have been studied (Cournar *et al.* 2004, Knudson *et al.* 1996, Lee *et al.* 1996). Boyadzhyan and Choma (1998) found that tunneling accelerometers can survive strong direct gamma radiation (Boyadzhyan and Choma 1998).

2.05.6 Packaging

The structure placed around the mechanical spring–mass system of an accelerometer creates a package that mechanically interfaces the accelerometer sensing mechanism with the mechanical stimulus that is being measured. Accelerometers are one of the few MEMS devices that can be sealed in an IC package. Most other sensors, for example, pressure sensors, must allow media to enter the package. The accelerometer package performs several different functions. The primary purpose is to electrically interconnect and mechanically mount the sensor. The package also isolates the internal atmosphere from the environment and therefore protects it from contamination. For resonant and tunneling accelerometers, the package must also provide a low-pressure environment to achieve high quality factor and reduce noise (Lee *et al.* 2000, Wang *et al.* 1997). For thermal accelerometers, the package should be hermetic and maintain a constant chamber pressure. Electrical signals due to leakage or coupling to electromagnetic fields must be isolated from the sensor to minimize error.

Packaging can occur after IC dicing within a preformed container or by molded encapsulation of the sensing element. Alternatively, packaging can occur at the silicon die or wafer level in a procedure commonly referred to as capping. There are two types of capping: bond capping and thin-film encapsulation.

2.05.6.1 Capping

The attachment of a structure over the mechanical MEMS features can be accomplished at the die level and therefore makes it possible to assemble a MEMS die with the same tools and procedures as typical ICs.

The cap is made from a silicon or glass wafer with an etched cavity and is aligned and bonded to the MEMS wafer (**Figure 49(a)**). The most common bonding material is a glass frit paste that is screen printed onto the cover or cap in a shape that outlines the bonding area (Felton *et al.* 2004, Li and Tseng 2001, Lutz *et al.* 1997, Yun *et al.* 2005). The

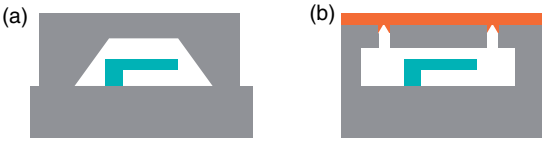

Figure 49 Cross-sections of capping. (a) Bond capping. (b) Thin-film encapsulation.

paste is dried of solvents and sintered, then aligned with the MEMS wafer. Sufficient force and temperature is applied to ensure contact across the wafer and wetting of the interfaces. The atmosphere used during the bonding operation should remain oxidizing to ensure adequate glass wetting and avoid reduction of the oxide to metals such as lead, as lead oxide is a common constituent in the frit. A low-moisture sealing atmosphere and gettering with borates are commonly used to ensure that the atmosphere remains dry inside the cap. Glass frit can create a seal over topology including circuitry and therefore preserve the die area, as space need not be reserved for sealing. Sealing is also possible with solders or thermocompression of gold-to-gold surfaces. In addition to using hot plates, the thermal energy for bonding can also be provided by localized heating of on-chip polysilicon heaters (Lin 2000). When the cap is etched for the cavity over the sensor, a channel is also created around the perimeter of the seal area. A diamond saw that is used for wafer dicing makes a cut through the cap wafer and into the perimeter channel. To avoid loose fragments of silicon, this perimeter is filled with wax from the edges of the wafer. After the cap wafer is cross-cut, the wax and fragments are removed. The final step in the capped and sealed sensor wafer is sawing through the wafer to create an individual die.

Protecting the MEMS structure by depositing additional layers of material over the MEMS structure to create a cover is referred to as thin-film encapsulation or in situ capping (Hochst *et al.* 2004, Liu and Tai 1999, Metzger *et al.* 2007, Park *et al.* 2006). The use of vapor etchants such as xenon difluoride or vapor HF makes it possible to remove silicon or silicon dioxide after the cap or top layer is in place. To complete the sealing of the MEMS structure, the access areas for vapor etch are plugged, as illustrated in **Figure 49(b)**. Bosch has used the high-speed deposition rates achieved in epitaxial silicon reactors to deposit thick polysilicon layers over oxide. This results in a polysilicon structure that can be layered to form sensor elements and a cap. The limitation with this approach is that the temperatures are over 850 °C.

With capped die, it is possible to create wafer scale packaging. This is accomplished by creating solder bumps on the capped die and directly mounting the die with the solder bumps. Vias through the cap or the substrate can provide interconnection to the sensor.

2.05.6.2 Hermetic and Plastic Packaging

Although dust and protective seals can occur with polymers, they allow moisture to enter the part. Glass or metal sealing creates a moisture barrier and is referred to as hermetic. Accelerometers, along with temperature sensors and magnetic sensors, can function inside of a hermetic package while most pressure sensors and flow and chemical sensors must interact with the environment and are open. A large base of experience has been developed for IC hermetic packages and is directly applicable to MEMS accelerometers. A sealed package, assuming a proper atmosphere exists inside, helps to ensure a stable and reproducible device. Moisture and condensable vapors can change the mass or pressure or create leakage paths for accelerometers and thus change the indicated acceleration. Reliability issues with corrosion, stress corrosion, and migrated resistive shorts can occur as well as electrical drift.

It is common for MEMS devices to have special coatings on the structures to minimize stiction (Ashurst *et al.* 2001, Srinivasan *et al.* 1998). These coatings can migrate and agglomerate with time, temperature, and moisture and reduce the effectiveness of the antistiction coatings. Hermetic packages ensure that the internal atmosphere remains dry and in equilibrium with the antistiction coatings. In the case of structures to be operated in resonance, such as resonant accelerometers, a vacuum environment is used and therefore a sealed package will maintain pressures less than 100 mTorr and, with careful package construction and gettering, this pressure can be reduced to 1 mTorr.

Plastic packages, although not hermetic due to the nature of moisture diffusion through polymers, are still widely used for MEMS accelerometers. Through the use of capping or sealing at the die level, a plastic package with a hermetic cavity around the MEMS structure is created. This makes it possible to

assemble the accelerometer on a conventional IC packaging line. An uncapped die must be handled in a class 100 clean room, which is unconventional for die attach and wire bonding operations, and special tools and processes must be used to protect the fragile MEMS structure from liquids and particles as well as mechanical damage.

Plastic packages are a cost-effective and high-volume method of packaging, which can be found to occur in two types of configurations, postmolded and premolded. The premolded package is made by injecting plastic around a lead frame to form an outline with a cavity for future die placement. The postmolded plastic package process begins with the die attachment to the lead frame followed by gold thermocompression bonds connecting the pads on the die to the leads on the frame. The part is then molded over with plastic.

2.05.6.3 Package Outline and Mounting

Although MEMS accelerometers have no standard outline or mounting conventions, the main features have been fashioned from IC packages and therefore have common outlines with single and dual-in-line packages and surface-mounted parts. The very high volume use of hermetic LCCs for cell phones and crystal oscillators is a popular package for accelerometers as well. With the strong trend to smaller size parts both in footprint and in thickness, the use of plastic packages has been the only economic solution. To achieve thin packages, the back grinding of the die and often the cap is performed to achieve a total device thickness of less than 1 mm (Lacsamana *et al.* 2005), as shown in **Figure 50**.

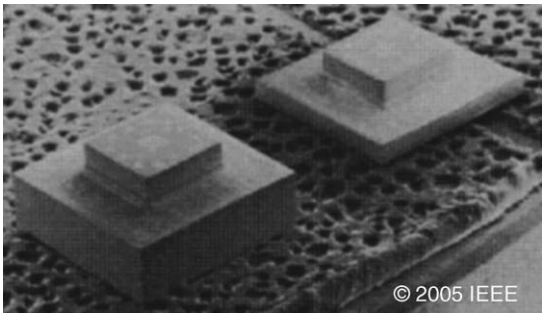

Figure 50 Scanning electron micrograph (SEM) showing a standard thickness capped die and 250-μm backgrinded capped die. The die size is 2.3 mm × 2.3 mm.

2.05.7 Application Considerations

The applications of accelerometers in different areas have different considerations. High-volume and low-cost applications such as in automotive, consumer, and health care value pricing and reliability, while high-performance and low-volume applications in defense and aerospace value accuracy and measurement dependability. **Figure 51** gives an overall view of accelerometer applications in various markets (Jean-Michel 2004). In the following, we discuss accelerometer applications in automotive, aerospace, measurement and instrumentation, and consumer markets.

2.05.7.1 Automotive Markets

MEMS accelerometers are most widely known for their applications in safety systems or airbags (Sulouff 1991). The deceleration of a vehicle can be sensed throughout the car, but due to the deformation that occurs during an impact, it is possible to have a large deceleration in the initial impact zone and very little change in velocity at the passenger location. Initial MEMS acceleration applications were at the center of the vehicle in the region referred to as the transmission hump or firewall. This made it possible to determine the amplitude and frequency spectrum of the deceleration and trigger the airbag after a threshold velocity change had occurred. The accelerometers in safety applications measure from 35–50 *g* of amplitude and 400 Hz of bandwidth (filtered). In measuring crash results the transfer function that includes the mounting of the accelerometer in the module is important as many printed circuit board configurations can have *Q*s of over 30 at

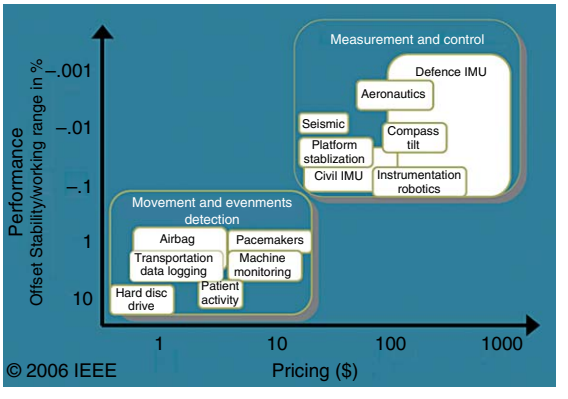

Figure 51 Representation of accelerometer market.

frequencies above 400 Hz and can create signals that appear as decelerations in the range of interest. Clipping of signals beyond the power supply limits also can confuse some algorithms when integration of acceleration to determine velocity is performed. In these algorithms, a measure of the velocity is derived from integration of the deceleration but when a nonsymmetrical response occurs the results are not indicative of actual low-frequency motion. The mechanical dampening as well as the electronic filtering of accelerometers in safety systems and for that matter in all applications must be determined to avoid errors. It is not uncommon to have an inappropriate system response to rocks, curbs, or road features when acceleration outside of the 400-Hz bandwidth of the electronic circuit excites large and often unsymmetrical signals.

The use of acceleration sensors in the forward or crush zone of a vehicle as well as in the side panels for better crash discrimination and side impact measurement has become common. The side impact event occurs in a much shorter time frame, which puts more of a burden on the sensor to discern the level of impact and the appropriate time to fire the side airbags. Frontal crashes have from 30 to several hundred milliseconds to measure and signal the start of an airbag inflation while side impact events must measure and initiate the inflation signal from 5 to 50 ms. In some systems, a pressure sensor along with the accelerometer is used to detect the crushing of the door panel to better discriminate the impact event. The structure of the vehicle is also part of the application consideration, as soft features such as a door panel will crush while support features such as a pillar will remain rigid and transmit the acceleration signal. The accelerometers mounted in the front areas of a vehicle give additional information for the inflation of airbags, especially for passenger side bags, which tend to be larger. Tragic results have occurred when individuals, especially children, have been out of the normal sitting position and a passenger airbag was inflated. This can occur when speeds are as low as 14 miles per hour. The variable inflation rate bags control the rate of inflation, which helps to match the impact event with the safety needs. Data recorded from the sensors mounted at the front crush region especially with an easily crushed vehicle give important information about the crash event.

Low-gee range devices for automotives are used for vehicle stability and vehicle dynamic control. Low-gee accelerometers have bandwidth of up to several hundred hertz and amplitudes from ± 2 to $\pm 10\,g$. The ability to control braking and suspension stiffness has made it possible to add additional handling response to a vehicle. When turning, especially on slippery surfaces such as wet pavement or snow, individual wheels can be braked and therefore tracking according to the driver intentions can be achieved. The low-gee accelerometer is used to measure the lateral acceleration that would create a spin as well as to measure the longitudinal acceleration that describes the increase or decrease in acceleration along the driving axis. These accelerations as well as the yaw rate and steering wheel angle give information to control the vehicle. In addition the vertical acceleration component or z-axis is measured to give a complete understanding of the acceleration. In recent years, information on vertical acceleration has been used to determine the onset of rollover, which is both a vehicle stability and a safety system input requirement. Rollover most often occurs during turning so lateral and longitudinal accelerations and yaw rate are beneficial information as is a rate sensor that measures roll. During rollover, airbags and seat belts can be activated in the most appropriate sequence to minimize injury. This points out the merging of safety systems and vehicle control systems in automotive applications that use accelerometers to sense the increased possibility of a safety event such as rollover while increasing the stability of a vehicle with electronic sensing and controls.

In addition to airbag and vehicle control system applications, accelerometers are finding increasing use in security systems in cars. Early security or alarm sensors were not sensitive to very low frequency so a vehicle could be jacked up slowly and the high-value wheels removed as well towing could occur. With accelerometers that can measure tilt, the alarm system can determine the onset of possible theft. This has become a feature built into some vehicles at the manufacturing stage rather than as an add-on.

2.05.7.2 Aerospace Markets

Accelerometers for aerospace applications have a long history in both small and large missile applications and more recently in projectiles that are used for delivering explosives. Because accelerometers along with gyroscopes can determine the position of a missile, ship, or airplane without additional information, accelerometers for navigational applications have been used for decades. The major source of error in determining position by the use of an accelerometer is the drift in the zero value. With the

double integration of acceleration any DC bias or error would contribute to progressively larger position error with time. Navigational accelerometers with nautical mile per hour of measurement errors have bias stability less than 25 micro-g and are very well characterized for response to vibration, shock, and temperature, which are modeled and compensated for to achieve the nautical mile in an hour's performance. The alignment errors between the different axes are corrected and compensated in an inertial measurement unit or IMU, which has three gyroscopes typically ring laser-based and three accelerometers. To achieve the overall accuracy or performance, trade-offs in accelerometer and gyro performance occur within the IMU. Tactical-grade accelerometers are required to perform for shorter periods of time such as minutes, in harsh environments of shock, vibration, and temperature extremes. They are several orders of magnitude less accurate in terms of positional measurement with null or bias stability from 200 to 1000 μg and scale factor accuracy of 300 ppm. Noise in the range of 50 $\mu g\,\mathrm{Hz}^{-1/2}$ is also typical of tactical-grade accelerometers.

The higher performance of military and aerospace accelerometers coupled with their lower volumes of usage result in higher pricing. **Figure 52** shows a view of an accelerometer used in aerospace applications such as instrument readout. The capacitive accelerometer and its associated electronics are mounted inside of a metal package and the silicon accelerometer has larger mass than automotive accelerometers. The larger mass creates a greater signal and thus makes it possible to achieve a better signal-to-noise ratio and higher resolution.

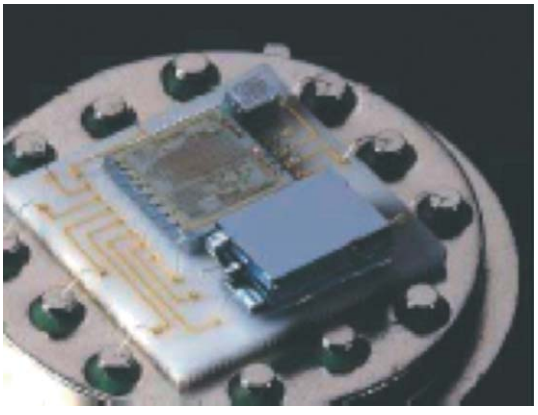

Figure 52 Photo of a Colibrys microelectromechanical systems (MEMS) accelerometer for aerospace applications.

2.05.7.3 Measurement and Instrumentation Markets

The application of accelerometers to measurement and instrumentation is a wide field with many different areas. The measurement of acceleration for shock and vibration has been a major engineering design activity for the last 50 years or more. The piezoelectric properties of quartz and ceramic materials such as PZT have been used to determine the vibration characteristics of mechanical structures from rotating machinery to missile frames and wing sections among others. Accelerometers are mounted over the structure of interest, which can be full size or a scale model and the structure is stressed, tested, or operated in extreme conditions to determine the mechanical response. Small size is crucial in this case to ensure little change of response caused by adding the accelerometer(s).

One example is the controlled crash test to certify that automotive safety systems perform to the specified standards. Accelerometers are used to instrument the vehicle initially to characterize the structure for the proper calibration and operation of an airbag system and later as a confirmation that the proper level of impact and response has occurred. Accelerometers are also used in rotating machinery to monitor bearing noise and predict time to failure. Increases in noise due to metal-bearing surface changes can be sensed with accelerometers. An increase in signal at selected frequencies can be used to determine bearing life. Dynamic balancing of wheels and other mechanisms can be aided by the measurement of acceleration during rotation. The measurement of tilt or deviation from a vertical reference is a common application of accelerometers. Drilling into or under structures and the profiling of structures as referenced to a vertical datum can be helpful in construction, crane operation, and robotic applications.

Another example is dishwasher and washing machines, the vibrations can degrade the machine performance and reduce their lifetime. MEMS accelerometers can be used to measure the vibrations and eventually to identify potential machine problems before equipment failure and allow preventive maintenance to be implemented.

2.05.7.4 Consumer Markets

Accelerometers in consumer products have found some interesting applications in such areas as disk drive protection and gesture recognition. A major change is occurring due to the increase in

functionality along with a significant reduction in pricing. The use of accelerometers to measure motion, when applied as input signals to computers, has been well documented for many years (Cheok *et al.* 2002). The accelerometer-enabled 3D wireless mouse makes it possible to move an object in space and have a corresponding object or cursor follow in a computer-generated visual model. Computer or video games can exploit this technique and make it possible to play the games or do virtual activities such as swinging a tennis racket or drive a vehicle by moving a hand-held controller. Starting from 2005, the availability of three-axis accelerometers with prices less than $2 has opened up new markets for accelerometers in video game controllers and cell phones. With the use of accelerometers a cell phone can conserve power needs by darkening the display when not needed or make selections by scrolling down a list by tilting. It can also convert the display to a horizontal or vertical format. Moreover, the measurement of activity or steps by an accelerometer creates a pedometer function that can encourage a healthy lifestyle.

Accelerometers when synchronized with a row of light-emitting diodes (LEDs) can spell out a message when the LEDs are waved across a room. A common consumer application of accelerometers now increasingly used in cell phones is the correction for tilt for a magnetic sensor. With the use of global positioning system (GPS) and a magnetic sensor, location-based services are enabled, making it possible to identify special sales or lunch menus by just pointing a cell phone at a building. There are of course many ways to analyze a golf swing or other types of motion to improve performance or rehabilitate in physical therapy and the wide range of applications to activate toys and robotic objects are just starting to be discussed.

2.05.8 Summary and Future Prospects

In this section, various acceleration sensing mechanisms are discussed. Among them, piezoresistive sensing needs standard IC processing and materials only, can be batch fabricated using inexpensive bulk micromachining, and does not require small gaps or precise gap control. Its major limitation is the large temperature sensitivity. Capacitive sensing has good temperature stability, high resolution, and low fabrication cost, but its performance is greatly affected by parasitic capacitance and it is also susceptible to EMI. Optical sensing is immune to EMI and no connecting wires are needed especially in an electrically noisy environment. Optical sensing also inherently has the capabilities of remote access and multiplexing. The challenge is the packaging as discrete optical components are involved. Piezoelectric sensing has large bandwidth and high resolution. It is also suitable for building resonant accelerometers because of its dual nature of actuation and force sensing. Its main limitation is poor DC response due to leakage. The use of non-IC materials also increases the fabrication cost. Tunneling accelerometers have the potential to obtain ultrahigh nano-g resolution, but the fabrication process is complicated and the tunneling tip height control is still challenging. Thermal sensing has very simple structures with no moving parts. It is also very inexpensive and completely foundry CMOS compatible, but its resolution and bandwidth are limited.

Accelerometers can be fabricated in many different ways. The basic process modules include bulk micromachining, surface micromachining, wafer bonding, and DRIE. In most cases, the fabrication involves a combination of two modules or more. The majority of the commercial accelerometers are surface micromachined. One advantage of surface micromachining is its potential of CMOS integration. However, due to some technical challenges, two-chip solutions are still dominant in commercial products. Bulk micromachining is often combined with wafer bonding (glass–silicon or silicon–silicon) to produce high-performance accelerometers. A recent development in which SCS sensing elements are created in CMOS substrate by using DRIE shows some promising results.

In terms of materials, almost all MEMS accelerometers are based on silicon including SOI. Various structural materials have been used, including polysilicon, silicon, SiC, nickel, quartz, PZT, ZnO, poly-SiGe, and oxide/aluminum composite. Poly-SiGe is a promising material for CMOS integration due to its low deposition temperature. There are also a variety of sacrificial materials such as oxide, polysilicon, silicon, metals, photoresist, and various polymers.

Due to the universal presence of motion, vibration, and shock, accelerometers can be applied almost everywhere, from underground drilling to space navigation, from menu selection of cell phones to safety control of vehicles, and from personal assistance of elderly people to performance improvement of athletes. The principal driving force for

accelerometer development has been the automotive industry. With the price decreasing rapidly, we will be witnessing the consumer market emerging as a driving force at a much larger scale. Capacitive accelerometers will continue their dominance overall and especially in consumer markets. Thermal sensing will play a big role in low-bandwidth applications such as physiological activity monitoring in health care. Optical accelerometers may find their niche applications in harsh environments.

The recent competition on monolithic three-axis accelerometers will continue on for a few years. The large volumes have demonstrated a price elasticity and an expectation that three-axis accelerometers will be below $1 each. More and more new applications will be enabled by the small size and low price. Meanwhile, new materials and new processes with CMOS compatibility will continue to be developed especially using SOI wafers. Single-chip integrated wireless accelerometers are not far out of reach. Body motion wireless sensor networks for health monitoring or rehabilitation, household motion sensor networks for security, and self-powered implantable accelerometers are just a few examples that are under development.

Acknowledgments

During the preparation of this manuscript, the authors had help from many people in searching papers, making drawings, providing device pictures, and reviewing the manuscript. The authors are grateful to all of them. In particular, the authors thank Drs. Wilhelm Frey and Zhiyu Pan of Bosch, Drs. Michael Judy and Jinbo Kuang of Analog Devices, Inc., Dr. Dave Monk of Freescale Semiconductor Inc., Mr. Xin Liu and Dr. Yongyao Cai of MEMSIC Inc., Kristine Wiseman of ST Microelectronics Inc., Prof. Hongwei Qu of Oakland University, Dr. Brett Warneke of Dust Networks, and Kemiao Jia and Lei Wu of the University of Florida.

Biographies

Huikai Xie is an Associate Professor at the Department of Electrical and Computer Engineering of the University of Florida. He received his MS in electrical engineering and computer science from Tufts University in 1998, and Ph.D. degree in electrical and computer engineering from Carnegie Mellon University in 2002. He also holds BS and MS degrees in electronics engineering from Beijing Institute of Technology. From 1992 to 1996, he was a research faculty member and lecturer at Tsinghua University, Beijing, China, working on various silicon-based chemical and mechanical sensors. He spent the summer of 2001 at Robert Bosch Corporation designing 6-DOF (degree of freedom) inertial measurement units. He received the 1996 Tsinghua University Motorola Education Award and the 1996 Best Paper Award from *Chinese Journal of Semiconductors*. He was also named the 2006 *Small Times*® magazine Best of Small Tech Researcher of the Year Finalist. He has published over 80 technical papers, and has two US patents granted and eight patents pending. He also serves in the technical program committees of several international conferences in the areas of MEMS and Photonics. His present research interests include micro/nanofabrication, integrated inertial sensors, microactuators, integrated power converters, optical MEMS, biomedical imaging, and fiberoptic sensors.

Mr. Robert E Sulouff is the Director of Business Development for the Micromachined products Division of Analog Devices Inc. (ADI), Cambridge, MA. He has led the start-up of the MEMS business area at ADI and is now addressing the longer-term strategic and business development opportunities of MEMS products. He joined ADI in 1993 as Product Line Director for Accelerometers and took the business from its first sales to the world's major market share producer of accelerometers and gyros. Before ADI, for seven years he was the Manager of Advanced Sensor Technology for Siemens Automotive. Preceding Siemens he was the Manager of Advance Sensors for Honeywell, Solid State Electronics Center. Mr. Sulouff was the VP of Engineering and Technology at Insouth Microsystems, a start-up which he co-founded and where he invented a MEMS accelerometer (G-Chip). He has over 35 published papers and two patents in accelerometer design. He is an active organizing member of several international technical conferences in MEMS including Hilton Head Sensors and Actuators. Educated at the University of Central Florida with BS and MS degrees in engineering materials with executive course work at MIT Sloan.

Gary K Fedder is the Howard M Wilkoff Professor of Electrical and Computer Engineering and the Director of the Institute for Complex Engineered Systems at Carnegie Mellon University (CMU). He joined CMU in 1994 with a joint appointment in ECE and the Robotics Institute. He received the BS and MS degrees in electrical engineering from MIT in 1982 and 1984, respectively. From 1984 to 1989, he worked at the Hewlett-Packard Company on circuit design and printed-circuit modeling. In 1994, he obtained the Ph.D. degree from UC-Berkeley, where his research resulted in the first demonstration of multimode control of an underdamped surface micromachined inertial device. He received the 1993 AIME Electronic Materials Society Ross Tucker Award, the 1996 Carnegie Institute of Technology GT Ladd Award, and the 1996 NSF CAREER Award. Currently, he serves as a subject editor for the *IEEE/ASME Journal of Microelectromechanical Systems*, on the editorial board of the IoP *Journal of Micromechanics and Microengineering* and as coeditor of the Wiley-VCH *Sensors Update* and *Advanced Micro- and Nanosystems* book series. He served as general cochair of the 2005 IEEE MEMS Conference. He has contributed to over 100 research publications and several patents in the MEMS area. His research interests include microsensor and microactuator design and modeling, integrated MEMS manufactured in CMOS processes, and structured design methodologies for MEMS.

2.06 Vibrating Gyroscopes

2.06.1 Introduction

Gyroscope is a sensor that measures the rate or the angle of rotation. Micromachined gyroscopes constitute one of the fastest growing segments of the microsensor market. The application domain of these devices is rapidly expanding from automotive to consumer electronics industry and personal navigation systems. A multitude of applications exist in the automotive sector including navigation, antiskid and safety systems, rollover detection, and next-generation airbag and antilock brake systems. Consumer electronics applications include image stabilization in digital cameras and smart user interfaces in handhelds, gaming, and inertial pointing devices.

Miniature gyroscopes can also be used for navigation purposes. Inertial navigation is the process of determining the position of a body in space by using the measurements provided by accelerometers and gyroscopes installed on the body. Inertial measurement units (IMUs) are vital components in aircraft, unmanned aerial vehicles, global positioning system (GPS)-augmented navigation, and personal heading references. An IMU typically uses three accelerometers and three gyroscopes placed orthogonally along the coordinate axes to gather information about an object's direction and heading. The components of acceleration and rotation rate can consequently be interpreted to yield the object's accurate position in space. An IMU is self-contained and can aid in accurate short-term navigation of a craft or an object in the absence of GPS-assisted inertial navigation (Lawrence 1993).

The applications space of microgyroscopes can be divided based on performance requirements. Table 1 summarizes the performance requirements for rate-grade and navigation-grade gyroscopes. The majority of automotive and consumer electronics applications require rate-grade performance (as indicated in Table 1), whereas higher-precision navigation-grade devices are suitable for IMUs and high-end applications in aerospace and petroleum industry. The petroleum industry uses gyroscopic sensors for real-time monitoring and correction of drilling in offshore rigs. Guidance systems and platform stabilization of missiles are but a few of the military applications that require accurate angular measurements.

Table 1 Performance requirements for rate-grade and navigation-grade gyroscopes

	Rate grade	*Navigation grade*
Angle random walk ($\deg h^{-1/2}$)	>0.5	<0.005
Bias drift ($\deg h^{-1}$)	10–1000	<0.1
Scale factor accuracy	0.1–1%	<10 ppm
Full scale range ($\deg s^{-1}$)	50–1000	>500
Shock level (g)	1000	10^3–10^4
Bandwidth (Hz)	>70	~10–100

Micromachined gyroscopes are projected to become practical alternatives to expensive and bulky conventional inertial sensors in the near future. Current high-performance rotation sensors including precision fiber-optic gyroscopes, ring laser gyroscopes, and conventional rotating wheel gyroscopes are too expensive and/or too large for use in most emerging applications. With micromachining processes allowing mass production of micromechanical systems on a chip together with their control and signal conditioning electronics, low-cost and micromachined silicon gyroscopes will provide high-accuracy rotation measurements. Moreover, advances in the fabrication techniques allow the detection and control electronics to be integrated on the same silicon chip together with the mechanical sensor elements. Thus, miniaturization of vibratory gyroscopes through innovative microfabrication processes and gyroscope designs is expected to become a very attractive solution to current inertial sensing market needs as well as to open new market opportunities.

In the past decade, much of the effort in developing micromachined gyroscope has concentrated on rate-grade devices driven by investments from the automotive industry. These applications require a resolution of about $0.1°\deg s^{-1}$ in a 50-Hz bandwidth. Small form factor, lightweight, and low power consumption make micromachined microgyros ideal for use in handheld applications, many of which requiring multiaxis devices. As mentioned earlier, short-range navigation and guidance require resolution and bias drift properties approaching or better than $0.1°\deg h^{-1}$. Such performances have yet to be demonstrated by current silicon micromachined gyroscopes. However, in recent years, several Defense Advanced Research Projects Agency (DARPA)-sponsored initiatives have been made to examine the feasibility of navigation-grade performance in micromachined silicon gyroscopes.

Although bulk mechanical and optical gyroscope technologies have successfully demonstrated navigation-grade performance, their constituent components

are difficult to miniaturize and develop on silicon substrate using conventional CMOS fabrication technique. Hence, microelectromechanical systems (MEMS) research has almost exclusively focused on the third class of devices referred to as vibratory gyroscopes.

2.06.2 Coriolis Vibratory Gyroscopes

Vibratory gyroscopes use vibrating mechanical elements to sense rotation. They have no rotating parts that require bearings and can easily be miniaturized and batch fabricated using micromachining techniques. Vibratory gyroscopes are based on the transfer of energy between two vibration modes of a structure induced by Coriolis acceleration. Coriolis acceleration, named after the French scientist and engineer Gaspard Gustave de Coriolis (1792–1843), is an apparent acceleration that arises in a rotating reference frame and is proportional to the rate of rotation. The Coriolis effect may be illustrated with an example of a flying object as viewed through the eyes of an observer located on a rotating reference frame as shown in Figure 1. The observer located along the x-axis of the xyz coordinate system views an object traveling above him/her in space with a certain velocity $\mathbf{v}$. If the observer's reference frame rotates normally (about the z-axis) with an angular velocity $\vec{\Omega}$, to the observer the object appears to move toward the x-axis with an acceleration $2\vec{v} \times \vec{\Omega}$. Although no real force has been exerted on the flying object, to the observer located on the rotating reference frame, an apparent force has resulted which is directly proportional to the rate of rotation.

2.06.2.1 Coriolis Acceleration

To better understand Coriolis acceleration, it is often helpful to study it analytically. In Figure 1(b), frames A and B are the inertial and the rotating reference frames, respectively. The component $\vec{r}_A$ and $\vec{r}_B$ are position vectors relative to the inertial and rotating frames. Finally, $\vec{\theta}$ and $\vec{R}$ refer to the orientation and the position of the rotating frame B, respectively.

The time derivative of any vector $\vec{r}$, which is defined in frames A and B, is indicated by the transport theorem (Haim 1998) as

$$\frac{d}{dt}\overrightarrow{r_A(t)} = \frac{d}{dt}\overrightarrow{r_B(t)} + \frac{d}{dt}\theta \times \overrightarrow{r_B(t)} \quad [1]$$

Taking the second time derivative of the position vector, the acceleration of a body moving with the rotating reference frame may be calculated as

$$\overrightarrow{r_A(t)} = \overrightarrow{R(t)} + \overrightarrow{r_B(t)} \quad [2]$$

$$\frac{d}{dt}\overrightarrow{r_A(t)} = \frac{d}{dt}\overrightarrow{R(t)} + \frac{d}{dt}\overrightarrow{r_B(t)} + \frac{d}{dt}\theta \times \overrightarrow{r_B(t)} \quad [3]$$

$$\begin{aligned}\frac{d^2}{dt^2}\overrightarrow{r_A(t)} = {} & \frac{d^2}{dt^2}\overrightarrow{R(t)} + \frac{d^2}{dt^2}\overrightarrow{r_B(t)} + \frac{d}{dt}\theta \times \frac{d}{dt}\overrightarrow{r_B(t)} + \frac{d}{dt}\theta \\ & \times \left(\frac{d}{dt}\theta \times \overrightarrow{r_B(t)}\right) + \frac{d^2}{dt^2}\theta \times \overrightarrow{r_B(t)} \\ & + \frac{d}{dt}\theta \times \overrightarrow{r_B(t)}\end{aligned} \quad [4]$$

By replacing the first and second time derivatives of the reference frames with velocity and acceleration components, respectively, the acceleration expression reduces to

$$\vec{a}_A = \vec{A} + \vec{a}_B + \Omega \times \vec{r}_B + \Omega \times \left(\Omega \times \vec{r}_B\right) + 2\Omega \times \vec{v}_B \quad [5]$$

The term $2\vec{\Omega} \times \vec{v}_B$ is the Coriolis term. The vibratory rate gyroscope can essentially be viewed as an accelerometer measuring the Coriolis acceleration to

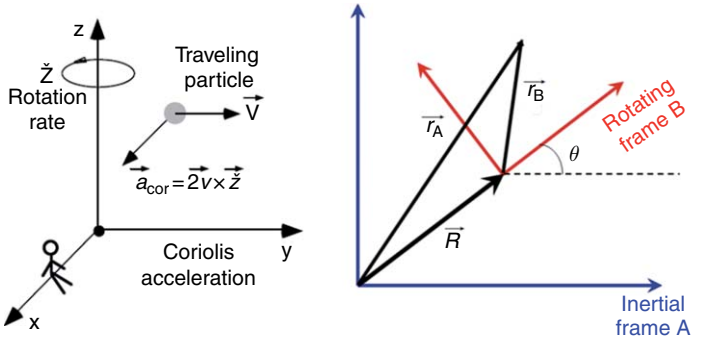

Figure 1 (a) Visualization of the Coriolis effect and (b) derivation of Coriolis acceleration.

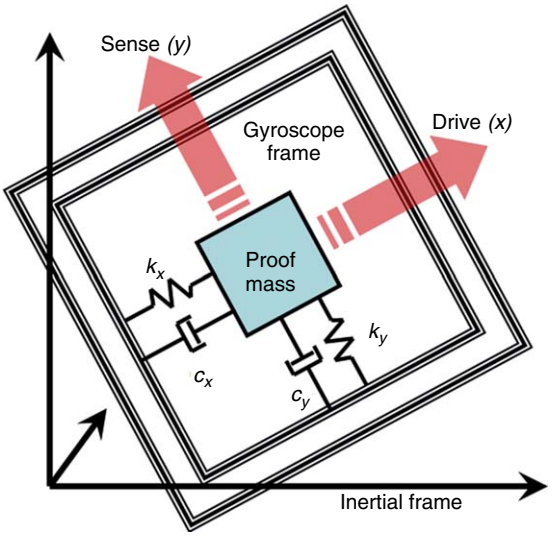

Figure 2 Illustration of a rotating gyroscope frame along an inertial frame.

calculate the rotation rate. Using **Figure 2**, we examine the equation of motion on a single proof mass subjected to rotation about an inertial reference frame.

$$\vec{F} = M\left(\vec{A} + \vec{a}_B + \Omega \times \vec{r}_B + \Omega \times (\Omega \times \vec{r}_B) + 2\Omega \times \vec{v}_B\right) \quad [6]$$

In eqn [6] $\vec{A}$ and $\vec{\Omega}$ are the linear acceleration and angular velocity of the rotating gyroscope frame, respectively, while $\vec{v}_B$ and $\vec{a}_B$ are the velocity and acceleration vectors of the gyroscope proof mass with respect to the inertial reference frame, respectively. When the proof mass motion is decomposed along its two principal vibratory axes and linear accelerations are canceled out, the two equations of motions are expressed as (Acar and Shkel 2005)

$$\begin{aligned} m\frac{d^2}{dt^2}x + c_x\frac{d}{dt}x + \left(k_x - M\left(\Omega_y^2 + \Omega_z^2\right)\right)x \\ + M\left(\Omega_x\Omega_y + \frac{d}{dt}\Omega_z\right)y \\ = \tau_x + 2M\Omega_z\frac{d}{dt}y \end{aligned} \quad [7]$$

$$\begin{aligned} m\frac{d^2}{dt^2}y + c_y\frac{d}{dt}y + \left(k_y - M\Omega_x^2 + \Omega_z^2\right)y \\ + M\left(\Omega_x\Omega_y + \frac{d}{dt}\Omega_z\right)x \\ = \tau_y + 2M\Omega_z\frac{d}{dt}x \end{aligned} \quad [8]$$

For a constant angular rate, and neglecting the minimal contributions of second-derivative components of off-axis angular acceleration, the simplified 2-degrees of freedom equations of motion for the gyroscope proof mass may be expressed as follows:

$$m\frac{d^2}{dt^2}x + c_x\frac{d}{dt}x + k_x x = \tau_x + 2M\Omega_z\frac{d}{dt}y \quad [9]$$

$$m\frac{d^2}{dt^2}y + c_y\frac{d}{dt}y + k_y y = \tau_y + 2M\Omega_z\frac{d}{dt}x \quad [10]$$

The terms $2M\Omega_z\frac{d}{dt}x$ and $2M\Omega_z\frac{d}{dt}y$ are the rotation induced and causes dynamic coupling between the vibratory axes and are utilized for angular rate measurements in vibratory gyroscopes.

As can be seen from the previous discussion, it is necessary to devise a mechanism to excite the mass into its reference vibration. A second mechanism that must be implemented is a scheme to pick off the Coriolis-induced signal. Various schemes have been used to implement the drive and the pickoff mechanisms for Coriolis microgyroscopes. The reference drive excitation can be achieved using piezoelectric, capacitive electrostatic, or electromagnetic actuation schemes. Similarly, the Coriolis signal can be picked off using piezoresistive or capacitive means. The subject matter of the following sections refers mainly to the case of capacitive, silicon vibratory Coriolis microgyroscopes.

2.06.2.2 Classifications of Vibratory Gyroscopes

Vibratory gyroscopes are based on the transfer of energy between two vibration modes of a structure and can operate in either matched-mode or split-mode condition. Under matched-mode condition, the sense mode is designed to have the same (or nearly the same) resonant frequency as the drive mode. Hence, the rotation-induced Coriolis signal is amplified by the mechanical quality factor (Q) of the sense mode. In split-mode condition, the drive and the sense modes are separated in resonant frequency. The sense mode is then a controlled mode that operates similar to an accelerometer and measures the Coriolis acceleration. Owing to Q-amplification, gyroscopes operated under matched-mode configuration offer higher sensitivity and better resolution. Resonant matched devices are broadly classified into two types depending on the nature of their operating modes (**Figure 3**). Type I devices rely on nondegenerate vibration modes for driving and sensing. Tuning fork and frame gyroscopes are examples of type I gyroscopes. Type II devices on the contrary function with

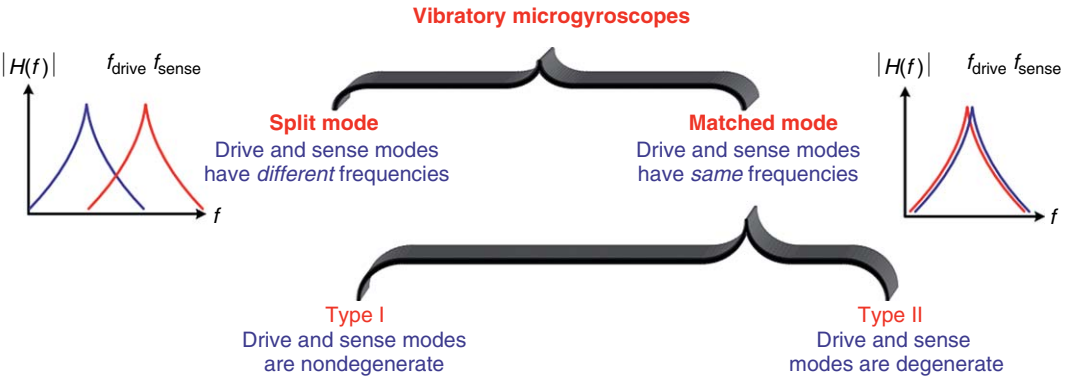

Figure 3 Classification of gyroscopes based on operational modes.

degenerate vibration modes and are invariably easier to match and operate under matched condition. Shell-type gyroscopes are examples of type II gyroscopes.

2.06.2.3 Gyroscope Performance Parameters

2.06.2.3.1 Resolution

The resolution of a gyroscope refers to the minimum rotation rate that can be distinguished from the noise floor of the gyroscope system. The overall resolution of the micromachined vibrating silicon gyroscope is determined by two uncorrelated components: the mechanical (or Brownian) and the electronic noise floors.

$$\Omega(\text{Overall}) = \sqrt{\Omega^2(\text{Brownian}) + \Omega^2(\text{Electronic})} \quad [11]$$

Brownian motion of the structure caused by molecular collisions from surrounding medium represents the mechanical noise component of any vibratory gyroscope (Yazdi *et al.* 1998). By equating the displacement caused by Brownian motion to the displacement induced by Coriolis acceleration, one may derive the mechanical resolution of a vibratory microgyroscope as given by eqn [12]. The quantities k_B, T, and BW represent the Boltzmann constant (1.38e–23 J K^{-1}), operating temperature (K), and measurement bandwidth (Hz), respectively. In the expression, ω_0 is the resonant frequency of the sensor, M its mass, q_{drive} the amplitude of vibration along the reference axis, and Q_{EFF} the effective quality factor of the system. For a given mechanical structure, Q_{EFF} can be maximized by matching the frequencies of the drive and the sense modes, as will be explained in a subsequent section.

$$\Omega(\text{Brownian}) \propto \frac{1}{q_{\text{drive}}} \sqrt{\frac{4k_B T}{\omega_0 M Q_{\text{EFF}}}} \sqrt{BW} \quad [12]$$

Evaluating the electronic noise floor is dependent on the interface electronics architecture. However, assuming the noise at the output V_n has a white spectrum near the operating frequency, the minimum detectable rotation rate limited by electronic noise can in general be simplified as follows (for a capacitive detection system):

$$\Omega(\text{Electronic}) \propto \frac{g_0^2}{V_P} \frac{\omega_0 C_{\text{parasitics}} V_n}{q_{\text{drive}} Q_{\text{EFF}}} \sqrt{BW} \quad [13]$$

In eqn [13], g_0 and V_P represent the rest sense gap and the polarization voltage applied to the substrate, respectively. $C_{\text{parasitics}}$ is the total parasitic capacitance between the sensor and the electronic front-end and that of pads, bond wires, and circuit gate. It is evident from both equations that drive amplitude, device mass, and sense gaps play a key role in determining the overall noise floor in a vibratory gyroscope system. Resolution is expressed in units of noise floor (deg h^{-1} Hz$^{-1/2}$) or in terms of angle random walk (ARW) (deg h$^{-1/2}$) (Ayazi 2000).

2.06.2.4 Sensitivity and Scale Factor

From eqn [10], the motion along the sensitive axis (y) in response to a normal rotation rate (Ω_z) may be expressed as follows:

$$y = \frac{2\Omega_z \omega_x q_{\text{drive}}}{\omega_y^2} \quad [14]$$

In this expression, ω_x and ω_y are the drive and the sense mode frequencies and q_{drive} is the displacement along the driven axis. It is quite evident that increasing q_{drive} has beneficial attributes beyond device resolution. As was with the case of the noise floor, for a given mechanical sensor, the sensitivity can be maximized by maximizing Q_{EFF}. The Coriolis-induced displacement produces a capacitance change that can be converted into a voltage using an electronic front-end. The sensitivity to (volts.degree^{-1}.second^{-1}) of the microgyroscope can then be expressed as

$$\text{Sensitivity} \propto \frac{2V_{\text{P}}}{C_{S0} + C_{\text{parasitics}}} \frac{C_{S0}}{g_0} \frac{Q_{\text{EFF}} q_{\text{drive}}}{\omega_0} \qquad [15]$$

Sense mode oscillations are typically detected through capacitive, piezoresistive, piezoelectric, or optical means. Rate sensitivity or scale factor in vibratory gyroscope is most commonly expressed in units of volts per degree per second. Another aspect to be considered with regard to scale factor is the linearity. This is a measure of the deviation from the normalized sensitivity line.

2.06.2.4.1 Bias stability

An important measure of long-term stability of a gyroscope is its bias drift. Very similar to offset in circuits, the bias drift of a gyroscope is composed of systematic and random components. The systematic components arise due to temperature variations, linear accelerations, vibrations, and other environmental factors (Institute of Electrical and Electronics Engineers (IEEE) 1997). Empirical studies have tried to formulate an expression that can predict drift in gyroscopes (Watson and Henke 2002), but considerable research remains to be done.

The random component of bias drift has a $1/f$ noise characteristic and is related to the ARW of the device, which in turn depends on the system noise floor. The bias stability of the gyroscope measures the drift of the output offset over time. The drift can be measured in several ways, but the most commonly used means at present is the Allan variance technique (IEEE 1997). A sample of this analysis will be examined during the case study of the matched-mode tuning fork gyroscope (M^2-TFG). The bias drift is usually expressed in units of degrees per hour.

The bias drift of a microgyroscope becomes important when the fact that it is used along with accelerometers to obtain heading information, i.e., position and orientation, is considered. The rate information from the microgyroscope is integrated to obtain the angle. Any long-term variations in the rate (of which the bias drift is an accurate indicator) add up and can cause a large error in angle and orientation information. Modern gyroscope systems periodically calibrate themselves with GPS to ensure that the heading information is accurate. The longer a system can function accurately without the need for calibration, the better and more accurate heading and orientation information it can deliver. A long interval between calibration sequences is crucial for applications such as deep-sea navigation and oil exploration where it is not possible to resurface very easily to calibrate with GPS.

2.06.2.4.2 Bandwidth and dynamic range

The bandwidth of the gyroscope system determines the response time of the system. This is the time required for the output to settle within a certain range of the expected value for an input step function.

The final performance criterion regularly used in specifying gyroscope performance is the dynamic range. This refers to the range of input values over which the output is detectable. Typically, it is computed as the ratio between the maximum input rotation rate (full scale rate) that the sensor can tolerate and the system noise floor.

2.06.2.5 Gyroscope Interface Electronics

As micromachined silicon gyroscopes scale aggressively to meet higher performance parameters, the interface electronics that actuate, sense, and control these micromechanical structures play a vital role in determining the overall performance of the microgyroscope system. **Figure 4** shows a schematic overview of the constituent system blocks in a typical microgyroscope system. Based on functionality, the electronics can be divided into the following subsystems:

(1) Drive oscillator: Sets up the reference vibration of the structure/proof-mass along the reference axis.
(2) Sense channel: Extracts the rotation-induced Coriolis signal along the sensitive axis.
(3) Quadrature nulling scheme: Measures and minimizes quadrature error in the sense channel.
(4) Automatic frequency tuning: Eliminates the frequency separation between the drive and sense resonant modes.
(5) Self-test and trimming: Calibrates the sensor periodically.

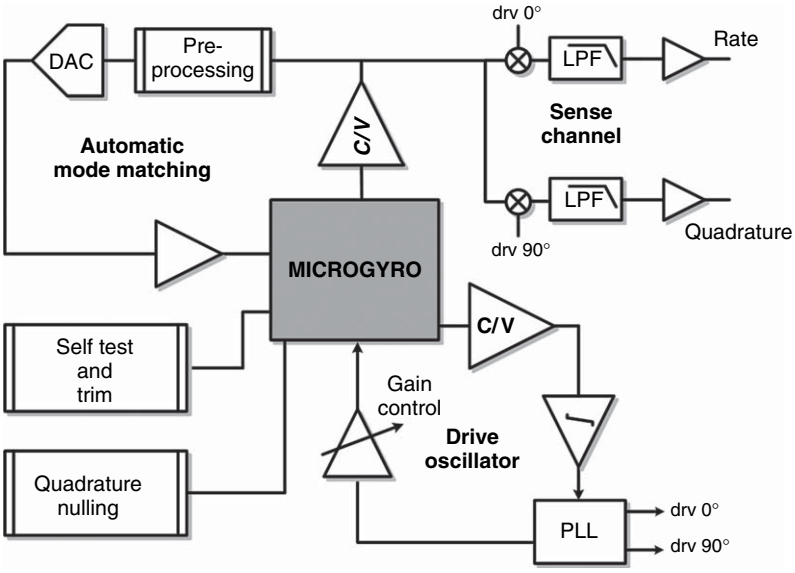

Figure 4 Overview of a typical micromachined vibratory gyroscope system.

2.06.2.5.1 Drive loop

The drive loop electronics is responsible for starting and sustaining oscillations along the reference axis at a constant amplitude. It is essential that a constant drive amplitude be maintained, as any variation in the drive amplitude manifests itself as a change in the velocity of the mechanical structure (along the driven axis). Velocity fluctuations modulate the sensor output and can result in a false or an inaccurate rate output. The drive loop uses an automatic level control (ALC) circuit to achieve and maintain a constant drive amplitude. Typically, there are two approaches to implement the drive loop:

(1) An electromechanical oscillator approach
(2) A phase-locked loop (PLL)-based approach

A high Q for the drive resonant mode can significantly ease the design of the drive oscillator. A large drive-Q enables the oscillations to be built up and sustained using much smaller voltage levels. Because the vibratory microgyroscope is a mass-spring system, it can be modeled using second-order dynamics. The drive mode of the microgyroscope can be modeled in a fashion similar to that for a micromachined resonator (Pourkamali *et al.* 2004) using a series RLC circuit. While the L (inductance) and C (capacitance) components determine the modal frequency and get canceled at resonance, the motional impedance, R, represents a loss mechanism. The loss due to this motional impedance must be compensated for by an electromechanical oscillator. A large drive-Q implies low motional impedance. A low motional impedance drive loop allows for reduced voltages and alleviates gain requirements for the sustaining electronics.

The microgyroscope can be driven to oscillation by placing it in a feedback loop satisfying the Barkhausens criterion, i.e., maintaining unity gain and zero phase shift. The microgyroscope is the frequency-determining element in this loop, as shown in **Figure 5(a)**. The front-end is a current-to-voltage (I-V) converter cascaded with a phase-shifting buffer. In **Figure 5(b)**, the reference drive vibrations are setup using a PLL. A PLL locks on to the output of the front-end I-V converter. The PLL output is amplified or attenuated to achieve the desired voltage amplitude and used to drive the microgyroscope. Alternately, a variable gain amplifier can be used to implement the ALC.

The electromechanical oscillator approach is more attractive than the PLL approach as it has lower power dissipation. However, the mechanical motional impedance of the drive resonator can be on the order of a few megaohms in certain vibratory structures and thereby limit the use of this approach.

2.06.2.5.2 Sense channel

The rotation-induced Coriolis force is an amplitude-modulated (AM) signal where the carrier frequency is the drive oscillation frequency and the input rotation rate modulates the amplitude. The resulting Coriolis acceleration is a dual-sideband signal centered at the drive oscillation frequency. Synchronous

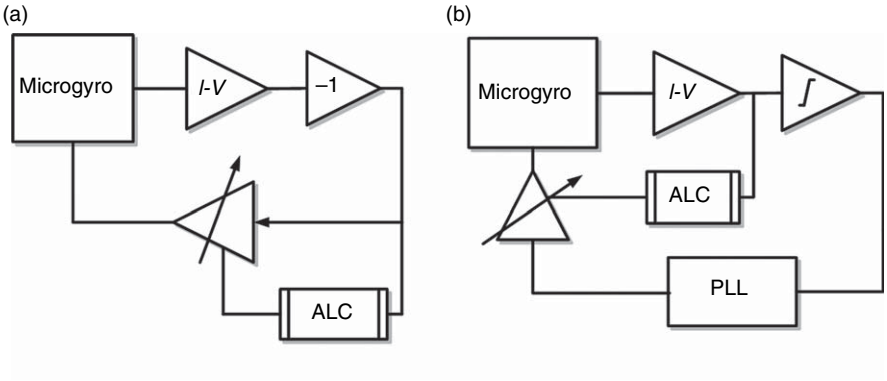

Figure 5 Drive loop implemented using (a) electromechanical oscillator and (b) phase-locked loop (PLL). ALC, automatic level control.

demodulation widely used in AM communication receivers can be utilized for extracting the rate information from the microgyroscope. The AM Coriolis output is demodulated using the drive oscillator signal. This phase-sensitive demodulation allows for rejection of the interfering mechanically generated quadrature error. The low-pass-filtered baseband signal is proportional to input rotation rate and may be amplified if necessary at a later stage. Because synchronous demodulation allows for phase-sensitive detection and therefore rejection of quadrature error, it is preferred to other techniques such as envelope detection.

The primary challenge in implementing the sense channel is to design a low-noise front-end for I-V conversion. The Coriolis-induced displacement of the microgyroscope along the sense axis is on the order of a few angstroms. For resolving such minute rate signals, the front-end noise floor and therefore the minimum detectable capacitance change must be minimized to the order of a few attofarads. The task of designing circuits that can accurately measure such capacitance changes is made all the more difficult by the presence of large parasitic capacitances. In a typical two-chip solution (where the IC and device are on separate substrates), the input parasitic capacitances are on the order of 1 to 10 pF.

As summarized in **Table 1**, commercial rate-grade applications require noise floors on the order of 10 to 100 deg h^{-1} and should typically be able to sense rotation rates as large as ± 500 deg s^{-1}. Navigation-grade gyroscopes typically have similar full-scale range, but the noise floor specifications are sub-0.1 deg h^{-1}. This is roughly two orders of magnitude lower than their commercial counterparts and calls for the sensor to have a large dynamic range. While mechanical structures can attain dynamic ranges greater than 120 dB, designing front-end electronics with such a large dynamic range is challenging. The dynamic range is limited by the supply voltage on the one hand and the noise floor on the other. With the continued scaling of CMOS process to narrower channel lengths, flicker noise in transistors and the reduced voltage headroom make the achievement of dynamic ranges greater than 100 dB extremely challenging.

There are a number of approaches for Coriolis rate detection (Boser 1997). Quartz rate sensors (QRSs) use piezoresistive techniques (Voss *et al.* 1997), while voltage buffers have also been commonly used (Ayazi and Najafi 2001, Putty and Najafi 1994) as front-ends for capacitive microgyroscopes. Transimpedance front-ends are the most promising candidates for tactical-grade systems as they offer low current noise and therefore subattofarad capacitance resolutions (Saukoski *et al.* 2005, Sharma *et al.* 2006). Because the output of the microgyroscope is a motion-induced current, charge amplifier integrators are preferred to voltage buffers as they allow a trade-off between gain and bandwidth (Clark *et al.* 1996).

2.06.2.5.3 Quadrature nulling

There exists a large error signal common to all vibratory rate gyroscopes that is caused by imbalances in the mechanical elements due to fabrication imperfections (Clark *et al.* 1996). These imbalances cause the proof mass to vibrate at an angle of θ_Q from the actual drive axis. This subsequently results in mechanical coupling of the drive resonator motion to the sensitive axis and an oscillatory deflection that is measured along the sense axis with the

Coriolis-induced deflections. Both the quadrature error and the Coriolis deflection are AM signals centered at the drive resonant frequency. The only distinguishing feature between the two signals is that they have a relative phase difference of 90°, and hence, the origin of the term quadrature error. The 90° phase difference is because the Coriolis acceleration is sensitive to proof mass velocity along the drive axis, while the quadrature error is proportional to the proof mass position along the drive axis.

The ratio of quadrature-induced displacement to the Coriolis-induced displacement at matched mode is expressed as

$$\left.\frac{\mathcal{Y}_{\text{Quadrature}}}{\mathcal{Y}_{\text{Coriolis}}}\right|_{\text{Matched-Mode}} \approx \frac{\omega_0 \cdot \theta_Q}{2\Omega_z} \qquad [16]$$

Eqn [16] indicates that even a small angle θ_Q can cause a significant quadrature error, much greater than the Coriolis-induced displacement. Micromachining silicon technology has much lower mechanical tolerances as compared with advanced CMOS processing. A 1.7-μm-wide flexure will typically be defined to no better than 0.2 μm (Geen *et al.* 2002). Consequently, the majority of the quadrature error results from off-diagonal elements in the spring stiffness matrix as shown in **Figure 6**. For this reason, reducing quadrature error is best achieved by ensuring that the spring stiffness matrix is diagonalized by applying specific quadrature nulling techniques.

Quadrature nulling of any gyroscopic sensor depends significantly on the nature of the mechanical structure. A number of techniques have been used to null quadrature error. Some of the earliest works (Barnaby and Morrow 1956, Barnaby and Reinhardt 1951) involved trimming and bucking to control quadrature error, but these techniques did not track over temperature and life. Other techniques involved servomechanisms whereby a force was applied to the mass so as to null any displacement of the proof mass that is in phase with position (Clark *et al.* 1996). The surface micromachined gyroscopes developed by researchers at HSG-IMIT are based on the decoupled angular velocity detector (DAVED) approach (Geiger *et al.* 2001). The technique has been shown to reduce quadrature error by a factor of 5, by the use of two types of one-dimensional springs. The first restricts the drive resonator motion to one dimension, while the second restricts the motion of the sensing mass relative to the driven mass to one dimension as well. The Analog Devices gyroscope uses a set of optimally designed levers (Geen *et al.* 2002) to reduce quadrature error to less than 1 ppm by improving the selectivity of the suspension flexures. Yet another technique that has been implemented is the use of torque cancelation electrodes (Putty and Najafi 1994, Sharma *et al.* 2007) to correct for any misalignment between the drive and the sense axes.

2.06.2.5.4 Self-test and trim

To be viable in a large-scale manufacturing environment, the microgyroscope systems must be equipped with a self-test capability to ensure quality and reliability. Apart from significantly reducing test times at the production facility, these systems allow for calibration of the sensor in the field. Currently, most gyroscope systems use postfabrication trimming to a certain extent to account for microfabrication imperfections. With the development of more advanced lithographic tools and etching systems, the use of these trimming procedures can be minimized.

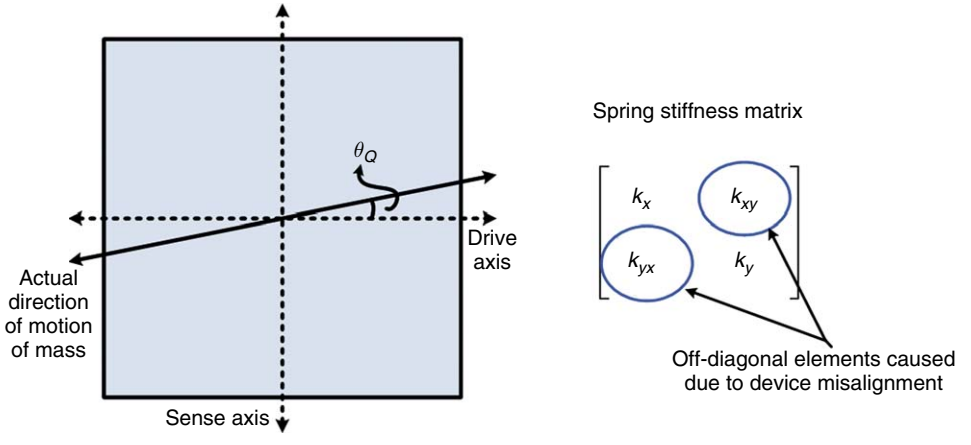

Figure 6 Demonstration of quadrature error in a proof mass of a vibratory gyroscope.

2.06.2.5.5 Advantages of mode matching

The system noise floor and the sensitivity of the microgyroscope depend on the Q_{EFF} of the system. The microgyroscope is a resonant MEMS sensor, and the Q_{EFF} represents the mechanical gain of the sensor. From eqns [11] through [13], it is evident that the noise floor and the sensitivity are maximized by maximizing Q_{EFF}. Q_{EFF} depends on the inherent mechanical quality factors of the structure as well as on the frequency split between the drive and sense modes. For a given mechanical structure, Q_{EFF} can be maximized by equalizing the drive and the sense resonant mode frequencies, i.e., drive resonant frequency (ω_x) = sense resonant frequency $(\omega_y) = \omega_0$. When the drive and the sense frequencies are matched, there is maximum energy coupling between the drive and the sense modes and therefore maximum sensitivity.

Mode matching is therefore essential for leveraging the maximum mechanical gain (Q_{EFF}) of the sensor. Empirical studies have suggested eqn [17] for the bias drift of gyros (Watson and Henke 2002), once again highlighting the need for mode matching.

$$N_B \frac{\omega_o^2}{Q_{drive} Q_{sense} Area_{electrodes}} \qquad [17]$$

Mode matching, however, is not without its own problems. First, Q-amplification increases the sensitivity of the gyro to the Coriolis-induced acceleration (by Q_{sense}). However, any spurious displacements in the y-direction, such as quadrature error, are also amplified by the same mechanical gain Q_{sense}. Second, after the modes have been matched, it is necessary to continuously monitor the modes and maintain matching. This demands continuous-time (CT) monitoring and correction of any mismatch that can occur as a result of environmental changes, shock, etc. Finally, from a commercial point of view, an automatic mode-matching circuit is more cost-effective as it can replace any expensive trimming that needs to be done. Hence, a robust technique and a feasible CMOS-compatible implementation that can achieve automatic mode matching must be developed.

2.06.2.5.6 Automatic mode matching and quadrature revisited

Mode matching of a gyroscope is closely related to the quadrature error problem. Quadrature error in vibratory gyroscopes has been recognized as the single most important factor that precludes perfect mode matching (i.e., zero frequency split between the drive and the sense resonant frequencies) (Clark *et al.* 1996).

It must be noted that a matched-mode device is one in which the drive and the sense modes are eigenmodes – i.e., they are degenerate. The quadrature-induced off-diagonal terms in the spring stiffness matrices prevent the eigenmodes to be degenerate, leading consequently to a mismatch in the resonant frequencies. In order to achieve mode degeneracy, it is necessary that these terms be electronically eliminated and the spring stiffness matrix be diagonalized. **Figure 7** shows how the K-matrix can be made symmetric by applying quadrature cancelation voltages to eliminate the off-diagonal terms. Hence, quadrature cancelation is essential to attain and maintain mode matching. Once the quadrature error has been nulled, the drive and the sense stiffness coefficients can be made equal to ensure that the drive and the sense frequencies are equal. This is achieved through electrostatic spring softening.

An automatic mode-matching system must be able to match the frequencies of the drive and the sense modes. There has been considerable work in this respect as such a system would be invaluable in applications where frequent calibration of the gyroscope is not possible, for instance, in IMUs for aircraft, unmanned surveillance vehicles, etc. Boeing and Jet Propulsion Laboratory (JPL) have implemented a mode-matching ASIC (Keymeulen *et al.* 2005) that uses evolutionary computation to achieve mode matching. The use of a dual PLL approach (Sung *et al.* 2006) has also been suggested to implement automatic mode matching.

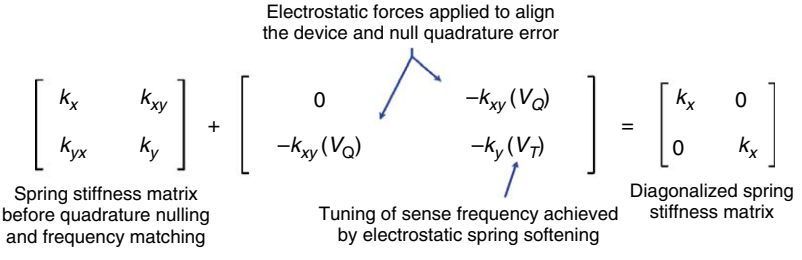

Figure 7 Application of a balancing voltage explicitly cancels off the off-diagonal terms.

2.06.3 Overview of Silicon Micromachined Vibratory Gyroscopes

The first batch-fabricated silicon micromachined rate gyroscope was demonstrated by the Charles Stark Draper Laboratory in 1991. This p-doped silicon bulk mechanical device was a double-gimbal vibratory gyroscope supported by torsional flexures (Greiff *et al.* 1991). In this design, an outer gimbal was electrostatically excited at a constant amplitude using drive electrodes. This oscillatory motion was transferred to the inner gimbal along the stiff axis of the inner flexures. When exposed to a rotation input normal to the plane of the device, Coriolis force causes the inner gimbal to oscillate about its sensitive axis. A rotation rate resolution of $4\,\mathrm{deg\,s^{-1}}$ was realized using this structure.

Two years later, in 1993, the Charles Stark Draper Laboratory also reported a silicon-on-glass tuning fork gyroscope (**Figure 8**) (Bernstein *et al.* 1993) fabricated using the dissolved wafer process (Gianchandani and Najafi 1992). This gyroscope was electrostatically vibrated in its plane using a set of interdigitated comb drives to achieve drive amplitudes as large as 10 μm. Any rotation signal normal to the drive mode would then excite the out-of-plane rocking mode of the structure that is capacitively monitored. The noise equivalent rate observed by this structure was $0.1\,\mathrm{deg\,s^{-1}}$ in a 60-Hz bandwidth.

Miniaturized gyroscopes, however, existed before 1993. Quartz-based vibratory gyroscopes had already been around in the early 1980s. Examples of these devices are fused-quartz hemispherical resonator gyro (HRG) by Delco (Ragan and Lynch 1984), quartz tuning forks such as the QRS by Systron Donner (Soderkvist 1990), and a piezoelectric vibrating disk gyro (Burdess and Wren 1986). Although quartz vibratory gyroscopes can yield high quality factors at atmospheric pressure and demonstrate high sensitivity, the fabrication technology is not compatible with IC fabrication technology.

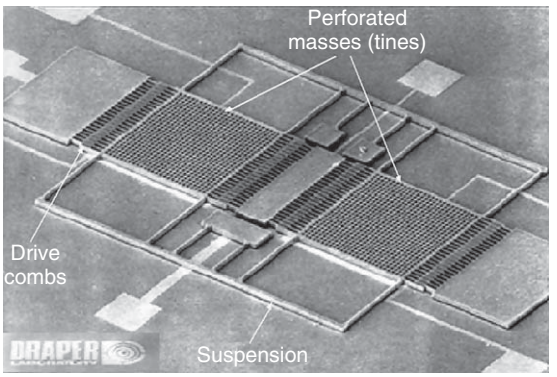

Figure 8 SEM view of Draper's silicon-on-glass tuning fork gyroscope. (Source: Bernstein J, Cho S, King T, Kourepenis A, Maciel P, Weinberg M 1993 A micromachined comb-drive tuning fork rate gyroscope. *Proc. IEEE Micro Electro Mechanical Systems Workshop (MEMS 93)*, Fork Lauderdale, FL, USA, pp. 143–148.

In the late 1980s, after successful demonstration of batch-fabricated silicon accelerometers, extensive efforts were initiated to replace quartz with silicon in micromachined vibratory gyroscopes. A number of vibratory gyroscope structures were demonstrated in the process: (i) tuning fork structures, (ii) vibrating beams or proof masses, (iii) vibrating shells, and (iv) frame gyroscopes. In Section 2.06.4.1 various capacitive micromachined gyroscopes in terms of the process technology are discussed. It was mentioned earlier that piezoresistive and capacitive techniques are the primary means of detecting Coriolis-based motion of vibratory gyroscopes. Although piezoresistive devices are easier to fabricate and require a simpler electronic interface because of their lower output impedance when compared with capacitive devices, they have high temperature sensitivity and consequently suffer from poor resolution and stability. For this reason this chapter focuses on capacitive vibratory gyroscopes. In general, micromachining processes for fabrication of capacitive vibratory gyroscopes fall into one of three categories: (i) silicon bulk micromachining and wafer bonding, (ii) polysilicon surface micromachining, and (iii) combined bulk–surface micromachining also commonly referred to as mixed processes.

2.06.3.1 Surface Micromachined Gyroscopes

The field of surface micromachined vibratory gyroscopes has been extensively researched (Juneau and Pisano 1996, Oh *et al.* 1997, Park *et al.* 1997). Implementing micromachined polysilicon structures in an integrated IC fabrication process is very attractive in an economic sense. A polysilicon structural material offers high quality factor and an orientation-independent Young's modulus. Furthermore, by integrating the readout electronic circuitry on a single silicon chip, it is possible to reduce the parasitic capacitances and hence increase the signal-to-noise ratio.

Single- and dual-axis polysilicon surface micromachined gyroscopes have been realized by researchers at the University of California, Berkeley. Berkeley's z-axis vibratory rate gyroscope (Clark *et al.* 1996) resembles a vibrating beam design and consists of

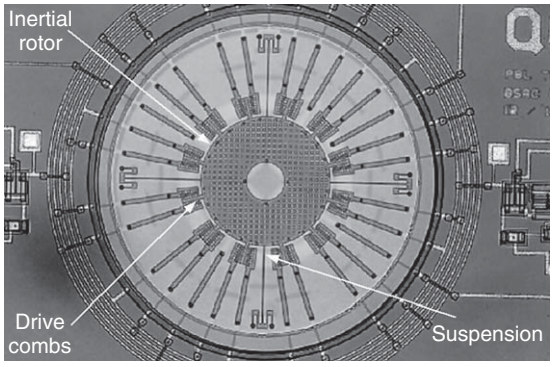

Figure 9 Close-up die shot of Berkeley's dual-axis rate gyroscope, integrated with sense and drive electronics. (Source: Juneau T, Pisano A 1996 Micromachined dual input axis angular rate sensor. *Tech. Dig. Solid-State Sensor and Actuator Workshop*, Hilton Head Island, SC, USA, pp. 299–302.)

an oscillating mass that is electrostatically driven into resonance using comb drives. Any deflections that result from Coriolis acceleration are detected differentially in the sense mode using interdigitated comb fingers. This device, 1 mm across, was integrated with a transresistance amplifier on a single die using the Analog Devices BiMEMS process. The remaining control and signal processing electronics such as the quadrature error nulling and mode matching was implemented off chip. This device demonstrated a resolution of 1 deg s^{-1} $Hz^{-1/2}$.

Berkeley has also reported a dual-axis surface micromachined gyroscope based on a rotational resonance of a 2-μm-thick polysilicon rotor disk as shown in **Figure 9** (Juneau and Pisano 1996). Because the disk is symmetric in two orthogonal axes, the sensor can sense rotation equally about both these axes. This device, integrated with electronics, yielded an ARW of 10 deg $h^{-1/2}$.

Perhaps the most successful commercial micromachined silicon gyroscope is the Analog Devices ADXRS iMEMS gyroscope series (Geen *et al.* 2002). The device implemented using the unique BiMEMS surface micromachining process integrates both the mechanical elements and electronics on a single die, thereby ensuring improved performance and robustness. The MEMS component as shown in **Figure 10** consists of two polysilicon sensing structures, each containing a dither frame that is electrostatically driven into resonance. This produces the necessary velocity element to produce a Coriolis force during angular rotation. At two of the outer extremes of each frame, orthogonal to the dither motion, lie movable fingers that are placed between pickoff fingers to capacitively monitor Coriolis

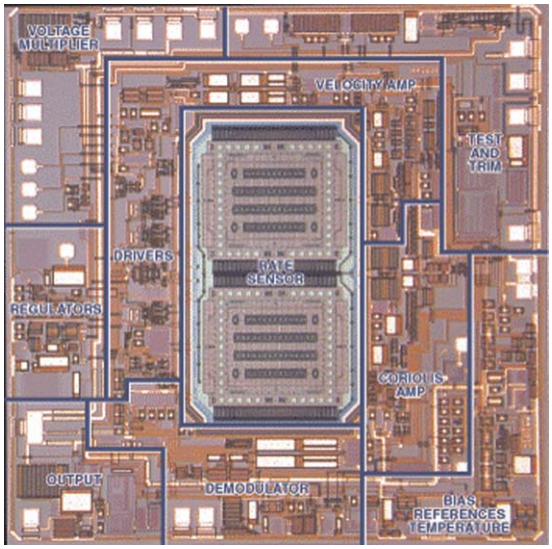

Figure 10 Die picture of an Analog Device ADXRS series microgyroscope. (Source: Geen J, Sherman S, Chang J, Lewis S 2002 Single-chip surface micromechanical integrated gyroscope with 50° Allen deviation. *IEEE J. Solid State Circuits*, **37**(12), 1860–6.)

motion. The ADXRS gyroscope demonstrates a rate sensitivity of 12.5 mV deg^{-1} s^{-1} and an estimated Allan deviation (bias drift) of 50 deg h^{-1}.

The final surface micromachined gyroscope discussed in this section has been developed by Robert Bosch GmbH (Gomez *et al.* 2005). The MEMS element consists of two identical mass-spring structures connected by a coupling spring. Each structure consists of three frames: (i) drive, (ii) Coriolis, and (iii) detection. Primary drive mode oscillations comprise movement of the drive and Coriolis frame in-plane along the x-direction, excited via comb-drive electrodes. The secondary mode (detection) is excited by Coriolis forces as a result of an angular rate around the z-axis; it comprises oscillation of the Coriolis and detection frame. Coriolis signals are detected by parallel plate capacitors within the detection frame. Decoupling of the detection frame from the primary oscillation reduces electrical crosstalk significantly. The Bosch gyroscope represents a two-die approach, with the IC interfaced with the MEMS element in a vacuum-sealed package. The Bosch gyroscope in testing yielded bias stability values approaching 1 deg h^{-1}, which is the highest reported for surface micromachined gyroscopes to date.

Surface micromachined gyroscopes discussed in the previous section suffer from thin-film residual stress, squeeze-film damping, and other problems associated with low mass. The low-mass problem implies that resolution levels of sub-0.1 deg h^{-1} typically required

for navigation-grade performance cannot be achieved. With limited device thickness, surface micromachined gyroscopes also suffer from a reduced capacitance area and thereby device sensitivity.

2.06.3.2 Bulk Micromachined Gyroscopes

The need to address the capacitance area and mass inadequacies of surface micromachined gyroscopes has directly led to research in bulk micromachined gyroscopes. The issues that originally plagued bulk micromachining such as high aspect ratio trench etching, wafer bonding, and vacuum packaging have been addressed in recent years with advancement in micromachining tools. Another trend in bulk micromachined gyroscope that is gaining popularity is the utilization of silicon-on-insulator (SOI) wafers. Because of their thick single-crystal silicon device layers, SOI wafers provide the necessary substrates for bulk mechanical structures, which are critical to gyroscope performance. Additionally, they also allow the possibility of integrating the mechanical structures of the gyroscope with the electronics, as in the case of integrated surface micromachined gyroscopes.

Bulk micromachined gyroscopes have made significant progress since 1995. In 1999, Murata reported a deep reactive ion etching (DRIE) gyroscope with decoupled sense and drive modes with a resolution of $0.07\,\mathrm{deg\,s^{-1}}$ with a 10-Hz bandwidth (Park 1999). Also reported by Samsung was a 40-μm-thick single-crystal silicon gyroscope fabricated using SOI technology (Tanaka *et al.* 1995). This device demonstrated a resolution of $0.015\,\mathrm{deg\,s^{-1}}$ in 25 Hz bandwidth, a bias drift of $500\,\mathrm{deg\,h^{-1}}$, a sensitivity of $145\,\mathrm{mV\,deg^{-1}\,s^{-1}}$, and −3 dB bandwidth of 12.5 Hz.

During the earlier development of bulk micromachined vibratory gyroscopes, no on-chip readout electronics were present because the fabrication process required Si–Si or Si–glass anodic bonding and two-side alignment. Carnegie Mellon University addressed this issue by implementing a lateral-axis angular rate sensor with in-plane vibration and out-of-plane Coriolis acceleration sensing. The sensor plus on-chip CMOS circuitry is fabricated using a post-CMOS micromachining process that utilizes interconnected metal layers as etching masks and a single-crystal silicon layer as the structural material (Xie and Fedder 2003).

The NASA JPL microgyroscope consists of three major components: (i) a silicon clover-leaf vibrating structure, (ii) a silicon baseplate that is bonded to the clover-leaf structure, and (iii) a metal post that is epoxied inside a hole on the silicon resonator. The last reported data on the electrostatically tuned and optimized JPL microgyroscope indicate an ARW of $0.1\,\mathrm{deg\,h^{-1/2}}$ with bias stability of $2\,\mathrm{deg\,h^{-1}}$ operating in vacuum under matched-mode condition (Bae *et al.* 2002).

So far the emphasis has been on gyroscopes operating with proof masses suspended by a flexural network and operating with nondegenerate vibratory modes. The focus now shifts to shell-type gyroscopes. This is a family of devices that rely on the Coriolis-induced transfer of energy between degenerate vibratory modes. Perhaps the most commonly known shell-type structure is the vibrating ring gyroscope. The vibrating ring gyroscope consists of a ring; semicircular support springs; and drive, sense, and control electrodes. Symmetry considerations require at least eight springs to result in a balanced device with two identical flexural modes that have equal natural frequencies. The ring is electrostatically vibrated into an elliptically shaped primary flexural mode with a fixed amplitude. When the device is subjected to rotation around its normal axis, Coriolis force causes energy to be transferred from the primary mode to the secondary flexural mode that is located 45° apart from the primary mode, causing amplitude to build up proportionally in the latter mode; this buildup is capacitively monitored.

The first micromachined version of the vibrating ring gyroscope was fabricated by electroforming nickel into a thick polyimide (or photoresist) mold on a silicon substrate in a postcircuit process (Putty and Najafi 1994). The gyroscope implemented by the University of Michigan demonstrated a resolution of approximately $0.5\,\mathrm{deg\,s^{-1}}$ in a 10-Hz bandwidth (limited by the readout electronic noise). However, the nickel electroforming technology used for this device has a major drawback. The thermal expansion coefficient of the silicon substrate is different from that of the nickel sensor element. Therefore, with temperature fluctuations, the ring expands (or shrinks) more than do the adjacent electrodes, which are attached to the substrate, causing the ring-to-electrode gap spacing to change; this in turn results in an increased temperature sensitivity of offset and scale factor.

In an effort to eliminate temperature sensitivity and low quality factor issues that plagued the nickel implementation, BAE systems developed a single-crystal silicon bulk micromachined implementation of the vibrating ring gyroscope. In 2002, the University of Michigan reported a high-resolution vibrating ring

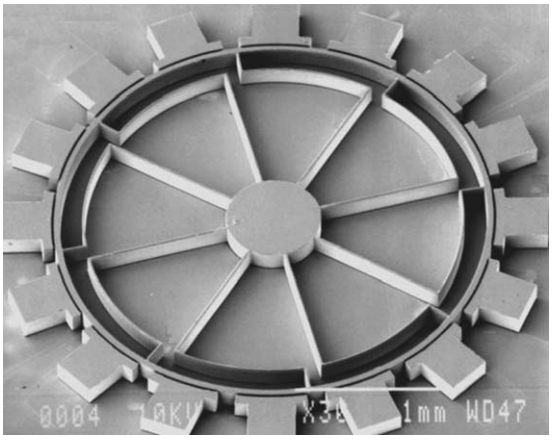

Figure 11 SEM image of the vibrating ring gyroscope implemented on (111) silicon substrate. (Source: He G, Najafi K 2002 A single-crystal silicon vibrating ring gyroscope. *Proc. IEEE MEMS 2002*, Las Vegas, USA, pp. 718–21.)

gyroscope implemented using (111) single-crystal silicon structural material (**Figure 11**) (He and Najafi 2002). The 150-μm structural device was defined by DRIE and it demonstrated an impressive noise floor of $10\,\mathrm{deg\,h^{-1}\,Hz^{-1/2}}$ in a 2-Hz bandwidth with a reported rate sensitivity of approximately $130\,\mathrm{mV\,deg^{-1}\,s^{-1}}$.

2.06.3.3 Mixed-Mode Micromachined Gyroscopes

As the trend toward greater device thickness increases, the need to maintain and improve the aspect ratio of the capacitive operating gaps also becomes essential. Even the most advanced deep reactive ion silicon etching tools are unable to define in a repeated fashion trench aspect ratio greater than 30:1. This severely limits the performance capability of silicon bulk micromachined vibratory gyroscopes. The solution to the aspect ratio issue is the development of novel fabrication technology that combines the aspects of both surface and bulk micromachined processes. The mixed-mode process technology utilizes bulk silicon structural material to define device geometries while relying on a sacrificial layer used in surface micromachining process to define the operating capacitive gaps.

To eliminate the myriad of problems faced by its nickel electroforming technology, the University of Michigan developed the high aspect ratio poly- and single-crystal silicon (HARPSS) process (**Figure 12**) (Ayazi and Najafi 2000). This novel, mixed-mode fabrication technology is capable of producing thick MEMS structures while implementing submicron high aspect ratio sensing and tuning capacitive gaps. This unique feature improves the device sensitivity and noise floor while dramatically reducing the operating voltages when compared with its nickel predecessor. The polysilicon HARPSS vibrating ring gyroscope demonstrated a rate sensitivity of $0.2\,\mathrm{mV\,deg^{-1}\,s^{-1}}$ in a dynamic range of $\pm 250\,\mathrm{deg\,s^{-1}}$. The measured noise floor of the gyroscope system was approximately $0.1\,\mathrm{deg\,s^{-1}\,Hz^{-1/2}}$ limited primarily by the poor quality factor associated with trench-refilled structural polysilicon.

An alternate shell structure was displayed by the Georgia Institute of Technology by utilizing the HARPSS process (Zaman *et al.* 2005). The RSG may be visualized as a superposition of two identical square shells that are 45° apart (**Figure 13**). This ensures pairs of degenerate flexural vibratory modes

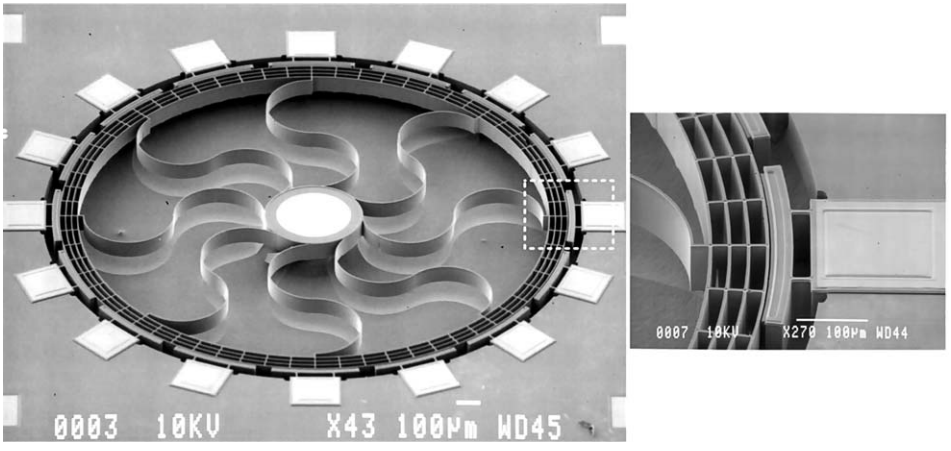

Figure 12 Implementation of the vibrating ring gyroscope using the high aspect ratio poly- and single-crystal silicon (HARPSS) process.

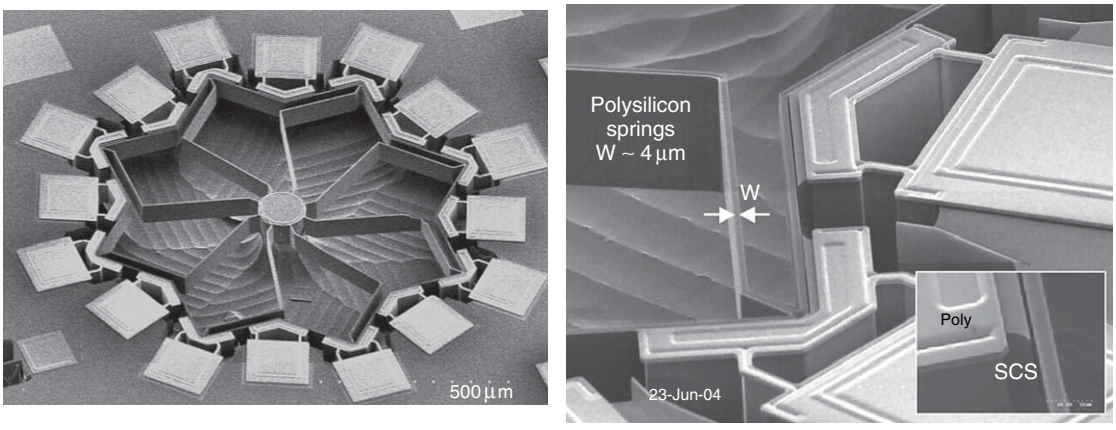

Figure 13 SEM overview of a 1-mm polysilicon resonating star gyroscope. *Right*: View of the electrode. *Inset*: Close-up of the 1-µm actuation gap defined through sacrificial oxide.

in the resulting eightfold star shell, which is anchored to a central post through flexural springs. The primary advantages of the RSG are improved quadrature minimization and increased electrode area. The RSG demonstrated a resolution and a sensitivity similar to those of the HARPSS vibrating ring gyroscope.

2.06.4 Case Study: An In-Plane M^2-TFG

The M^2-TFG (Zaman *et al.* 2006) is an example of a type I vibratory gyroscope. The M^2-TFG as illustrated in **Figure 14** consists of two proof masses supported by flexural springs and anchored at a

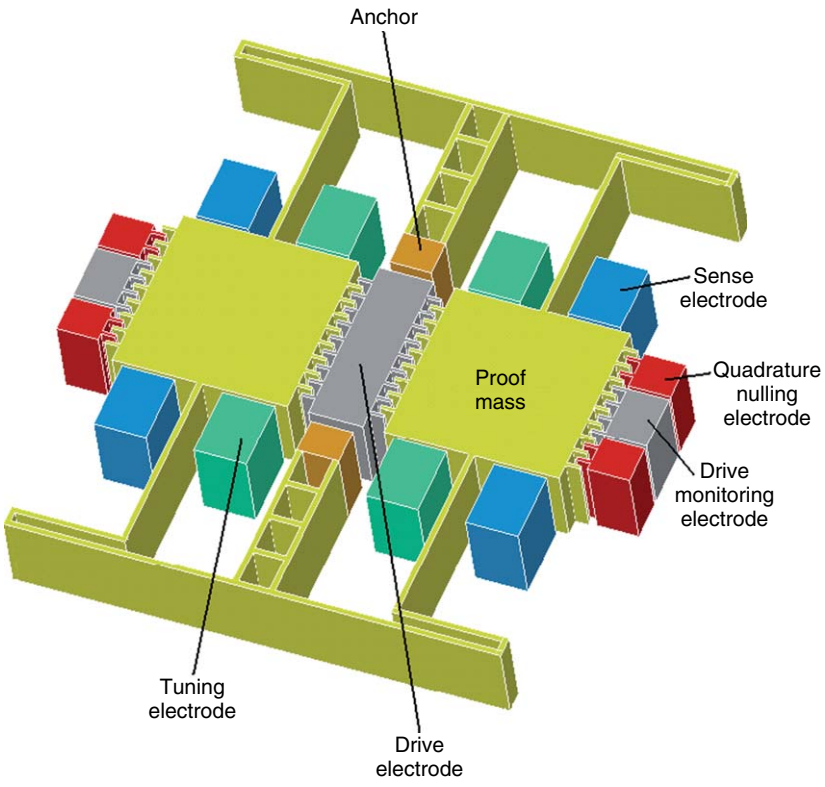

Figure 14 Schematic of the matched-mode tuning fork gyroscope (M^2-TFG).

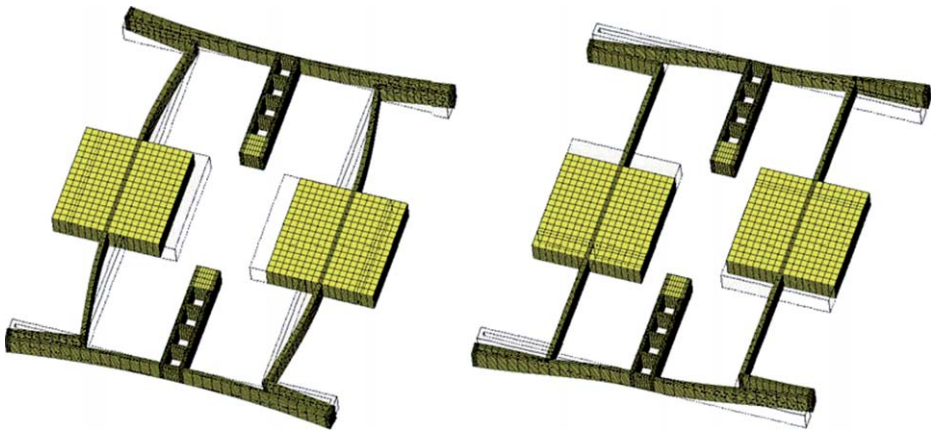

Figure 15 Resonant operating modes of the matched-mode tuning fork gyroscope (M^2-TFG): (a) drive mode and (b) sense mode vibrations.

central post. Actuation, sensing, and tuning electrodes are distributed around the proof masses and flexures. The operating principle is based on a standard tuning fork's response to rotation. The proof masses (akin to the tines of a tuning fork) are driven at resonance along the x-axis using comb-drive electrodes, and the Coriolis acceleration induced by rotation about the z-axis is sensed capacitively using electrodes along the y-axis.

The in-plane drive and sense resonant modes are illustrated in **Figure 15**. A major incentive in utilizing such a symmetric tuning fork architecture as opposed to a frame or single-mass design, is the differential sensing capability. As a result, linear acceleration signals are rejected as common mode without the need for complex electronics.

2.06.4.1 Flexural Spring Design

The flexural spring designs must satisfy a host of critical properties. The ideal spring design must ensure that there is zero/minimal coupling between the two resonant modes in the absence of rotation. To this effect, a fishhook architecture was developed, which ensures that the mode shapes are aligned laterally (two-directional flexibility), and more importantly, the two mode shapes move along independent axis during operation (Park *et al.* 1997). The spring structure design makes it possible to drive the solid proof masses linearly with displacement amplitudes in the range of 4–6 μm with minimal displacement along the sense axis. The second important criterion is to ensure that the two operating mode frequencies lie in close proximity to one another while remaining isolated from the other resonant modes (such as out-of-plane resonant modes). Detailed finite element analysis simulations of the flexural springs were performed to optimize the dimensions to allow the sense mode to occur 50–100 Hz higher than the drive mode. Upon fabrication, the sense mode frequency is electrostatically tuned (using the tuning electrodes) to match the drive mode frequency.

A key determinant of performance for a gyroscope is its Q. In order to achieve higher rate resolution and better bias stability, the design of gyroscopes with high sense mode Q is consistently pursued. A high Q in the drive mode is also necessary to obtain large drive amplitudes using small drive voltages – a highly desirable feature required in low-power CMOS interfacing. Several energy dissipation mechanisms exist in micromachined gyroscopes, such as air damping, thermoelastic damping (TED), surface loss, and support loss. Among them, air damping can be eliminated by operating the gyroscope in vacuum, whereas surface loss is often negligible through optimized processing. The measured unloaded Q is hence a combination of two dissipation mechanisms expressed as

$$\begin{aligned} 1/Q &= 1/Q_{\text{TED}} + 1/Q_{\text{support}} + 1/Q_{\text{surface}} + 1/Q_{\text{air}} \\ &\approx 1/Q_{\text{TED}} + 1/Q_{\text{support}} \end{aligned} \quad [18]$$

During resonant flexural vibrations, the proof masses exert a time-harmonic load on their support structure. Acting as an excitation source, this time-harmonic load excites elastic waves propagating through the support. Part of the vibration energy

dissipated through elastic wave propagation in the support media is commonly referred to as support loss (Hao *et al.* 2003). The lack of thermal equilibrium between various parts of the vibrating solid is responsible for TED in solids. In order for the equilibrium to be reinstated, irreversible heat flow driven by the temperature gradient occurs, also referred to as thermal relaxation. The irreversibility of such a relaxation process is associated with energy dissipation or damping. Q_{TED} defines the upper limit for maximum achievable Q in an M^2-TFG structure and is a function of the flexural spring width and the device operating frequency (Zaman *et al.* 2004).

The drive mode and the sense mode vibrations depicted in **Figure 15** show that the two proof masses vibrate in the opposite directions and consequently alleviate support loss. The vibrations in the drive mode cause the forces applied on the anchors in the opposite directions and thus lead to cancelation in support loss to a great extent. Similarly, the vibrations in the sense mode introduce forces to the anchors. However, the forces at the two anchors are off the center and lead to a net torque applied on the support structure. The flexural spring dimensions and operating frequency regime are carefully selected to alleviate support loss and operate in a region of high Q_{TED}.

2.06.4.2 Device Fabrication

The M^2-TFGs are fabricated on thick SOI substrates. The moving sections of the structure and the areas under the comb drives are first released from the backside of the wafer by etching the handle silicon layer through to the buried oxide layer using the Bosch process. The buried oxide is then removed in an RIE system. Finally, the device layer is patterned all the way through, leaving behind a suspended structure whose anchor is attached to the substrate via several support posts.

The fabrication process is very simple and precludes the requirement of any perforations in the proof mass, resulting in a larger mass per unit area (**Figure 16**). The simultaneous elimination of the ground plane under the comb drives prevents the excitation of the out-of-plane modes and detrimental effects associated with comb levitation. The fact that all the electrodes and the structure are defined using a single mask ensures that there are no horizontal misalignment errors of actuation/sense gaps. **Figure 17** shows a few SEM images of fabricated devices implemented on a thick SOI substrate.

2.06.4.3 Interface Electronics

The complete M^2-TFG system is shown in **Figure 18**. It consists of the drive, sense, quadrature nulling, and automatic mode-matching system blocks, implemented in a 0.6-μm CMOS process (Sharma *et al.* 2007). While the function of each of these systems had been highlighted previously, the following section contains a brief description of the M^2-TFG electronics and highlights some of the system aspects that are unique to the M^2-TFG interface system.

2.06.4.3.1 Front-end I-V conversion

A CT low-noise transimpedance amplifier (TIA) is used as the front-end interface (Sharma *et al.* 2006) as indicated in **Figure 19**. Such a circuit topology is capable of measuring subattofarads of capacitance change at low power, without the need for complex switched capacitor techniques. A CT approach is adopted to avoid the kT/C noise associated with switched capacitor front-ends (Jiang *et al.* 2000). The shunt-shunt feedback of a TIA represents low input impedance to the capacitive sensor, thereby mitigating the effects of the increased input parasitic capacitance (C_I) of a two-chip approach and minimizing Q-loading. **Figure 19** shows the major noise contributors in a TIA that is interfaced to a capacitive

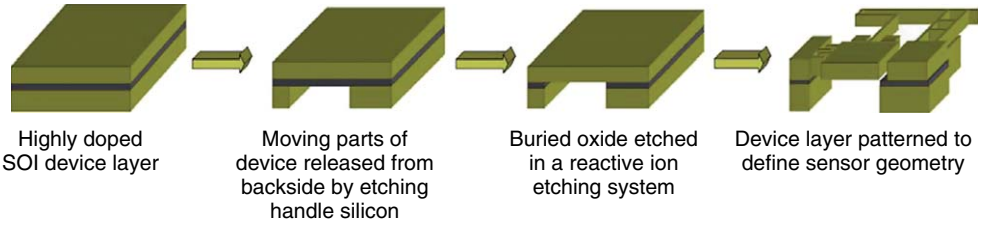

Figure 16 Outline of the fabrication process flow for silicon-on-insulator (SOI) matched-mode tuning fork gyroscope (M^2-TFG).

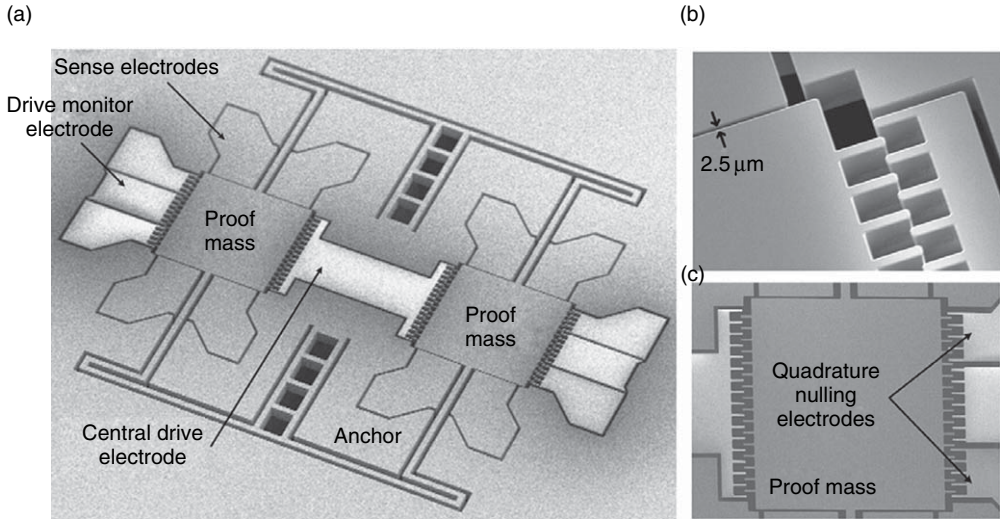

Figure 17 (a) A SEM image of a fabricated 60-μm-thick matched-mode tuning fork gyroscope (M^2-TFG), (b) a close-up of drive and sense gaps, and (c) a view of the quadrature nulling electrodes.

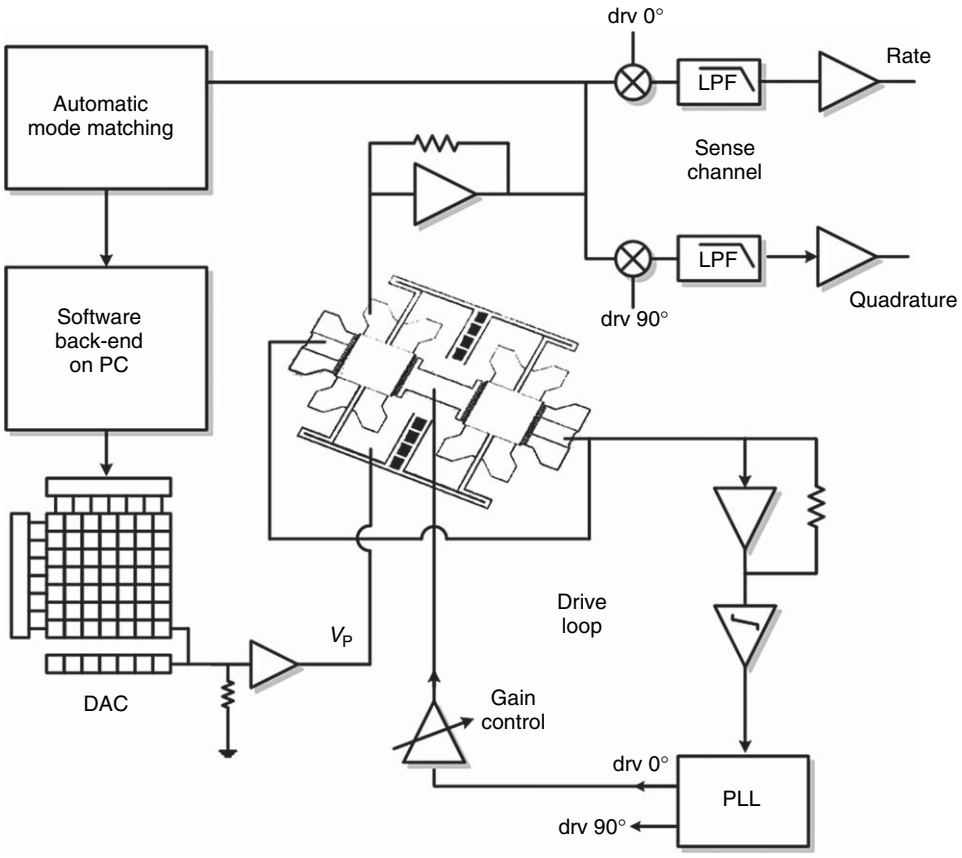

Figure 18 Schematic of the complete matched-mode tuning fork gyroscope (M^2-TFG) interface system.

sensor. $v^2_{\text{op-amp}}$ and $i^2_{\text{op-amp}}$ are the input-referred voltage and current noise of the core amplifier, respectively.

The advantage of using a TIA front-end for low-noise capacitive sensing is apparent from the expression for the TIA SNR. Increasing R_F not only allows

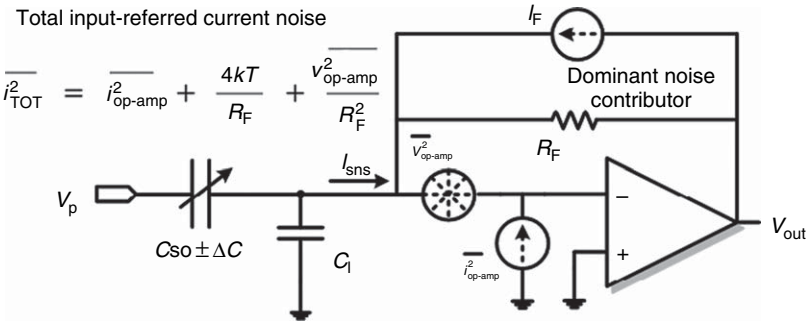

Figure 19 Schematic of transimpedance amplifier (TIA) front-end and various noise sources.

for a high first-stage gain but also improves the system SNR by a factor of $\sqrt{R_F}$ as indicated in eqn [19].

$$SNR = \frac{S_O}{N_O} = \frac{I_{SIGNAL}}{I_{NOISE}} = \frac{I_{SIGNAL}\sqrt{R_F}}{\sqrt{4kT}} \qquad [19]$$

Plots of the measured total input current noise of the T-network TIA for different values of V_{CNTRL} are shown in **Figure 20**. In the case of T-network TIA, in the signal band (10 to 20 kHz), the flicker plus thermal noise from the MOS resistor is the dominant noise contributor. As was explained earlier, the input-referred current noise decreases with increasing transresistance (R_F), and this is clearly evident from **Figure 20**.

In case of a high-Q resonant sensor, the spot noise at the signal frequency is the quantity of interest. At 10 kHz, the T-network TIA with a V_{CNTRL} of 0.96 V has a transimpedance gain of 1.6 MΩ and an input-referred current noise of 99 fA $Hz^{-1/2}$. This corresponds to a capacitive resolution of 0.04 aF $Hz^{-1/2}$ at 10 kHz. For this case, the measured output voltage noise at 10 kHz is −136 dB $Hz^{-1/2}$, which corresponds to a signal to noise plus distortion ratio (SNDR) of 104 dB in a 10-Hz bandwidth.

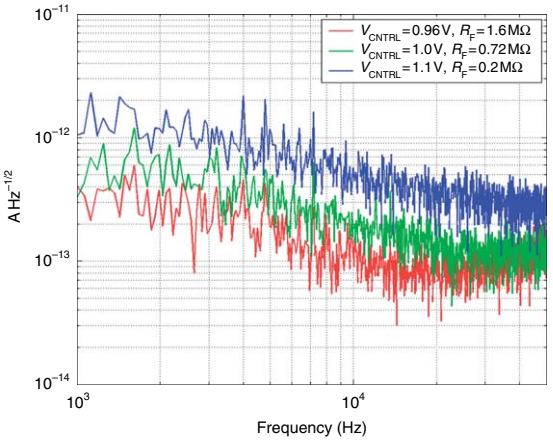

Figure 20 Measured input-referred current noise of a T-network transimpedance amplifier (TIA) for different V_{CNTRL}.

2.06.4.3.2 Synchronous I-Q demodulation

Synchronous I-Q demodulation is used to extract the rate signal from the sensor output electrodes and differentiate it from quadrature error. The sensor output is multiplied with a square wave that is in phase with the proof mass velocity and then low pass filtered to obtain an analog voltage proportional to the input rotation rate. An analog voltage indicative of the quadrature error is obtained by multiplying the sensor output with a square wave in phase with the proof mass position. The signals in phase with and in quadrature with the velocity are generated by using a frequency divider in the PLL as shown in **Figure 21(a)**. A CMOS Gilbert cell (Gilbert 1968) is used for the multiplication as shown in **Figure 21(b)**. The output of the four-quadrant multiplier is low pass filtered to yield analog signals proportional to the rotation rate and quadrature error.

2.06.4.3.3 Drive oscillator

The drive amplitude (q_{drive}), which is the maximum displacement of the oscillating proof mass, is a critical parameter in determining the noise floor and Coriolis sensitivity. The drive mode of the M^2-TFG is excited into resonance using interdigitated comb fingers. In a comb-driven structure, the maximum

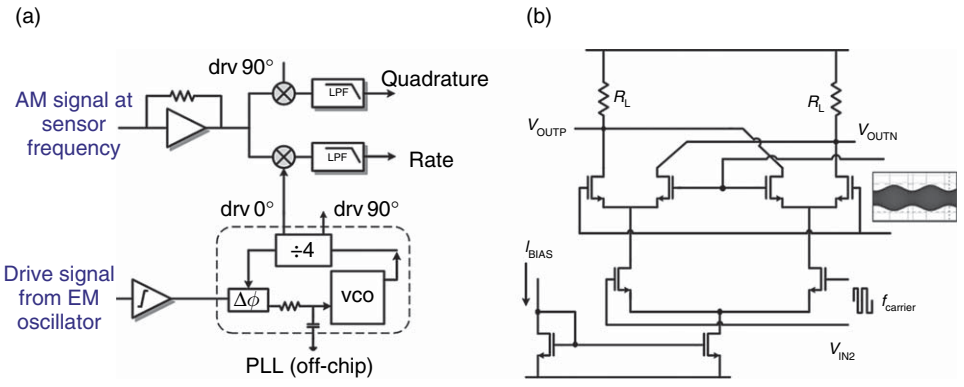

Figure 21 Schematic of the sense channel showing (a) I-Q demodulation and (b) Gilbert cells used for multiplication.

achievable drive amplitude is proportional to the square of the gap between adjacent combs. In the case of the M^2-TFG, this is further restricted by operation in the matched mode.

$$q_{\text{drive}} = \frac{-w_0 + \sqrt{w_0^2 + 2\left(k_x/k_y\right)d^2}}{2} \cong \frac{-w_0 + \sqrt{w_0^2 + d^2}}{2} \quad [20]$$

In eqn [20], w_0 indicates the initial comb overlap while d represents adjacent comb gap. An increased d also translates to increased mechanical motional impedance along the drive axis as given by eqn [21].

$$R_{\text{motional}} \propto \frac{\omega_0 M d^2}{Q V_P^2} \quad [21]$$

To illustrate with an example, in order to achieve drive amplitudes of 3 μm, the required comb gap is 7 μm, which corresponds to a motional impedance of 12 MΩ (at 15 kHz in vacuum). Consequently, larger drive voltages will have to be applied and larger on-chip loop gains need to be realized for sustaining the drive oscillations. Larger drive voltages imply higher power consumption, whereas larger loop gain implies more silicon real estate – both of which place constraints on electronic integration. Hence, there is a need for a front-end that can provide significantly high transimpedance gain with a low area overhead. The T-network TIA described in the previous section satisfies the above requirements. In the implemented M^2-TFG drive loop, the T-network TIA is cascaded with a phase-shifting buffer to satisfy Barkhausen's criterion and sustain oscillations in the series resonant electromechanical drive loop, as shown in **Figure 22**.

Once drive oscillations have been started, it is necessary to maintain a constant amplitude and prevent the modulation of the sensor output. An ALC circuit (Lee and Nguyen 2003) is therefore used to keep q_{drive} constant, thereby preventing false rate outputs. As shown in **Figure 22**, the ALC circuit consists of a full-wave rectifier, envelope detector, and instrumentation amplifier to supply the level control voltage. The ALC output voltage is used to control the MOS transistor in the T-network. **Figure 22** also shows the buffered closed-loop drive oscillation waveform and the spectrum of the signal when the drive loop is interfaced with a prototype M^2-TFG.

2.06.4.4 Device Characterization

Optimizing the flexural designs ensures minimal support loss and TED in flexures to result in high-Q in-plane drive and sense resonant modes, as well as in minimal coupling and frequency separation between the two modes (**Figure 23**). Typical open-loop quality factors measured for M^2-TFG operating modes are on the order of 80 000 and 50 000 for the drive and the sense modes, respectively.

Figure 24 shows the tuning characteristics of the sense resonant mode as the V_P on the MEMS structure is increased. This mode shows a variation of approximately 1600 ppm V^{-1} over a tuning voltage range of 20 V. The tuning characteristics of the sense mode are important as the sense frequency is tuned to match the drive frequency for mode matching. In addition, the tuning characteristics of the sense mode can be used to electrostatically maintain mode matching in the presence of temperature variations. Parabolic temperature compensation of micromachined resonators has been demonstrated to achieve frequency stabilities as low as 39 ppm $°C^{-1}$ (Sundaresan *et al.* 2005). A similar technique can be applied for the temperature compensation of micromachined silicon gyroscopes.

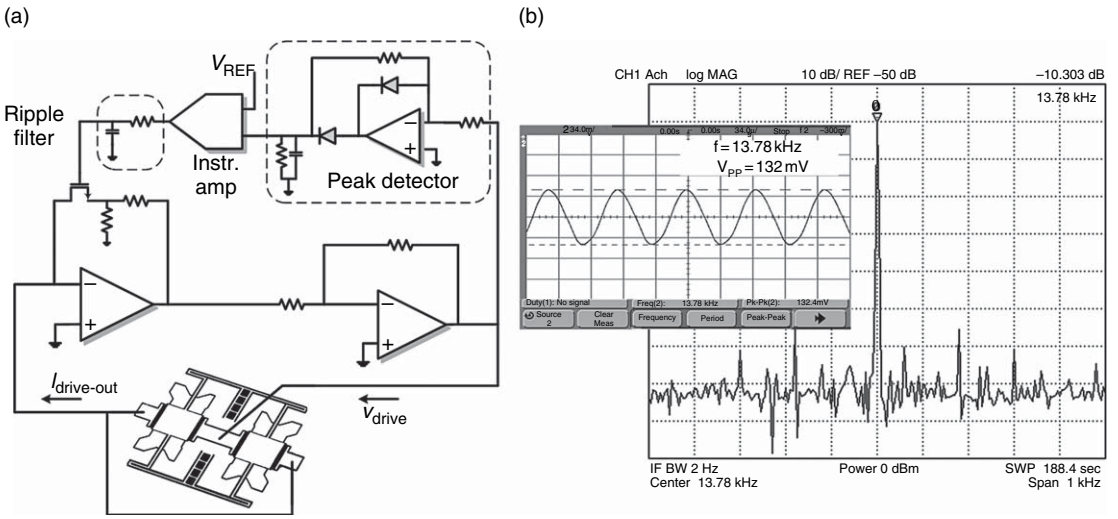

Figure 22 (a) Schematic of drive resonant oscillator and automatic level control (ALC) circuit and (b) waveform and spectrum.

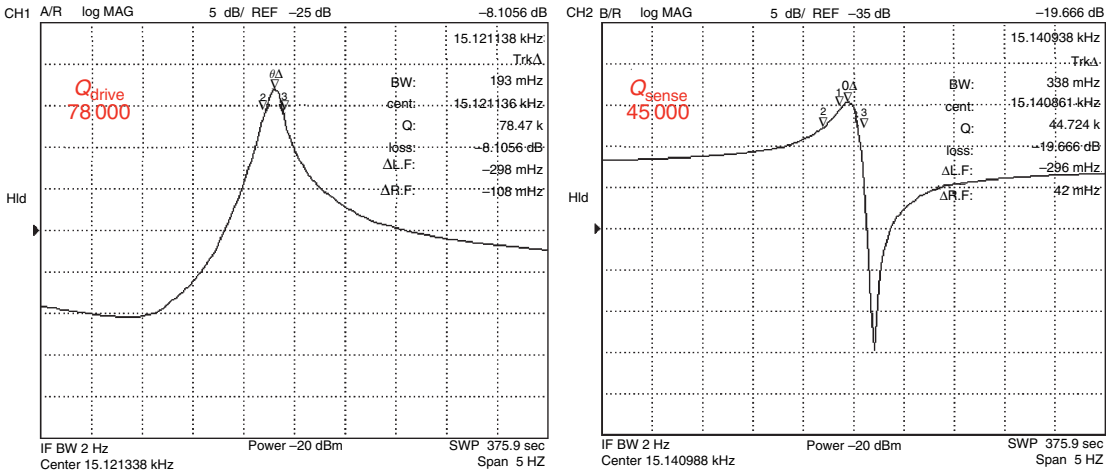

Figure 23 Measured drive and sense resonant mode *Q* (in mTorr vacuum).

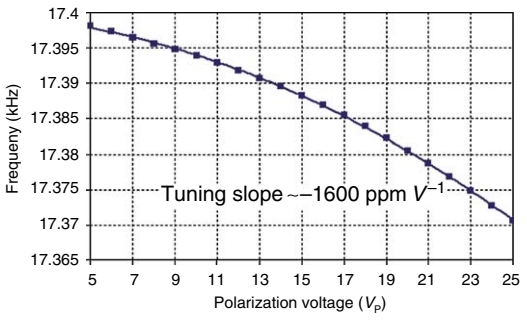

Figure 24 Variation of the sense resonant mode frequency as a function of the polarization voltage, V_P.

2.06.4.5 Quadrature Nulling and Mode Matching

The sense mode is designed to be slightly higher in frequency than the drive mode to enable mode matching even in the presence of process variations. Mode matching is achieved by increasing V_P on the MEMS structure until electrostatic spring softening decreases the sense mode frequency to become equal to that of the drive mode (0 Hz split). This feature differentiates the M^2-TFG from other MEMS gyros (Geen *et al.* 2002).

Despite a mechanically decoupled design, in practice, fabrication imperfections can lead to nonzero off-diagonal elements in the spring stiffness matrix resulting in an undesirable zero-rate output (ZRO) at the sensor operating frequency. As discussed earlier, this quadrature error signal prevents perfect mode matching. As shown in **Figure 25**, an initial frequency split of 60 Hz is reduced to 10 Hz without the need for any external quadrature cancelation.

Only through the electronic minimization of the quadrature error is the perfect matching of the drive and the sense resonant modes possible (Clark *et al.* 1996). The ZRO is minimized in a postfabrication trimming step by applying DC voltages at specific quadrature nulling electrodes to properly align the device. These electrodes are shown in **Figure 17**. Despite quadrature nulling, there exists a finite amount of ZRO. The term perfect mode matching practically implies that the drive and the sense modes are so close in frequency that one is indistinguishable from the other (i.e., frequency separation of less than 100 mHz). Once matched, synchronous I-Q demodulation (Putty and Najafi 1994) is used to distinguish between the ZRO and the Coriolis signal. **Figure 25** shows a perfectly matched M^2-TFG device after quadrature nulling. It is generally observed that mode matching and quadrature nulling do not degrade the operating Q.

2.06.4.6 Performance Analysis

2.06.4.6.1 Scale factor measurements

The sensor output voltage was measured at varying angular speeds to characterize the sensitivity of the M^2-TFG system. The scale factor of the M^2-TFG under matched-mode operation was measured to be 24 mV deg^{-1} s^{-1} as indicated in **Figure 26(a)**. **Figure 26(b)** shows the time domain response of the sensor to clockwise and counterclockwise rotation steps respectively, whereas **Figure 26(c)** shows the response of the M^2-TFG to an input sinusoidal rotation.

Scale factor linearity is of significant concern in angular rate sensing. Typically, scale factor linearity is expressed in terms of percentage of full scale (% of FS) range. There are a number of factors that affect scale factor linearity. Driving the proof masses beyond their linear regime along the drive axis can result in nonlinearity in the drive velocity and hence in the Coriolis-induced sense axis displacement. Fabrication-induced imperfections along the sidewalls of the proof mass and sense electrodes can lead to a nonuniform sense rest capacitance and can cause significant variation in scale factor linearity. Distortion in the front-end capacitance-to-voltage converter can easily result in significant distortion of the Coriolis signal. The bandwidth of the signal chain that is used to amplify and demodulate the Coriolis signal must be higher than the gyro resonant frequency. Otherwise there can be excess phase change (Clark *et al.* 1996) that can result in unwanted phase variations. Finally, the multiplier must have sufficient linearity to perform the synchronous demodulation. As discussed earlier, there are a number of factors that affect SF linearity. Therefore, the design of a linear signal processing chain for Coriolis detection is nontrivial.

The scale factor stability is directly affected by the fluctuations in the matched-mode Q (Q_{EFF}) over time. It was, however, observed that the measured Q_{EFF} for the M^2-TFG remained constant over a period of 24 h at a fixed room temperature and pressure and over the course of week only varied by less than one-tenths of percent.

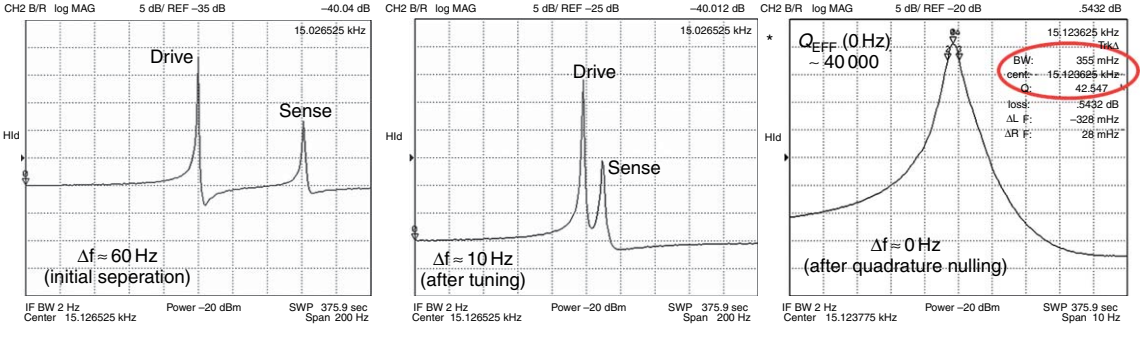

Figure 25 Pair of frequency response plots showing initial electrostatic tuning to compensate frequency split and perfect matched-mode tuning fork gyroscope (M^2-TFG) after quadrature nulling.

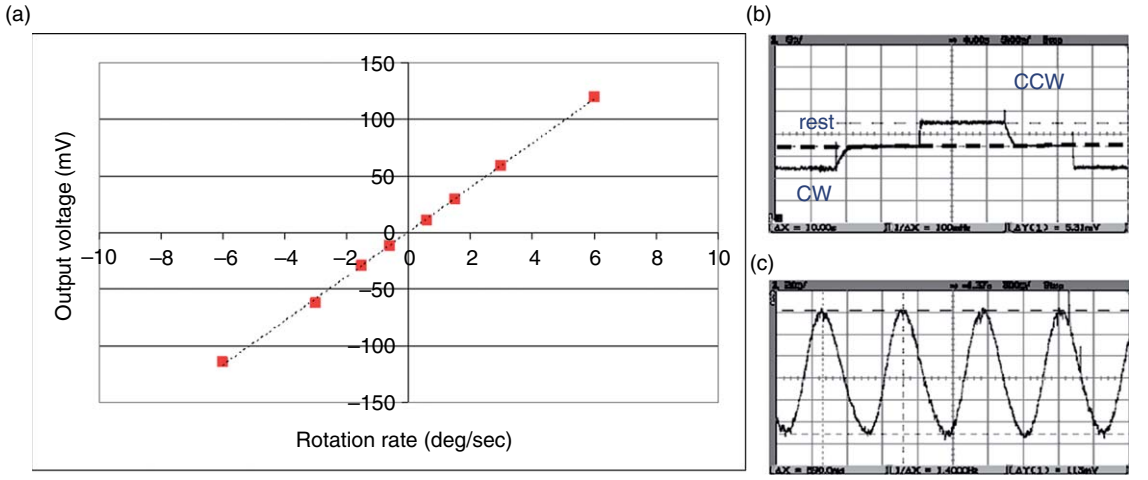

Figure 26 (a) The rate sensitivity plot for the matched-mode tuning fork gyroscope (M^2-TFG) under matched-mode operation, (b) response of the gyro to clockwise (CW) and counterclockwise (CCW) step inputs, and (c) response of the gyro to a sinusoidal input rate.

2.06.4.6.2 Bias drift measurements

Bias drift is a fundamental performance gauging parameter in any IMU. The bias drift of the M^2-TFG system interfaced with the electronics was evaluated using the guidelines set by the IEEE (1997). The bias drift has been estimated using the Allan variance technique. The Allan variance curve was subsequently curve-fitted to determine the different noise contributions of the gyro system.

The ZRO of the device was sampled every 100 ms for a period of 12 h (at room temperature and vacuum). Using the collected ZRO data, an Allan variance analysis was performed to characterize the long-term stability of the matched-mode device. A time slice of the ZRO from one electrode is shown in Figure 27(a). The ZRO level may be minimized through proper vibration isolation and elimination of other extraneous common-mode noise. The root Allan variance plot of the M^2-TFG is shown in Figure 27(b).

The minima point of the Allan variance graph is a measure of the bias stability of the system. From the Allan variance graph, the measured bias instability of the system (IEEE 1997) is 0.96 deg h^{-1}. The bias drift of a microgyroscope becomes important when one considers the fact that it is used along with accelerometers to obtain heading information – i.e., position and orientation. The rate information from the microgyroscope is integrated to obtain the angle. Any long-term variations in the rate (of which the

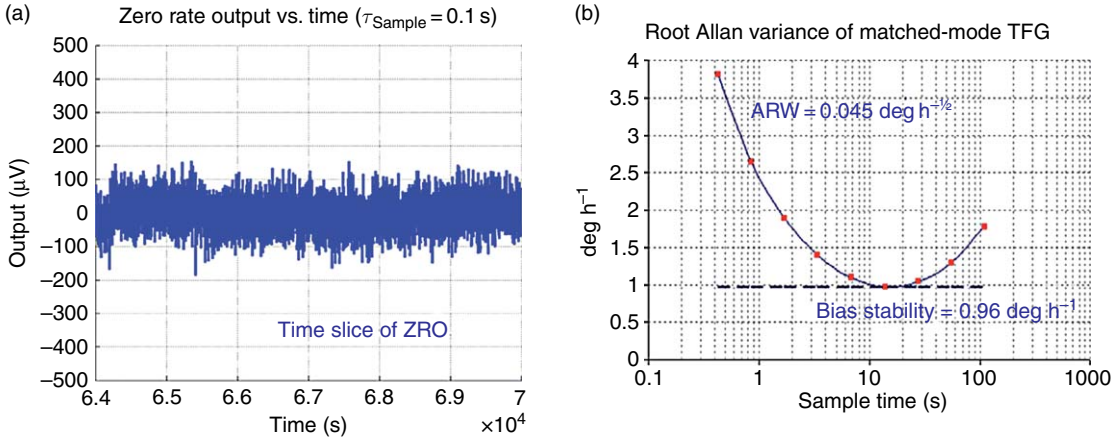

Figure 27 (a) Time slice of the zero-rate output (ZRO) and (b) root Allan variance plot of the matched-mode tuning fork gyroscope (M^2-TFG) interfaced with electronics.

bias drift is an accurate indicator) add up and can cause a large error in angle and orientation information. Modern gyroscope systems periodically calibrate themselves with GPS to ensure that the heading information is accurate. The longer a system can function accurately without the need for calibration, the better and more accurate heading and orientation information it can deliver. A long interval between calibration sequences is crucial for applications such as deep-sea navigation and oil exploration where it is not possible to resurface very easily to calibrate with the GPS.

Apart from the long-term stability of the microgyro, the Allan variance plot also gives information about the short-term stability of the device. The short-term stability of the device is directly dependent on the noise floor or resolution of the sensor. The $\tau^{-0.5}$ region of the Allan variance curve gives a measure of the ARW of the microgyroscope. From the Allan variance curve, the measured ARW is $0.045\ \text{deg h}^{-1/2}$.

2.06.4.6.3 Temperature measurements

In order to guarantee scale factor stability and ensure low bias drift, it is essential that the mode matching be maintained over temperature. The M^2-TFG was tested under both matched and split-mode conditions to determine accurately the effects of temperature on device performance. **Figure 28(a)** shows the measured frequency variation in the individual (unmatched) resonant modes of an M^2-TFG sample as a function of temperature. Such a frequency shift is attributed to the temperature dependency of Young's modulus of signal crystal silicon (SCS). The drive mode temperature coefficient of frequency (TCF) is measured to be about $-22\ \text{ppm}\ ^\circ\text{C}^{-1}$. As indicated by **Figure 28(a)**, the TCF of the drive and of the sense resonant modes vary by less than $1\ \text{ppm}\ ^\circ\text{C}^{-1}$.

The TCF data for a matched-mode device are shown in **Figure 28(b)**. Matched-mode condition is maintained over temperature because the two modes have similar TCFs and track with temperature. Q_{EFF} was observed to slightly decrease at elevated temperature and may be attributed to TED or finite frequency split generated due to variation in TCF between the individual modes. The effect of degradation in Q is reflected in the Allan variance analysis at 70°C which yielded a bias instability of $1.1\ \text{deg h}^{-1}$.

2.06.4.6.4 Comparison between matched- and split-mode operations

In this section, performance parameters of an M^2-TFG operating in split-mode condition are examined. **Figure 29(a)** depicts the modes of an M^2-TFG matched to within 2 Hz of each other. The measured Q_{EFF} in this case is roughly 10 000. The measured scale factor is approximately $7.2\ \text{mV deg}^{-1}\ \text{s}^{-1}$. As indicated in eqn [22], the sensitivity is a direct function of the Q_{EFF}.

$$\text{Sensitivity} = \frac{2V_P}{C_{S0} + C_{\text{Parasitics}}} \frac{C_{S0}}{d_0} \frac{Q_{\text{EFF}} x_{\text{drive}}}{\omega_{\text{sense}}} \qquad [22]$$

.

Another subtle effect of mode mismatch is that the scale factor of the microgyroscope can vary with the input signal frequency. As the modes are mismatched, the sensitivity varies as a function of bandwidth. Bandwidth enhancement techniques that maintain relatively constant sensitivity (although reduced as compared with the matched-mode case) are an area of active research (Acar and Shkel 2005).

Table 2 lists the main performance metrics of the M^2-TFG and compares the values at matched-mode

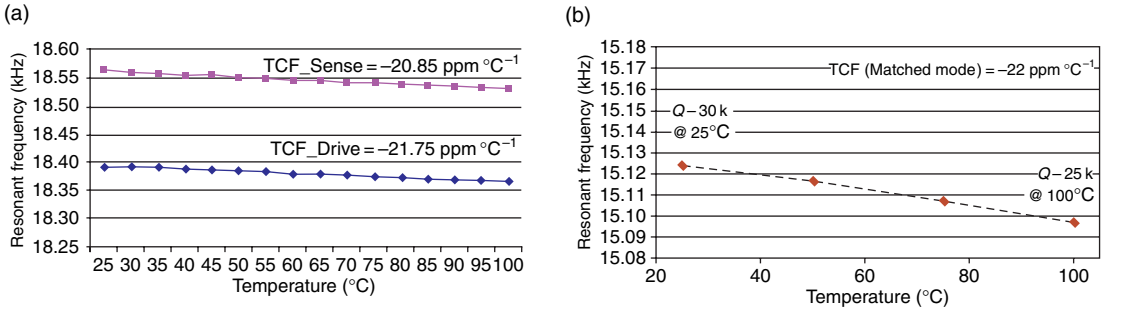

Figure 28 (a) Temperature coefficient of frequency (TCF) measurements of individual operating modes of a matched-mode tuning fork gyroscope (M^2-TFG) operating at 18.4 kHz and (b) TCF measurements of a device operating at a matched-mode condition.

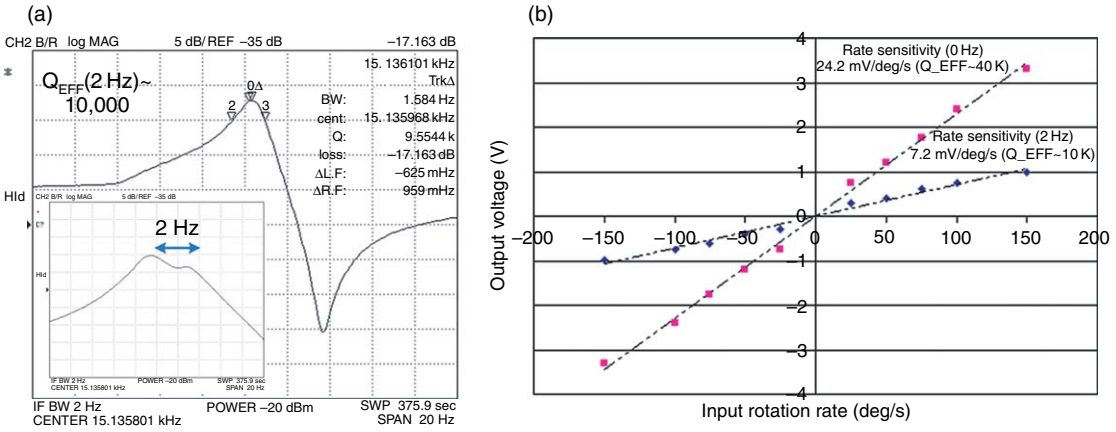

Figure 29 (a) Drive and sense modes matched to within 2 Hz and effective quality factor and (b) scale factor at 12 Hz separation where effective sense *Q* is 10 000.

Table 2 Performance comparison of the matched-mode tuning fork gyroscope (M^2-TFG) under two separate matching conditions and basic device parameters

Device parameter	*Mismatched*	*Matched*
Frequency split (Hz)	2	0
Effective sense quality factor	10 000	40 000
Theoretical Brownian noise floor (deg °h^{-1} $Hz^{-1/2}$)	1.1	0.5
Measured bias drift (at 25°C) (deg °h^{-1})	5.4	0.96
Rate sensitivity (mV deg^{-1} s^{-1})	7.2	24.2
Effective mass (μg)	30	
Drive amplitude (μm)	3	
Temperature coefficient of frequency (ppm °C^{-1})	−22	
Operating frequency (kHz)	15	

condition with those obtained when the modes are mismatched by about 2 Hz (corresponding to the case illustrated in **Figure 29**).

2.06.5 Future Trends in Micromachined Silicon Gyroscopes

Most of the research and development of silicon micromachined gyroscopes since the early 1990s has been driven by the automotive industry. The performance of micromachined gyroscopes has drastically improved over a rather short period, as illustrated in **Figure 30**, which is based on a sample of devices reported in the literature. Since 1991, the performance of micromachined gyroscopes, indicated by the ARW, has improved by a factor of 10 every 2 years. It is anticipated that a continuing improvement in the performance of micromachined gyroscopes (resolution, bias stability, dynamic range, etc.) will be seen over the next 10–20 years. As mentioned earlier, this will open up new avenues and market segments for micromachined gyroscopes, specifically inertial navigation for military and civilian applications.

Performance improvement is but one aspect of microgyroscope development. Considerable effort is under way for large-volume production of these micromachined sensors. Packaging and reliability are the two most important factors that must be considered before micromachined gyroscopes can be viably commercialized. The Analog Devices iMEMS® gyroscopes are hermetically sealed but operate at atmospheric pressure. Although this might suffice for rate-grade sensors, robust vacuum packaging will be required for navigation-grade gyroscopes. Additionally, to facilitate low-cost production of microgyroscopes, there is an increased emphasis on the design-for-manufacture and design-for-test.

The importance of robust vacuum packaging that can withstand temperature variations and shock has been recognized, and there is considerable research effort in that direction (Chae *et al.* 2005, Yoon *et al.* 2006). Researchers at the University of Michigan and Georgia Tech are developing hermetically packaged, environmentally protected, near-inertial-grade micromachined silicon gyroscopes. This work aims at developing wafer-scale micromachining technologies with high reliability, long lifetime, low power

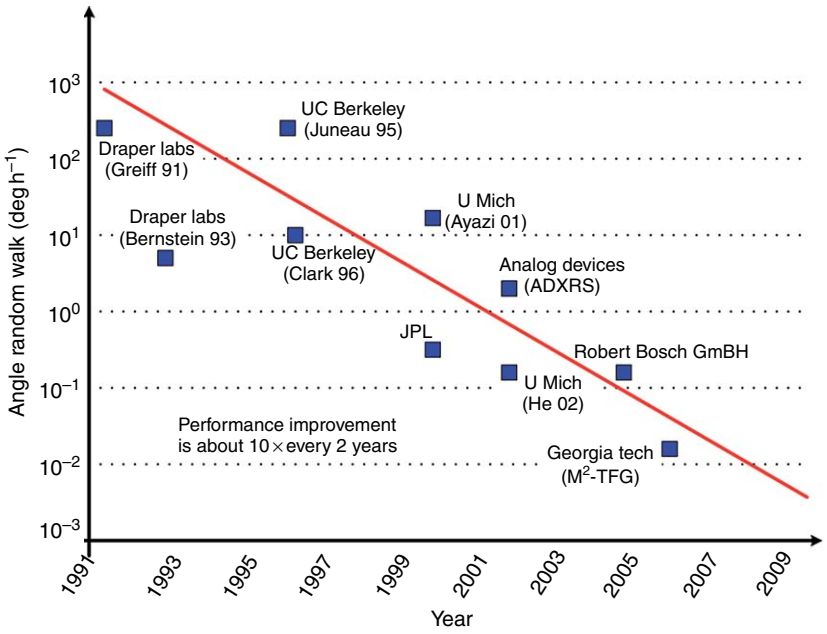

Figure 30 Performance of micromachined gyroscopes has improved by a factor of 10 every 2 years since 1991.

consumption, and high resistance to shock and environmental variations such as temperature.

While high aspect ratio micromachining provides significant improvement in sensor performance, it also enables the development of MEMS gyroscopes that can operate at lower voltages. The MEMS devices can then leverage the benefits offered by state-of-the-art CMOS processes and operate off a low-voltage battery.

Biographies

Farrokh Ayazi is an associate professor in the School of Electrical and Computer Engineering at the Georgia Institute of Technology. He received his BS degree in electrical engineering from the University of Tehran, Iran, in 1994, and his MS and Ph.D. degrees in electrical engineering from the University of Michigan, Ann Arbor, in 1997 and 2000, respectively. He joined the faculty of Georgia Tech in December 1999. Professor Ayazi's research interests are in the areas of integrated micro- and nanoelectromechanical resonators, RF MEMS, MEMS inertial sensors, VLSI analog circuits and techniques, and microfabrication technologies.

Professor Ayazi is a 2004 recipient of the NSF CAREER award, the 2004 Richard M. Bass Outstanding Teacher Award (determined by the vote of the ECE senior class), and the Georgia Technical College of Engineering Cutting Edge Research Award for 2001–2002. He received a Rackham Predoctoral Fellowship from the University of Michigan during 1998–1999. He serves on the technical program committee of the IEEE International Solid State Circuits Conference (ISSCC).

Mohammad Faisal Zaman received his BS degree (High Honors) in electrical engineering at the Georgia Institute of Technology (Atlanta, GA), in 2001. He is currently pursuing his Ph.D. degree at the IMEMS lab at the Georgia Institute of Technology. His doctoral research involves the design, fabrication, and analysis of high-precision micromachined gyroscopes. He has held internship positions with General Electric and Sprint-Nextel. He is a member of the Eta Kappa Nu and IEEE.

Ajit Sharma received his BE (Hons.) degree in electrical engineering from the Birla Institute of Technology and Science, Pilani, India, in 2001 and his MS degree in electrical engineering from Oregon State University, Corvallis, OR, in 2003. His masters' research focused on the prediction of substrate noise coupling in mixed-signal SOCs and methodologies for accurate substrate parasitic extraction in CMOS substrates. He is currently pursuing his Ph.D. degree at the IMEMS lab at the Georgia Institute of Technology, Atlanta, GA. His doctoral work involves the design of low-power and low-noise CMOS analog interface circuits for high-precision MEMS gyroscopes and modeling of microsystems. He has held co-op positions at Infineon Technologies, Singapore, and Biotronik Inc., Lake Oswego, OR. He received a Texas Instruments Analog Fellowship during 2003–2006.

2.07.1 Introduction

The flow of fluids has always interested mankind. From rudimentary weather predictions based on the direction of the winds to the simulation of fluid flow over a jet foil, measuring and modeling flow has played a central role in predicting its behavior and its effects on the surroundings. Even prior to the emergence of microsystem technology, a wealth of different flow sensors based on varying principles was developed. The advent of micromachining has allowed the miniaturization of existing sensors and resolutions that were not possible before. The batch manufacturability of many micromachined flow sensors makes them suitable for commercialization. Reproducibility has opened up the field of array sensing at relatively low cost, offering the possibility of obtaining an instantaneous representation of a complex flow. New sensor principles have emerged as well that take advantages of new materials such as carbon nanotubes (CNTS). Over the past few decades, an entirely new field, microfluidics, has emerged and with it the need for flow sensing on microscales. But not all of the problems have been solved, and no one sensor is applicable in all situations.

The goal of this chapter is to provide an overview of the micromachined flow sensors presented in the literature to date. The sensors are classified according to the domain in which they function and their operating principle. Due to the close relationship between micromachining and integrated circuits, a section is devoted to on-chip electronics. Two applications are also discussed.

The study of fluids in motion, fluid dynamics, is a complex field and plays an important role in the design of flow sensors. The large theoretical background to this field will be touched upon only when deemed necessary to clarify the flow-sensing principles presented. The theory behind the principles used to measure the flow, such as heat transfer, will also be introduced but not covered in detail. For more in-depth information on these subjects, references to the specialized literature have been provided.

2.07.2 Thermal Flow Sensors

Among micromachined flow sensors, thermal flow sensors make up the largest group, accounting for more than half of all the sensors described in the literature. They are also the oldest type of micromachined flow sensors, as a natural evolution from the integrated circuits, with which the observation of the air cooling of a simple heated resistor is sufficient to obtain a measurement of the flow. In this section, some basic fluid dynamics and heat transfer theory are introduced to serve as reference for the subsequent discussions on thermal flow sensors. At the end of the section, an overview table covering thermal flow sensors is given.

2.07.2.1 Laminar and Turbulent Flow

Figure 1 shows a time-averaged 1D flow profile near a wall. U is the speed of the flow in the direction of the flow, and y is the direction normal to the surface. The flow in the figure is the average of a flow that fluctuates with time. A measure for the amount of fluctuation, in other words the turbulence, is the Reynolds number. The Reynolds number at a certain

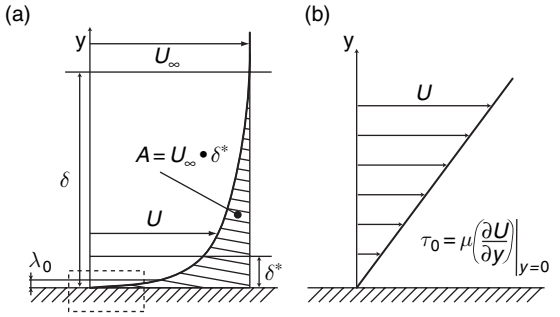

Figure 1 Time-averaged 1D flow profile near a wall. (b) Close-up of the region in the square of (a): the viscous sublayer, where the flow velocity is linearly dependent on the distance to the wall.

point is defined as $Re \equiv UD/\nu$, where U is the fluid velocity at that point, D is the characteristic length, for example, the distance of the point to the wall, and ν is the kinematic viscosity of the fluid (defined below). This dimensionless number is the ratio between the inertial and viscous forces in a fluid and is a measure of how turbulent a fluid flow is at a certain point. Roughly, one can say that for Reynolds numbers less than 10^3, the flow is not turbulent, that is, it is laminar, and for Reynolds numbers greater than 10^5, the flow is completely turbulent.

For a straight, parallel, and uniform flow, the shear stress, τ, between layers is proportional to the velocity gradient in the direction perpendicular to the layers:

$$\tau = \mu \frac{\partial U}{\partial y}$$

This is Newton's law of viscosity, and the proportionality constant μ is called the dynamic viscosity. Most gases as well as many liquids follow this law of viscosity. The kinematic viscosity, ν, is defined as the quotient of the fluid's dynamic viscosity and its density:

$$\nu = \frac{\mu}{\rho}$$

When talking about fluids near a wall, the term boundary layer is often used to define the layer close to the wall where a certain quantity, such as velocity or temperature, changes the most. The thickness of the layer is defined as an arbitrary value, e.g., the edge of the hydrodynamic boundary layer is often defined as the position off the wall where the fluid velocity is 99% of the free-stream velocity.

2.07.2.2 Heat Transfer

When a sensor is placed in a fluid with a different temperature, it will exchange heat with the fluid and with its attachment point. There are three mechanisms of heat transfer: conduction, convection, and radiation. Conduction is defined as the heat transfer from molecule to molecule. For an isotropic and homogenous medium, the behavior of the temperature T due to conduction can be described as follows:

$$\frac{\partial T}{\partial t} = \kappa \nabla^2 T$$

where κ is the thermal diffusivity, a material-specific quantity dependent on the material's thermal conductivity k, density ρ, and specific heat capacity c_p

$$\kappa = \frac{k}{\rho c_p}$$

Convection of the fluid increases the effect of conduction, as molecules with larger temperature differences are brought into contact with each other. Mathematically, this can be described by adding a convection term to the heat transport equation:

$$\frac{\partial T}{\partial t} + U \nabla T = \kappa \nabla^2 T$$

For sensors, the practical effect of convection is that, at the surface of a body in a fluid, heat transfer, Q, occurs that can be described as follows:

$$Q = hA(T_b - T_f)$$

where A is the surface area of the body, T_b the temperature of the body, T_f the temperature of the fluid, and h the heat transfer coefficient. The heat transfer coefficient is dependent on the fluid as well as on the flow. Since the flow velocity is zero at the wall, the heat transfer into the fluid is defined by conduction and can also be expressed as a function of the temperature gradient at the wall ($y = 0$) (Holman 1997):

$$\frac{Q}{A} = h(T_b - T_f) = -k \frac{\partial T}{\partial y}\bigg|_{y=0}$$

A dimensionless parameter used to characterize the enhancement of the heat transfer due to convection is the Nusselt number. It is the ratio of heat transferred from a surface to heat conducted away by the fluid. Defined as $Nu \equiv hL/k$, where L is the characteristic length scale and k is the thermal conductivity of the fluid, the Nusselt number is often correlated with the Reynolds and Prandtl numbers.

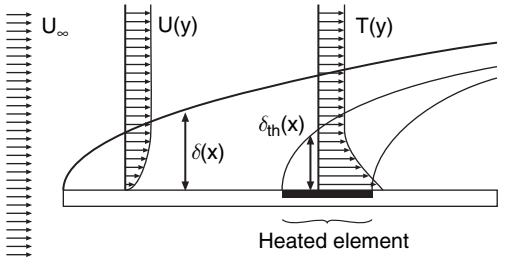

Figure 2 Typical average velocity and temperature profiles for a plate with a heater placed in the flow. $\delta(x)$ is the hydrodynamic boundary layer thickness, $\delta_{th}(x)$ is the thermal boundary thickness.

The Prandtl number is defined as the ratio of the fluid velocity boundary layer thickness to the fluid temperature boundary layer thickness and can be expressed as $\mathrm{Pr} = \mu c_p / k$.

The third mechanism for heat transfer is radiation. The amount of heat, P_{rad}, that is radiated follows the Stefan–Boltzmann law:

$$P_{\mathrm{rad}} = e\sigma A T^4$$

where σ is the Stefan–Boltzmann constant, A the area of the radiating body, T the temperature, and e the emissivity, a value between 0 and 1 where 1 is an ideal radiator. Since the surroundings (T_∞) also emit radiation, the net heat transfer of a body is $P_{\mathrm{net}} = e\sigma A(T^4 - T_\infty^4)$. Most often, for micromachined flow sensors, the heat emitted by radiation can be neglected as it is much smaller than the heat losses due to conduction and convection.

Figure 2 shows the typical average velocity and temperature profiles for a plate with a heater placed into the flow. The illustrated case is of the common situation where the Prandtl number is approximately 1 or greater, resulting in the thermal boundary layer being completely enveloped in the hydrodynamic boundary layer. This is the case for gases (where $Pr \sim 1$) and most liquids (water 6.75, glycerol 7250), with the exception of liquid metals (e.g., mercury 0.044) (Elwenspoek and Wiegerink 2001).

2.07.2.3 Thermal Flow Sensor Principles

Thermal flow sensors can be classified in function of three different principles: thermal anemometers, calorimetric flow sensors, and time-of-flight flow sensors. Figure 3 illustrates the principles.

The defining feature of thermal anemometers is that the flow is measured by its cooling effect on a heated entity. For calorimetric flow sensors, a temperature sensor is placed separate from the heated entity yet still within the thermal boundary layer of the heated body, and the heating effect of the flow is measured. By placing a sensor both upstream and downstream of the heater, the flow direction can also be measured. Time-of-flight flow sensors have the temperature sensors placed outside the thermal boundary layer of the heater and measure the time it takes for a thermal pulse to reach the sensors. Like calorimetric flow sensors, time-of-flight flow sensors can be made direction sensitive by adding sensing elements.

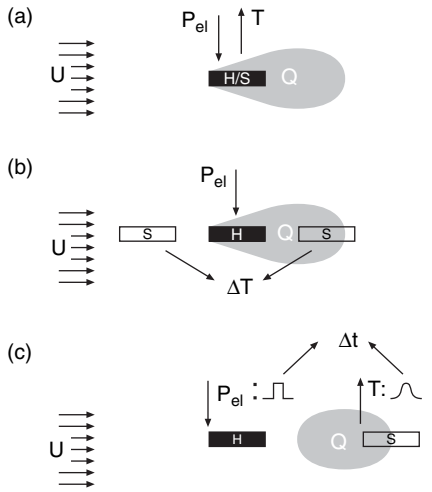

Figure 3 The three principles used in thermal flow sensing: (a) thermal anemometry, (b) calorimetric flow sensing, and (c) time-of-flight flow sensing (H, heater; S, sensor). (Source: Ashauer M, Glosch H, Hedrich F, Hey N, Sandmaier H, Lang W 1999 Thermal flow sensor for liquids and gases based on combinations of two principles. *Sens. Actuators A (Phys.)* **A73(1–2)**, 7–13. © 1999 Elsevier.)

An ideal thermal flow sensor is sensitive only to the thermal effects of the flow. All sensors, however, need to be supported in some way. Therefore, there is always some heat conduction through the supporting structure. In the worst case, the amount of heat conducted away is dependent on the flow outside the volume that the sensor is intended to measure. This results in reduced resolution and nonlinearities.

2.07.2.3.1 Thermal anemometers (alternative name: heat-loss flowmeters)

Depending on the heated element in a thermal anemometer, sensors of this type are called hot-wire, hot-chip, or hot-film anemometers. Conventional

hot-wire anemometers have been in use for more than a century and range from 1 µm diameter and 0.25 mm length upward (Bruun 1995). Though microsystem technology has enabled them to be miniaturized even more, most micromachined thermal flow sensors are of similar dimensions as the smallest conventional thermal flow sensors. They provide other advantages such as the possibility to form arrays to integrate control electronics on the sensor chip. **Table 2** provides an overview of micromachined anemometers.

In 1914, King (1914) derived an equation for infinitely long hot-wire anemometers in low Reynolds number flows that describes the relationship between the dissipated power (Q_{diss}) and the free-stream velocity (U). This equation is referred to as King's law:

$$Q_{\text{diss}} = A + B\sqrt{U}$$

where A and B are functions of the temperature and the dimensions of the wire. A dimensionless expression for the same equation is $Nu = A' + B'\sqrt{Re}$. For wires of finite length and with a linear temperature dependence on resistivity, the resistance at temperature T_w can be written as $R_w = R_0(1 + \alpha_0(T_w - T_0))$ where R_0 is the resistance and α_0 the temperature coefficient of resistance (TCR), both at temperature T_0. Let $V_w = R_w I_w$ be the voltage over the heated wire, then

$$\frac{V_w^2}{R_w} = (A + BU^n)(T_w - T_0)$$

where the exponent n differs from 0.5 due to the finite length of the wire (Bruun 1995).

A hot wire does not have an ideal single-axis flow direction sensitivity. For a circular wire, suspended by a pair of prongs that do not interfere with the flow, the response for flow components in the plane normal to the wire will be independent of the direction. The tangential component of the flow will give a small response as well (i.e., for wires with a length short of infinity). Let U_N be the flow's component normal to the hot wire and parallel to the prongs suspending it, U_T the component tangential to the hot wire, and U_B the binormal component perpendicular to the first two. Then the effective velocity, U_e, that the wire will measure can be described by Jørgensen's equation (Jørgensen 1971):

$$U_e^2 = U_N^2 + k_T^2 U_T^2 + k_B^2 U_B^2$$

where k_T and k_B are probe-dependent coefficients. For a standard plated conventional hot wire, $k_T = 0.2$ and $k_B = 0.2$ (Bruun 1995). For further information on hot wires, the interested reader is referred to the specialized literature and references therein (Bruun 1995).

Micromachined thermal anemometers differ from each other in the heater and sensor type, thermal insulation, whether or not they compensate for fluid temperature, and in the mode in which they are run. Nearly all thermal anemometers use some kind of resistor as a heating element. The most straightforward and common heating element is a doped silicon resistor. The high resistivity of silicon enables heating with low currents. Different metals have also been used, platinum being the most common. For measuring the temperature of the heated element, often the same resistor is used. A high TCR is an advantage. **Table 1** provides a short overview of the TCR values of metals commonly used for flow sensing.

Alternative temperature sensors used for thermal anemometers are thermopiles (e.g., n/p Si or Al–Si) and diodes. An advantage of thermopiles is that they measure the temperature difference. Assuming that the bulk of the sensor has the slowly varying temperature of the fluid, the temperature of the heated element can be kept more easily at a constant temperature difference (CTD) with the fluid, which has certain advantages over constant temperature (CT) (see below). Diodes are used for the linear temperature dependence of the threshold voltage (MacHattie 1979). Their advantage over implanted or diffused resistors lies in their temperature behavior being almost independent of the fabrication process (van der Wiel *et al.* 1993). Among the more exotic sensing variants, one can count capacitive sensors, where the temperature dependence of the dielectric's permittivity is used (Kwok *et al.* 1996, Lin *et al.* 1996), and surface acoustic wave (SAW) sensors, where temperature changes cause a resonance frequency shift (Ahmad 1985, Joshi 1994, Rebiere *et al.* 1994).

Table 1 TCR values of metals commonly used for micromachined thermal flow sensors

Metal	*TCR (Goodfellow, 2007) (‰ K^{-1})*
Pt	3.92
Au	4.0
Mo	4.35
Ni	6.8
Ta	3.5
Al	4.5
Ti	3.8
Cr	2.14

[a]Implanted resistor: using ion implantation.
[b]Silicon dioxide and silicon nitride are abbreviated to SiO and SiN, respectively, irrespective of stoichiometry.
[c]Mode indicates the operating mode in which the sensor has been evaluated. CC, constant current; CP, constant power; CT, constant temperature; CTD, constant temperature difference; CV, constant voltage.
[d]Italicized sensitivities indicate that the figure has been estimated from plots.
[e]In cases where the output signal is not described by a sensitivity factor, only the output at the largest measured flow rate is given.
[f]In cases of different parameters for similar devices (e.g., temperature difference), the highest response was given.
[g]Sensitivity range: the sensitivity indicated is only valid within this range, if absent, the sensitivity is valid for the entire measured range.
[h]Italicized values indicate that the figure was estimated from plots.
[i]ΔT/I/V/P: the temperature, current, voltage or power at which the sensor is operating; the indicated value depends on the operating mode. If the temperature is indicated in degree celcius, it implies the absolute temperature at which the sensor is driven; otherwise, itrefers to the temperature difference with the fluid. Values between brackets are approximate values of a non- constant parameter.
[j]Time constants differ often between heating and cooling. The smallest time constant is given. In case a percentage is given, the value specifies the rise time needed to reach this percentage of the steady-state value.
[k]T_b: Temperature at which the resonant buckles.
[l]Assumed, not specified in the article.

Thermal insulation is arguably the most important aspect of thermal sensors. For an all-silicon sensor that does not have any precautions for thermal insulation, the high thermal conductivity of silicon will result in a hot-chip configuration where the entire silicon die is heated up to the same temperature, effectively reducing the resolution to the chip size and resulting in a relatively large power consumption (Bruschi *et al.* 2004a, Dominguez *et al.* 2005, Huang and Tong 1989, MacHattie 1979, Toda *et al.* 1996, Tong and Huang 1987). Placing the heater on silicon, silicon dioxide, and silicon nitride membranes is a common insulation method (e.g., Kersjes *et al.* 1993, Tabata 1986, Yoon and Wise 1988). **Figure 4(a)** and **4(b)** illustrates two basic methods of achieving such membranes: back-side etching and front-side etching. While back-side etching requires an extra mask step, it does not require etch openings in the membrane, which can allow natural convection in the cavity below to affect the measurements (Gajda and Ahmed 1995, Hung *et al.* 2000). A slightly more complex process, using membrane transfer bonding on cavities at low pressure (e.g., Breuer *et al.* 1999) or resealing of a cavity created by a sacrificial layer using low-pressure chemical vapor deposition (e.g., Huang *et al.* 1995), overcomes this problem and can further reduce conduction downward. Thermal insulation can also be obtained with an insulating substrate, such as glass (Kohl *et al.* 1994, Kuttner *et al.* 1991, Ma *et al.* 1995, Platzer 1976, Esashi 1991) or low-temperature cofired ceramics (LTCC) (Schmid 2002), or by having a thick thermally insulating layer, either below or around the heated area, made of, for example, polyimide (Dittmann *et al.* 2001, Ebefors *et al.* 1999, Kälvesten *et al.* 1995, Löfdahl *et al.* 1989a, 1992, Stemme 1986) or oxidized porous silicon (Dominguez *et al.* 1993, Pagonis *et al.* 2004, Perichon *et al.* 2000, Tabata 1986, Tabata *et al.* 1987) (see **Figure 4(d)**, **4(e)**, and **4(i)**). As in conventional hot-wire anemometers, thermal insulation, or at least control over thermal conduction, can be obtained by prongs that suspend the hot element (Chen and Liu 2003, Chen *et al.* 2003, 2002, Ebefors *et al.* 1999, Haasl *et al.* 2005, Jiang *et al.*, 1994a, b, Löfdahl *et al.* 2003). In microchannels, an equivalent to this is a heater that crosses the channel edge to edge, as illustrated in **Figure 4(i)**. Achieving insulation in microchannels is a challenge as the channel walls can conduct away a large portion of the heat. **Figure 4(j)** shows the principle presented by Wu *et al.* (2001) where a polysilicon heater is integrated into a suspended silicon nitride channel.

Since thermal anemometers are inherently sensitive to fluid temperature changes, many devices include a separate sensor that measures the fluid temperature. For hot-chip configurations, this can be an identical but unheated sensor at a different point in the flow, often upstream, (Esashi 1991, Kersjes *et al.* 1996, Kohl *et al.* 1994, Kuttner *et al.* 1991, Toda *et al.* 1996), while for sensors with the heated element isolated from the rest of the chip, it can be a sensing element such as a resistor or a diode on the bulk area (e.g., Stemme 1988, Tabata 1986). A different approach for measuring the fluid temperature was used by Bruschi *et al.* (2004b) with the sensor illustrated in **Figure 5**. A polysilicon heating resistor

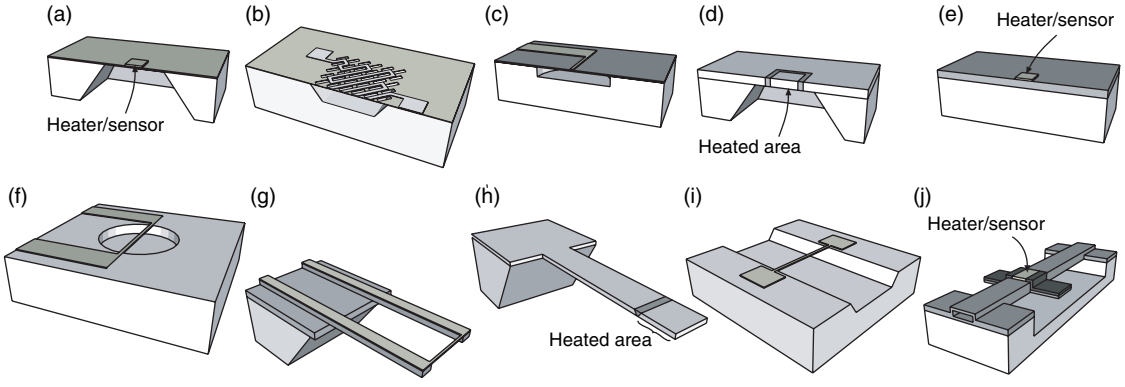

Figure 4 Cross sections of thermal anemometers to illustrate thermal insulation methods: (a) back-side-etched thermally insulating membrane; (b) front-side-etched thermally insulating membrane (Hung *et al.* 2000); (c) membrane transfer bonded to the cavity or the resealed sacrificially etched cavity (Breuer *et al.* 1999); (d) thermally conducting membrane with thermally insulating grooves; (e) thick thermally insulating layer on the substrate or thermally insulating substrate; (f) open cavity; (g) prong suspension (Jiang *et al.* 1994a); (h) insulating groove suspension; (i) cross-channel bridge (top half of the channel not shown), with or without thermally insulating reinforcement; and (j) insulating channel walls (Wu *et al.* 2001).

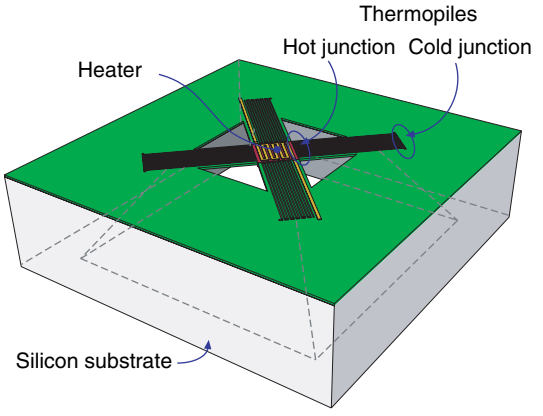

Figure 5 Thermal anemometer used in pulse mode to obtain flow temperature compensation. (Source: Bruschi P *et al.* 2005).

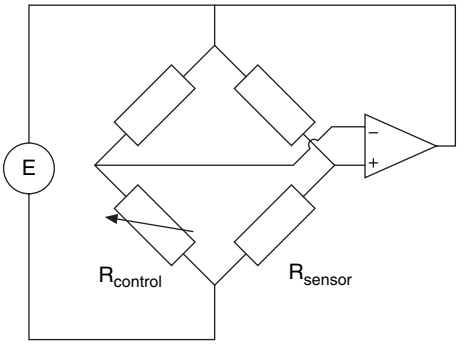

Figure 6 Constant temperature (CT) circuit. The temperature of the sensing resistor is controlled by $R_{control}$. The bridge voltage E is a measure of the flow.

is positioned on a cross-shaped membrane that has n/p-Si thermopiles on its arms measuring the temperature difference between the membrane and the bulk of the chip. Due to the low thermal mass of the heater, operating it in pulsed mode enables the temperature difference between the fluid and the bulk of the chip during the off state of the pulse to be measured.

2.07.2.3.2 Thermal anemometers: modes of operation

Thermal anemometers can be run in several different modes. Constant voltage (CV) and constant current (CC) require the least control. For sensors where a resistor is used both for heating and sensing, the resistance, and thus the temperature, can be easily calculated from the current or the voltage. A common implementation for these modes is to use a Wheatstone bridge. With this set-up, a fluid temperature sensor can also be easily introduced to provide temperature compensation. Both methods are approximations of a slightly more complex approach: the constant power (CP) control of the heater. All three methods suffer, however, from the time constant of the system being limited by the thermal time constant of the heated element.

A solution to this is to run the sensor in CT mode. By using a feedback circuit to keep the temperature of the sensor constant and by measuring the feedback voltage, the time constant of the system is only limited by the response time of the circuit (**Figure 6** for a standard analog CT circuit). Another advantage, specific for liquid flowmeters, is that there is no risk of overheating when the sensor is removed from the liquid during operation. In conventional hot-wire anemometry, CT is the most common measurement method, while a wire operated at a low current (to avoid self-heating) in CC mode is often used for fluid temperature measurements. **Figure 7** shows the typical response curve of a thermal anemometer run in CT mode, $V = \sqrt{A + B\sqrt{U}}$, which illustrates the general characteristic of thermal flow sensors, namely that the sensitivity is highest at low flow velocities and decreases at higher velocities.

In cases where the fluid temperature can vary much (e.g., Castaner *et al.* 1997, Steurer and Kohl 1998) or where the sensor's ambient temperature is only slightly above the ambient (e.g., Kuttner *et al.* 1991), it is desirable to control the heating element's temperature at a CTD with the ambient. However, this puts more demands on the circuitry, and, as Lammerink *et al.* (2000) pointed out, in all cases cannot generate an output signal that is independent

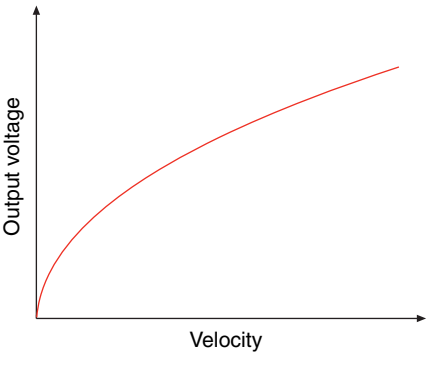

Figure 7 Typical response curve of a thermal anemometer run in constant temperature (CT) mode.

of the fluid temperature. The requirement for a CTD circuit to provide a fully ambient-temperature-independent signal is that the response of the ambient and heated element temperature sensors is linear or at least the same in the ambient temperature range as in the heated element's temperature range. The solution presented by Lammerink *et al.* (2000) is an operating-mode dubbed temperature-balance anemometry (TBA) using two hot-element calorimetric flow sensors as described further below.

It is also possible to combine several heated elements to achieve higher sensitivity. By placing four rectangular hot-element sensors in a square, a full Wheatstone bridge is formed (Betzner *et al.* 1996, Ma *et al.* 1995, van Putten 1983). The flow will cool down the elements perpendicular to it more than those that are parallel to it, resulting in a bridge imbalance. A second effect used, as described by van Putten (1983), is that, for a chip placed in the flow, the thermal boundary layer is thinner at the leading edge, resulting in a higher temperature gradient and hence a higher heat transfer coefficient. Van Putten, moreover, designed a double Wheatstone bridge to increase the differential-mode sensitivity and common-mode suppression. The second bridge is placed inside the first bridge and is electrically linked at a 90° angle (**Figure 8**). The temperature gradient due to the thermal boundary layer thickness difference was isolated in a later version of the double-bridge sensor. Van Putten (1988) and van Putten *et al.* (1997) split up the bridges and used heating from the inner bridge to keep the average temperature of the outer bridge constant. In this way the outer bridge, driven in CC mode, is kept at aCV, resulting in constant current, constant voltage (CCCV) mode. The bridge voltage of the outer bridge is shown to be dependent on the heat dissipation difference between the upstream and downstream resistors. Besides resulting in a direction-dependent signal, this operating method provides a high rejection of the common-mode dissipation variations caused by varying flow and ambient temperature. The sensor is still sensitive to ambient temperature variations, but the dependence is reduced to a linear effect.

Stemme (1988) designed an integrated digital feedback circuit that oscillates the hot element's temperature between two set temperatures. A CC source heats the element until it reaches the top temperature, then switches off until the element has cooled down to the bottom temperature. The output signal consists of the lengths of the current pulses in the supply voltage. The ratio between the heating and the cooling time is a function of the flow rate. Yoon

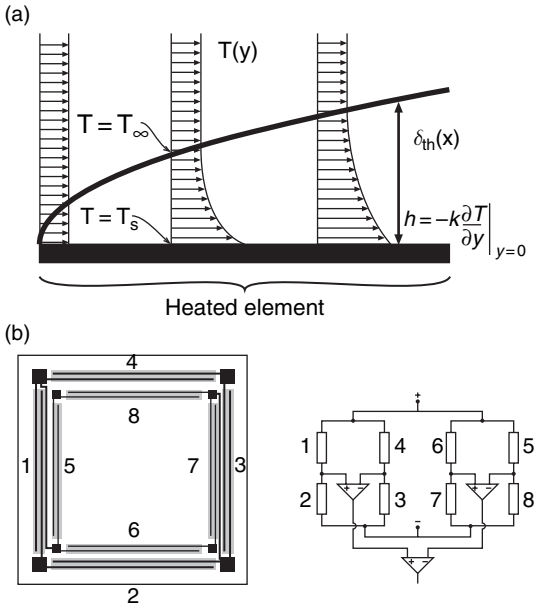

Figure 8 (a) Near-wall flow profile evolution for a chip placed in the flow. (b) Double Wheatstone bridge configuration by van Putten (1983) (Source: Van Putten A 1983 An integrated silicon double bridge anemometer. *Sens. Actuators* **4(3)**, 387–96. © 1983 Elsevier.) chip layout and circuit. Note that the very high resistivity polysilicon heaters (gray) are contact with aluminum leads (black) such that they are wide and short to reduce the resistance. For a flow *U* coming from the left, the resistors 1, 3, 5, and 7 are cooled down more than the others, resulting in a differential output from both bridges.

and Wise (1992) used this operating mode as a self-test mode for a sensor that, under normal conditions, is run in CT mode. The pulse time is dependent on both the thermal time constant and the flow rate. A second flow-rate sensor on the same chip, operated in CT mode, measures the latter. Comparing signals of both modes allows the thermal time constant to be monitored. Surface film depositions, such as oil and carbon from a dirty environment, can in this way be monitored with a stated sensitivity of below 1 μm. At these film thicknesses, velocity errors are at the same level as the resolution of the sensor. Stenberg *et al.* (1988) presented a two-element calorimetric sensor for the same purpose of measuring surface film thickness together with flow (see below).

Alternating current (AC) driving modes are uncommon for single-element thermal anemometers and used only in some special cases where they have specific advantages. One is the anemometer based on a single thermopile developed by Al Khalfioui *et al.* (2003), shown in **Figure 9**. The thermopile consists

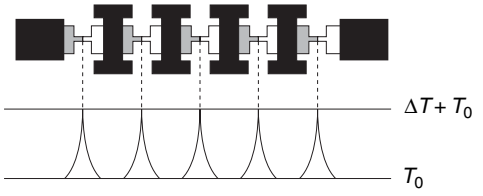

Figure 9 Linear thermopile with temperature profile. (Source: Al Khalfioui M, Michez A, Giani A, Boyer A, Foucaran A 2003 Anemometer based on Seebeck effect. *Sens. Actuators A Phys.* **107(1)**, 36–41. © 2003 Elevier.)

of a small number (e.g., 5) of $Bi_2Te_3-Sb_2Te_3$(P)/$Bi_2Te_3-Bi_2Se_3$(N) thermocouples placed in a line on a polyimide substrate. Each cold junction is covered with a Ni/Ag heat radiator to keep it at room temperature. The hot junctions are heated using AC, thus allowing the direct current (DC) thermoelectric voltage to be read out independent of the driving current.

On the border between micromachining and conventional technology, flow sensors based on acoustic waves have been presented by different groups (Ahmad 1985, Brace *et al.* 1989, Joshi 1989, Joshi and Jin 1990, Rebiere *et al.* 1994). A piezoelectric substrate (e.g., $LiNbO_3$) is heated and a pair of interdigitated transducers is used to generate an acoustic oscillation. The flow-induced cooling of the entire chip is detected as a frequency shift in the oscillation. Heating can be generated by thin- or thick-film resistors in between and around the transducers and also by the acoustic waves themselves (Brace *et al.* 1989). Care needs to be taken in the spacing of the heating meanders to avoid acoustic reflection (Joshi 1994). The large size of the sensors used (ranging from 0.2 to 2.7 cm^2) causes large time constants ranging from 10 to 90 s. Joshi (1994) suggested that time constants can be drastically reduced using ultrasonic Lamb wave oscillators on silicon nitride membranes as presented by Wenzel and White (1988). Most of the presented devices use SAW modes with the exception of the one presented by Rebiere *et al.* (1994), who evaluated a device using a shear horizontal acoustic wave mode traveling through the bulk and facilitating the placement of the ultrasonic transducer contacts outside of the flow.

Another type of resonance-based flow sensor makes use of temperature-dependent stress in membranes and beams. A membrane (Bouwstra *et al.* 1989) or a bridge (Bouwstra *et al.* 1990) is heated with a polysilicon resistor to an elevated temperature with a DC signal and is excited into vibration by superimposing an AC signal at its resonance frequency. The stress in the resonating structure is dependent on its temperature and affects the resonance frequency. As the sensor is cooled by airflow, the change in the resonance frequency can be measured by piezoelectric resistors on the edge of the resonator. Compared to the membrane resonator, the bridge resonator has a higher sensitivity since heat conduction to the support structure is reduced and both sides of the structure are in contact with the flow. The resonance frequency was found to change the most near the buckling stress of the beam and had a larger absolute sensitivity to flow in the buckled state than in the unbuckled state (Legtenberg *et al.* 1991).

Using the temperature dependence of the dielectric constant of high-k dielectrics such as Ta_2O_5 and $SrTiO_3$, Kwok *et al.* (1996) and Lin *et al.* (1996) constructed thermocapacitive metal oxide semiconductor (MOS) flow sensors. The sensing capacitor placed on a thermally insulating membrane or beam is heated with a polysilicon resistor. The capacitance is measured by having the capacitor form the floating gate of a MOS transistor (Lin *et al.* 1996) or by using a dedicated capacitance readout circuit (Kwok *et al.* 1996).

Lee *et al.* (2002) developed a vortex-based flow sensor. By means of a nozzle placed in front of a V-shaped obstruction (**Figure 10**), a flapping mode can be generated. The frequency of the planar liquid jet flapping between the two exits from the channel formed by the obstruction is a function of the flow velocity and the geometry. A number to characterize

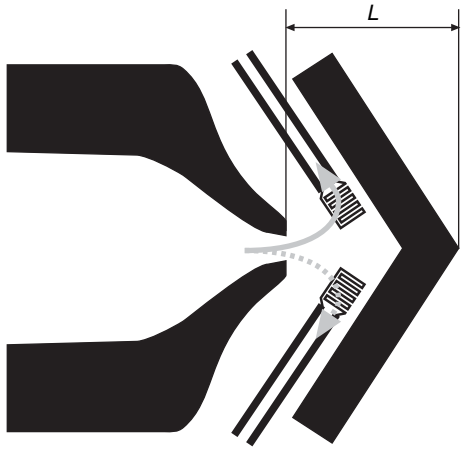

Figure 10 Top view of nozzle, obstruction, and sensing resistors; arrows indicate the flapping mode. (Source: Lee G-B, Kuo T-Y, Wu W-Y 2002. A novel micromachined flow sensor using periodic flapping motion of a planar jet impinging on a V-shaped plate. *Exp. Therm. Fluid Sci.* **26(5)**, 435–44. © 2002 Elsevier.)

this behavior is the Strouhal number, defined as $St = fL/U$, where U is the average flow velocity, f the oscillation frequency, and L the characteristic length scale (defined in **Figure 10**). The Strouhal number for this geometry was shown to be a constant over the measured flow range (0.16–4 mm s^{-1}) and two tested distances ($L = 1.44$ and 2.79 mm), the result being a linear relationship between the flapping frequency and the average flow velocity. The flapping frequency, ranging from 0.01 to 0.31 Hz, was measured by a pair of resistors in the CC mode. A peculiarity with the measurement method is that it was possible to create a flapping flow on a V-shaped plate at the low Reynolds numbers (0.2–5.4) associated with this setup. The limitations of this method are the high pressure loss and the low frequencies involved; at 0.083 Hz mm^{-1} s the fluid will flow 12 mm in one flap period. The latter might be improved by miniaturizing the device, and if successful, eliminate the need for low-frequency electronics.

2.07.2.3.3 Calorimetric flow sensors (alternative names: thermotransfer, thermal dilution)

This class of thermal flows sensors measures flows by using at least two elements: a heater and a downstream sensor. The sensor measures the temperature change of the fluid by the heater. The thermal capacity of the fluid is an important parameter, hence the name calorimetric. As mentioned above, thermal anemometers can use distinct heater and sensor elements, but in that case the sensor element measures the temperature of the same thermal entity, measuring the heat loss without the heat passing through the fluid to get to the sensor. Ideal calorimetric flow sensors have heater and sensor in perfect thermal isolation from each other except for the fluid. In reality, however, a large gray zone exists, and the conduction of heat from the heater to the sensor via the substrate produces an unwanted signal. **Table 3** provides an overview of micromachined calorimetric flow sensors.

Nearly always a second sensor is placed upstream. This makes the flow sensor bidirectional and provides a differential signal, so that the effect of the conduction through the substrate can be removed. An offset is still created in cases where the temperature behavior of the upstream and downstream sensors differs. For resistive sensors, for example, this results in a difference of resistance. By placing a pair of sensors orthogonally to the first pair, a 2D flow sensor is obtained (Fürjes *et al.* 2004, Kim *et al.* 2004, Mayer *et al.* 1996, Park *et al.* 2003a, Robadey *et al.* 1995).

A subclass of calorimetric flow sensors uses multiple hot sensors: heaters that double as sensors measure the difference in heat loss between the upstream and the downstream heater (Lammerink *et al.* 2000, Lyons *et al.* 1998, Nagata *et al.* 2001, van Oudheusden *et al.* 1989, Stenberg *et al.* 1988). What differentiates these sensors from the full Wheatstone bridge sensors described above is that the difference in temperature between the upstream and the downstream heater is a result of the flow-induced heat transfer between them, one heating the other through the fluid, and not from the difference in hydrodynamic boundary layer thickness. With this method, besides flow velocity, other parameters, such as, for example, in the case of Stenberg *et al.* (1988), the thickness of fouling biofilms growing on the sensor surface, can be measured.

2.07.2.3.3.(i) Calorimetric flow sensors: modes of operation As with thermal anemometers, the heater can be run in different operating modes.CC, CV, and CP are easy to implement but have disadvantages. Lammerink *et al.* (1993) calculated the behavior of a three-wire calorimetric flow sensor in a microchannel (cross-channel bridge, see **Figure 4(i)**), operated in CP mode. The temperature is assumed to be constant along the wire and to decrease linearly in the direction perpendicular to the flow and the wire. This results in the addition of a term $-\kappa T/l_z^2$ to the steady-state ($\partial T/\partial t = 0$) 1D heat transfer equation along the length axis of the channel:

$$U\frac{\partial T}{\partial x} = \kappa\frac{\partial^2 T}{\partial x^2} - \kappa\frac{T}{l_z^2}$$

with l_z being the height of the channel. With boundary conditions set to a heating power P for the heater width $2L$ and $\lim_{x\to\infty} T = 0$, the solution of this equation becomes $T = T_0$ for $-L<x<L$, $T = T_0\exp(\lambda_1(x+L))$ for $x>L$ (downstream), and $T = T_0\exp(\lambda_2(x-L))$ for $x<L$ (upstream), with

$$\lambda_{1,2} = \frac{1}{2\kappa}\left(U \pm \sqrt{U^2 + 4\kappa^2/l_z^2}\right)$$

and $T_0 = Pf(k, \lambda_{1,2}, \text{geometry})$, where f is a function of the geometry (height and width of the channel and

[a]Silicon dioxide and silicon nitride are abbreviated to SiO and SiN, respectively, irrespective of stoichiometry.
[b]Italicized fluid type indicates that the fluid was not specified in the reference.
[c]Italicized sensitivities indicate that the figure has been estimated from plots.
[d]In cases where the output signal is not described by a sensitivity factor, only the output at the largest measured flow rate is given.
[e]In cases of different parameters for similar devices (e.g., temperature difference), the highest response was given.
[f]Sensitivity range: the sensitivity indicated is only valid within this range, if absent, the sensitivity is valid for the entire measured range. Italicized values indicate that the figure was estimated from plots.
[g]Time constants differ often between heating and cooling. The smallest time constant is given. In case a percentage is given, the value specifies the rise time needed to reach this percentage of the steady-state value. Italicized values indicate that the figure was estimated from plots.
[h]Assumed, not specified in the arich.

width of the heater), the thermal conductivity, k, and $\lambda_{1,2}$. In **Figure 11**, the results are plotted for some typical values of U.

Figure 12 illustrates how, at low flow velocities, the temperature difference between the downstream and the upstream sensors, ΔT, increases linearly. However, at increasing velocities, the heater is cooled so much that ΔT decreases again.

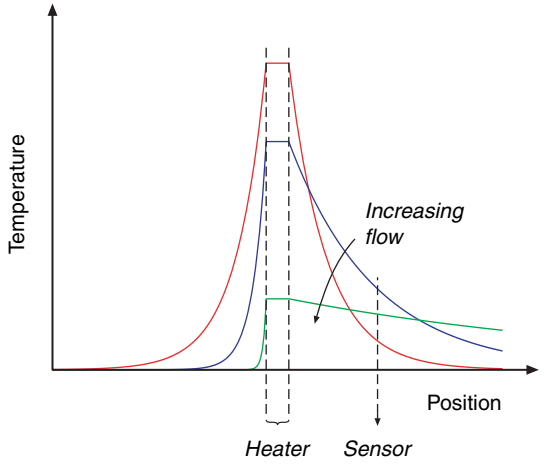

Figure 11 Temperature profile near the heater for three different flow rates. The vertical line indicates the position of the downstream sensor.

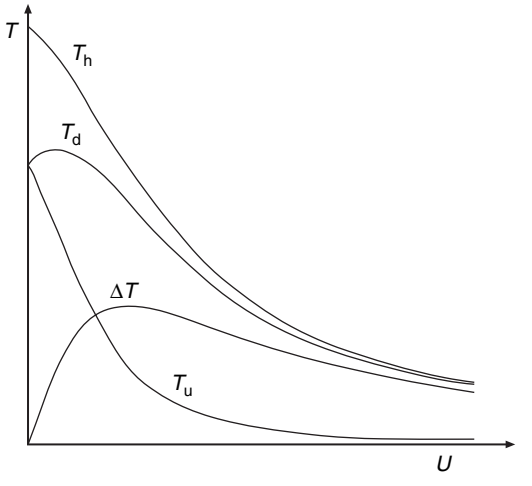

Figure 12 Sensor temperatures as a function of the flow velocity U. T_h is the heater temperature, T_u and T_d the upstream and downstream sensor temperatures, respectively, and ΔT the temperature difference between the downstream and the upstream sensor. (Source: Lammerink T, Tas N, Elwenspoek M, Fluitman J 1993 Micro-liquid flow sensor. *Sens. Actuators A (Phys.)* **A37–A38**, 45–50. © 1993 Elsevier.)

CT control of the heater overcomes this problem and provides a monotonously increasing ΔT. As with thermal anemometers, it is also possible to control the temperature of the heater to maintain a CTD with the fluid.

The aforementioned TBA operating mode (Lammerink *et al.* 2000, Makinwa and Huijsing 2002a) is based on two heated elements at a small distance from each other kept at the same temperature by a CP controller. The total power to the two heated elements remains constant and the ratio of the power distribution between the two elements is a measure for the flow. Because of this, the restraint on the response of the temperature sensors is loosened, so that the two sensors only have to have the same response, unlike CTD where the response of the two sensors has to be the same at both the ambient and the heated temperature. This gives the freedom to use sensing methods that are highly sensitive and reproducible but nonlinear, such as metal–semiconductor thermocouples. An AC-driven variant was presented by Lammerink *et al.* (2001) that consisted of two heating elements driven at 90° phase shift (creating a pair of 180° phase-shifted thermal signals) and a third element between them to sense the temperature variations using a phase-lock amplifier. The advantages of this system lie in the avoidance of DC offset and $1/f$ noise.

Although most often the heater and the sensor type do not directly require a specific operating mode, a specific subclass of sensors based on the pyroelectric effect does. Pyroelectric materials form a subclass of piezoelectric materials that distinguish themselves by generating a surface charge when undergoing temperature changes. **Figure 13** shows

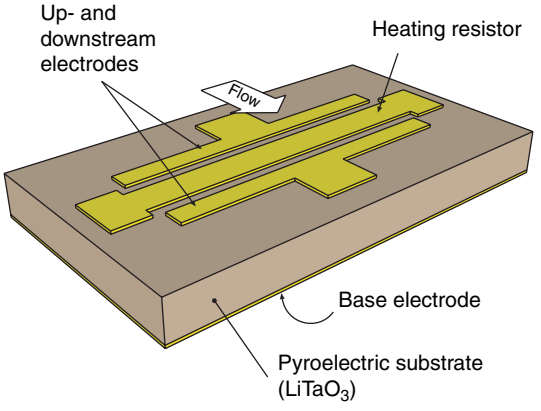

Figure 13 Flow sensor based on the pyroelectric effect. (Source: Zemel and Rahnamai H 1980).

a sketch of the device invented by Zemel and Rahnamai (1980) in which the electrodes on a lithium tantalate ($LiTaO_3$) substrate enable readout of the local charges upstream and downstream of a heating resistor. By applying a constant-amplitude low-frequency voltage (1–3 Hz) on the heating resistor, a signal at the double frequency is generated at both electrodes. The downstream electrode will experience a larger temperature fluctuation and so generate a larger voltage fluctuation. Advantages of the method are its low power consumption and large measurement range (0.5 ml min^{-1}–20 l min^{-1} was reported in Hsieh *et al.* (1991)). The voltage is measured differentially over the two capacitors. A thin-film pyroelectric flow sensor was presented by Polla *et al.* (1983). Sputter-deposited ZnO was used, and the charge buildup was measured in DC mode. The charge decay was found to be 85 h. A disadvantage of both variants, however, is the large time constant, which ranges from seconds to tens of seconds. A thorough overview of pyroelectric flowmeters is given in Hsieh and Zemel (1995), Hsieh *et al.* (1995a, b).

SAW sensors, which are described in Section 2.07.2.3.1, have also been used in calorimetric mode. Brace *et al.* (1989) used two SAW chips, thermally and acoustically isolated from each other, operating the upstream oscillator at a high CP and the downstream oscillator at low power.

Recently, a new application area for calorimetric flow sensors has emerged. Instead of avoiding natural convection effects, the heater is heated up to a high temperature (150–700°C) to create fluid flow away from the heater. If placed in an enclosed cavity, the direction of the flow is determined only by the acceleration force acting on it, and the airflow becomes a measure for the acceleration and the inclination. The principle was first patented by Plöchinger (1994), and micromachined variants followed soon after (Billat *et al.* 2001, Chaehoi *et al.* 2005, van Honschoten *et al.* 2000, Leung *et al.* 1997, Lin and Jones 2005, Luo *et al.* 2001, Milanovic *et al.* 1998). With the exception of the microflown-based sensor described by van Honschoten *et al.* (2000), all are based on the three-element caloric principle: one heater in the center and one temperature sensor on either side in a bridge formation over a cavity (**Figure 14**) The step to two-axis designs is not big and has been demonstrated both for inclinometers (Billat *et al.* 2001) and accelerometers (Leung *et al.* 1998). Luo *et al.* (2002) have presented an elaborate analysis of the parameters affecting the linearity, sensitivity, and frequency response of convective accelerometers.

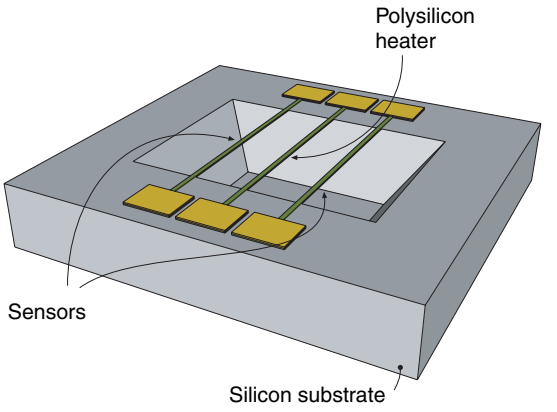

Figure 14 Thermal accelerometer. (Source: Leung *et al.* 1998).

2.07.2.3.3.(ii) The microflown The microflown, conceptualized by de Bree *et al.* (1995), is a flow sensor designed to measure particle velocity. This quantity, defined as the flow volume rate per unit area, is used in acoustic theory together with acoustic pressure to describe acoustic waves. Since normal microphones measure acoustic pressure, the combination with a microflown allows the measurement of acoustic intensity, the product of both. Combining a pressure microphone with a microflown provides a low-cost alternative to the conventional method of measuring flow intensity using two phase-matched microphones, as the phase-matching circuitry demands are high and, hence, expensive (Elwenspoek 1999). Conversely, two microflowns can be placed at a distance from each other and have their signals combined to calculate the acoustic pressure (de Bree *et al.* 1996). The operating principle can be applied to different calorimetric set-ups: a heater with one or two sensors or a two hot-sensor principle (de Bree *et al.* 1995, van Honschoten *et al.* 2005). In contrast to pressure microphones, the particle-velocity measurement is direction sensitive and does not have a low-frequency cutoff. de Bree *et al.* (1999) used the common-mode and differential signals from a microflown operated at CP to create a large-range direction-sensitive flow sensor. The magnitude of the common-mode signal is used as it shows the typical flow dependency of a CP-operated thermal anemometer ($P/(A+B\sqrt{U})$) but is insensitive to the flow direction. The differential-mode signal behaves like a typical nonuniform calorimetric flow sensor (see **Figure 12**), in which the sign as well as the highly sensitive low-flow signal can be used to complement the common-mode signal.

2.07.2.3.4 Time-of-flight flow sensors

An alternative operating method for a heater/sensor setup is to measure the time it takes for a heat pulse to travel from the heater to the sensor. Like calorimetric flow sensors, this sensor type can also be made direction sensitive. As the distance between the heater and the sensor is known, the calculation of the flow speed might at first sight seem easy. However, on a microscale, the thermal diffusivity of the fluid plays a major role and causes the measured signal to deviate from the ideal relationship $t_{peak} = x/U$ between the peak of the pulse measured at a distance x and the flow U.

For the simplified case of a line heat source in a uniform flow, Marshall (1958) derived an analytical solution describing the thermal response to a heat pulse. For this he started from the combined diffusion and convection heat transport equation with a heat generation term $Q/\rho c$, where Q is the generated heat (in W m^{-1}), ρ the density of the medium, and c_p the specific heat capacity of the medium:

$$\frac{\partial T}{\partial t} + U\nabla T = \kappa\nabla^2 T + \frac{Q}{\rho c_p}$$

The general solution at a point at a distance x from the heat pulse source for some different velocities are plotted in Figure 15(a). At low velocities, the thermal pulse significantly broadens before reaching the sensing point. The time at which the temperature peaks at a point at a distance x from the heat pulse source is expressed as (Figure 15(b)):

$$t_{peak} = \frac{\sqrt{4\kappa^2 + U^2x^2} - 2\kappa}{U^2}$$

Rewriting this as a function of the flow velocity results in the following equation:

$$U = \frac{\sqrt{x^2 - 4\kappa t_{peak}}}{t_{peak}}$$

This implies that in order for the ideal relationship $U = x/t_{peak}$ to be valid, $4\kappa t_{peak}$ needs to be much smaller than x^2, which is equivalent to the requirement that $U \gg 4\kappa/x$. Table 4 shows the velocities at some typical distances for which $U = 10 \times 4\kappa/x$ and illustrates the low threshold to nonideal behavior.

Further nonidealities are introduced as micromachined thermal flow sensors are often wall-mounted or consist of wires spanning a microchannel, in which cases the uniform flow assumption no longer holds. Table 5 provides an overview of micromachined thermal time-of-flight sensors.

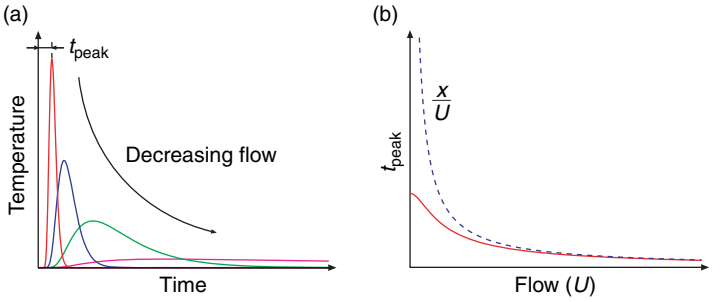

Figure 15 (a) Temperature signal at the downstream sensor for different flow velocities and (b) heat pulse peak time versus flow at the downstream sensor.

Table 4 Threshold for nonideal behavior of thermal time-of-flight sensors for some fluids

van Kuijk *et al.* (1995)	Pt resistor	Pt resistor	Hoya glass substrate	No	He/N_2 mixture, varying concentrations			$0.1-100\,mm\,s^{-1}$ in a 300 μm-wide flow channel	
Yang and Soeberg (1992)	Diode	Diode	Si membrane (3 μm) on glass substrate	Yes: upstream resistor	Lamp oil	AC	Phase difference: 500° at $0.1\,ml\,min^{-1}$ – 80° at $10\,ml\,min^{-1}$		

van Kuijk *et al.* (1995) and Lammerink *et al.* (1995) used Marshall's results to develop a flow sensor that calculates both the flow velocity and the diffusivity by combining a thermal anemometer with a thermal time-of-flight sensor. With these measured values as inputs to an artificial neural network, the flow rate and the composition of a nitrogen/helium mixture can be determined. The measurements were performed using silicon nitride-supported Pt resistors with 80 µm spacing spanning a 600 µm × 1000 µm channel.

Figure 16(a) shows the time-of-flight sensor presented by Shoji and Esashi (1994) using a comb-like structure with four cantilever structures extending from an 11-mm-wide base. The heating and sensing elements are Pt resistors thermally isolated from the bulk by a SiO_2/Si_3N_4 membrane and supported by a p^+-doped silicon frame. The resistors themselves are also supported to avoid bending of the frame due to thermal expansion. Designed to measure airflows up to 5 m s^{-1}, it measures at three different distances (1, 4.2, and 10.2 mm).

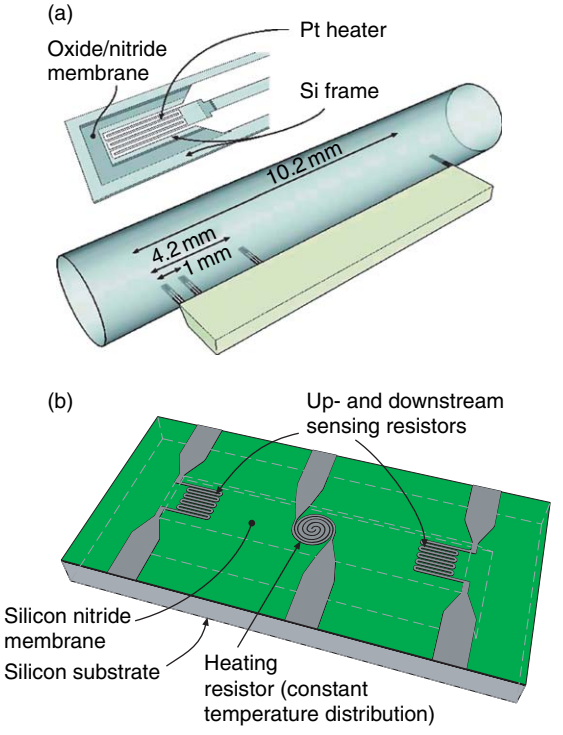

Figure 16 Thermal time-of-flight sensors: (a) chip with heater and sensor on cantilevers. (Source: Shoji and Esashi 1994). (b) Heater with constant temperature (CT) layout to avoid stress in the supporting membrane. (Source: Bedö G, *et al.* 2000).

Yang and Soeberg (1992) constructed a sensor by placing three diodes spaced 1500 µm from each other. The center diode is heated with a square wave signal, and the phase difference with the first harmonic of the measured temperature signal at the downstream diode is measured. The temperature signal at the downstream diode is measured relative to the reference upstream diode. This protects the amplifier inputs by compensating for fluid temperature variations. To be able to measure phase differences larger than 360°, the amplitude of the first harmonic is also taken into account. They were able to measure and theoretically model the flow of lamp oil in a 300 µm×1500 µm channel in the range of 10 down to 0.1 ml min^{-1}, with a resolution of 0.5 µl min^{-1} in the range 0.1–0.5 ml min^{-1}. The heater was driven at frequencies from 2 to 5 Hz, the sensitivity increasing with higher frequencies.

Phase-based time-of-flight sensors have also been presented by Bedö *et al.* (2000), Lambert (1986), and Lambert and Harrington (1986). Bedö and coworkers solve the 1D combined diffusion and convection heat transport equation for a sinusoidal temperature variation at a point in the flow. Similar to the findings of van Kuijk *et al.* (1995), a detection limit for flow velocity can be formulated at the point where conductive heat transfer becomes larger than convective heat transfer. The angular frequency below which the conductive heat transfer starts dominating is calculated for nitrogen and water in the described set-up and is found to be an issue only for nitrogen since the critical frequencies for water and nitrogen with a 2 mm heater/sensor distance are 10 mHz and 1.5 Hz, respectively. The average flow velocity above which the phase at the sensing resistor would become insensitive to the flow was also calculated for air and water and was found to agree qualitatively with the measurements. The flow sensor was tested in water and nitrogen at 1 and 4 Hz up to flow velocities of 8 m s^{-1}. To reduce thermal stress that could break the membrane upon which the heater is placed, the resistor was designed to have a CT distribution (see **Figure 16(b)**, the upstream resistor can be used for temperature compensation, but was not necessary.) Lambert (1986) used thermopiles as detectors on a polyimide film on silicon placing them 146 µm from the heater. The shorter heater/sensor distance results in a higher excitation frequency, 154 Hz (with air), and thus a faster response time.

Ashauer *et al.* (1999) have elegantly shown how a basic design of silicon nitride membrane with a polysilicon resistor and thermopile sensors on each side of

the resistor can be used in all three modes by altering the distance between the heater and the hot junctions of the thermopiles. If the hot junctions are placed very close to the heating resistor, the heater and the sensor will act as a single thermal entity, and the sensor can be used as a thermal anemometer. By placing the hot junctions at a larger distance, the device can be used in calorimetric (for low flow velocities) and time-of-flight mode (for high flow velocities). The calorimetric mode could be used from 0.125 up to 8 mm s^{-1}, after which the time-of-flight mode provided valid measurement values up to 128 mm s^{-1}.

2.07.2.3.5 Multiaxis thermal flow sensors

Flow is a 3D phenomenon, and, although in specific cases such as laminar flow through a tube the entire flow profile in the volume of interest can be derived from one single-axis measurement, in many cases one is interested in all three components of the flow. The batch fabrication methods used in microsystems lend themselves well for the integration of multiple flow sensors on one chip, providing an advantage over conventional methods, where the fabrication complexity and hence the cost for conventional flow sensors increase dramatically as multiple axes are to be measured. As an example, conventional hot wire probes roughly double in price for each additional axis.

Calorimetric flow sensors are the most straightforward devices for extending into a second dimension because placing a pair of sensors orthogonal to the first pair usually does not pose any structural problems. Caution needs to be exerted, since thermal crosstalk between sensors measuring in different directions can reduce the sensitivity (Kim *et al.* 2004). Hot-chip 2D sensors have been proven to work (Liu *et al.* 1997, Makinwa and Huijsing 2002a, b, van Oudheusden and Huijsing 1990), and have also been commercialized in wind sensors because of their ease of fabrication (Mierij Meteo 2006) (**Figure 17**).

Most types of calorimetric sensors have been shown to be relevant for adaptation to 2D measurements. To achieve thermal insulation, the entire structure with heater and sensors can be placed on a membrane (Kim *et al.* 2004, Park *et al.* 2003b, Robadey *et al.* 1995), or a cross-shaped half-open channel can be made to enable sensor bridges to be used (Fürjes *et al.* 2004). Hsieh *et al.* (1991, 1995a) designed a 2D pyroelectric flow sensor where one of the sensing electrodes was shared. The drawback of this reduced construction was that the two components needed to be sensed sequentially. Kim *et al.* (2004) and Yoon and Wise (1992) obtained a direction-sensitive sensor by using a thermal anemometer to measure the flow rate and a calorimetric flow sensor only for direction measurement.

Instead of having specific 2D calorimetric flow sensors that share the heater, it is most often possible to place a complete 90° rotated sensor on the same chip, next to the original one. Achieving 3D measurements is more complex for calorimetric sensors, as it is difficult to fabricate a sensor–heater–sensor structure in the direction out of the wafer plane. A two-element calorimetric sensor is somewhat easier and has been presented by de Bree (2003). Sensitivity in the third dimension is achieved by a pair of wires above each other, one on each side of the wafer, as illustrated in **Figure 18**.

For thermal anemometers to function in multiaxis applications, an asymmetry needs to be present in the design of the heating/sensing element. In practice, this implies that the sensor is a wire and cannot be, for example, a small circular meandering resistor.

Two-dimensional in-plane sensors have been designed by Breuer *et al.* (1999), Kälvesten *et al.* (1996), Xu *et al.* (2005a), and Yoshino *et al.* (2001) to measure wall shear stress. With the latter two, the wires are placed on a zig-zag line to get a two-component measure of the shear stress along this line (**Figure 19**).

Out-of-plane anemometers have been achieved by using folding structures. Ebefors *et al.* (1998) filled KOH-etched V-grooves with polyimide and used the shrinkage caused by curing to fold up 30 μm-thick silicon prongs of a hot wire. Each V-groove causes a limited angular deflection, depending on the curing parameters. By combining several grooves and a temporary bending stop (in place only during fabrication), the total deflection can be set to exactly 90° (**Figure 20(a)**). Designed to measure the small eddies in turbulent flows, the wires are 500 μm long and have a $2 \times 3\,\mu m^2$ cross-section. The design of the sensor allows it to be used in the same way as a conventional hot wire. Chen *et al.* (2003) fabricated a wall-mounted 3D hot-wire probe. Illustrated in **Figure 20**, the surface-micromachined prongs with the wires are released from the substrate by etching a sacrificial copper layer and bent up using an external magnetic field. The 2.7-μm-thick polyimide prongs are coated with a permalloy thin film to obtain this effect. After bending, the nickel hinges are strengthened by electroless plating. The entire process is performed at low temperature, providing freedom in the choice of substrate material. Pure time-of-flight flow sensors do not lend themselves to flow-direction sensing and have as yet not been presented in the literature.

2.07.3 Mechanical Flow Sensors

Mechanical flow sensors are perhaps the most intuitive and straightforward class of flow sensors. As the wind can be seen blowing through the trees, it is the mechanical effect of fluid flows on the surroundings that provides an indication of the direction and the magnitude of the flow.

The force that a body in a fluid flow experiences can be broken down into two components, one in the

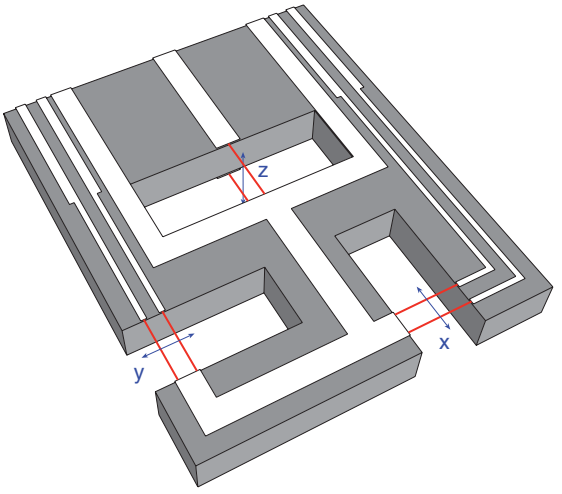

Figure 18 Three-dimensional microflown. (Source: de Bree H-E 2003).

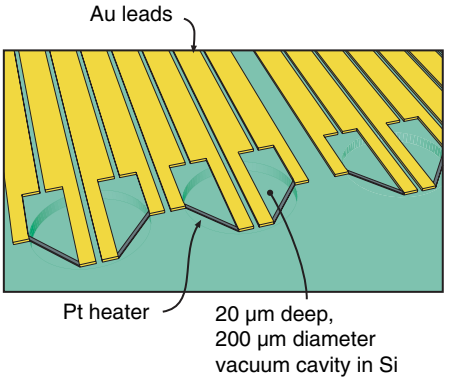

Figure 19 Row of two-component shear-stress sensors. (Source: Breuer *et al.* 1999).

direction of the flow, the drag force F_D, and one perpendicular to the flow, the lift force, F_L (**Figure 21**). For turbulent flows, these two forces can be described using the following equations:

$$F_D = C_D \frac{\rho U_\infty^2}{2} A$$

$$F_L = C_L \frac{\rho U_\infty^2}{2} A$$

where C_D and C_L are the drag and lift coefficients, dimensionless values dependent on the shape of the body, viscosity of the medium, and the roughness of the body's surface; ρ is the fluid's density; U_∞ the free-stream fluid velocity, and A the area of the body. For laminar flows, C_D becomes linearly proportional with the inverse of the flow velocity (Nakayama 1999). This results in a linear dependence of the drag force on the flow velocity.

Drag can be broken up into two components: induced drag and parasitic drag. Induced drag is caused by the production of lift while parasitic drag is defined as the remaining part. Parasitic drag in turn can also be broken up into two components: pressure drag and viscous drag. Pressure drag is caused by the pressure difference between the upstream and downstream parts of the body while viscous drag is caused by the skin friction of the fluid over the surface of the body.

Although both the lift force and the drag force can be used for obtaining a measure of the fluid velocity, the great majority of micromachined mechanical flow sensors use the latter. The definition of pressure drag also highlights the vague line between the class of differential-pressure sensors and that of pressure drag flow sensors. Differential-pressure sensors, described below, can be seen as drag flow sensors that measure the pressure difference caused by the drag of the orifice. In this chapter, the distinction is made based on the mechanical structure used for measuring the pressure drag. These devices using membranes to measure the pressure difference are classified as differential-pressure sensors, all others are considered drag flow sensors.

Optical readout of mechanical sensors provides a fully nonelectrical interface to the flow, which can be desirable in explosive or flammable environments. Mechanical flow sensors can be divided into three groups, based on the type of moving element used.

2.07.3.1 Drag-force Sensors

2.07.3.1.1 Cantilever flow sensors

The largest group of mechanical flow sensors are those that measure the deflection of a cantilever under the influence of the flow-induced drag forces. Gass *et al.* (1993) and Nishimoto *et al.* (1994) demonstrated the applicability of cantilever flow sensors in liquid. The liquid is guided past the cantilever, and the flow regime is laminar, which results in a linear deflection-flow dependence. The deflection is measured using piezoresistive strain sensors. Cantilever flow sensors with piezoresistive readout in air have been used by Su *et al.* (1996), van der Wiel *et al.* (1995), and Zhang *et al.* (1997).

To achieve maximum deflection while retaining mechanical stability, the cantilever is weakened at the clamp point where the sensing resistors are positioned. This can be done by thinning the beam in the out-of-plane direction (Gass *et al.* 1993) or by making it narrower in the wafer plane (Mireles 2005, Su *et al.* 2002, Zhang *et al.* 1997).

Syst.* **12(6)**, 979–88, © 2003 IEEE, see also Chen *et al.* 2003.).

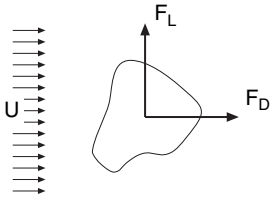

Figure 21 Drag and lift forces on a body in a fluid.

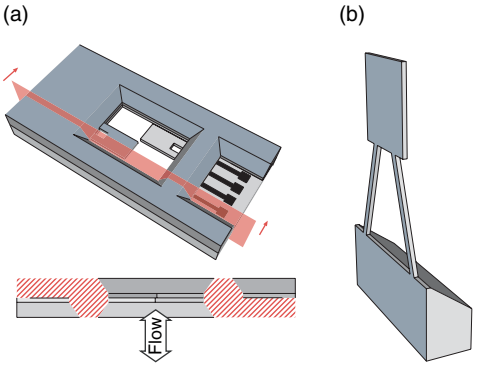

Figure 22 (a) Dual-cantilever bidirectional gas flow sensor. (Source: van der Wiel *et al.* 1995.) (b) Cantilever with weak support beams for high sensitivity. (Source: Su *et al.* 2002.)

A bidirectional mechanical gas flow sensor featuring sensitivity independent of the direction of the flow in a pipe has been fabricated by van der Wiel *et al.* (1995) (**Figure 22(a)**). Two identical chips with a cantilever are bonded to each other, resulting in a differential signal from the piezoresistors that is independent of the flow direction. An important design parameter of the cantilevers was the resonance frequency as it limits the measurement range as the cantilever starts resonating at high flow rates. The sensitivity of the Wheatstone bridge lay between 0.04 and 0.12 $\mathrm{mV\,V^{-1}(mg\,s^{-1})^{-2}}$ in air. Su *et al.* (1996, 2002) could present more sensitive airflow sensors with sensitivities $(\Delta R/R)/U_\infty^2$ ranging from 0.6 to 4.5×10^{-5} $\mathrm{(m\,s^{-1})^{-2}}$ by extending the support beams (see **Figure 22(b)**).

The cantilevers fabricated by Zhang *et al.* (1997) measure both pressure drag and viscous drag. Up to a flow regime of 10 $\mu\mathrm{l\,min^{-1}}$, the viscous drag forces are dominant, and the force on the cantilevers is linearly dependent on the flow rate. Above 100 $\mu\mathrm{l\,min^{-1}}$, the pressure drag forces dominate and the force on the cantilever is quadratically dependent on the flow. The transition region is nonlinear.

Chun *et al.* (1998) demonstrated the feasibility of using a waveguide cantilever as a flow sensor. The optical coupling the waveguide on the cantilever and a fixed waveguide is a measure for the flow rate over the cantilever. Mireles (2005) suggested a drag flow sensor based on the transfer of a surface-micromachined cantilever mirror structure to an optical fiber (**Figure 23(a)**). The drag-induced bending of the

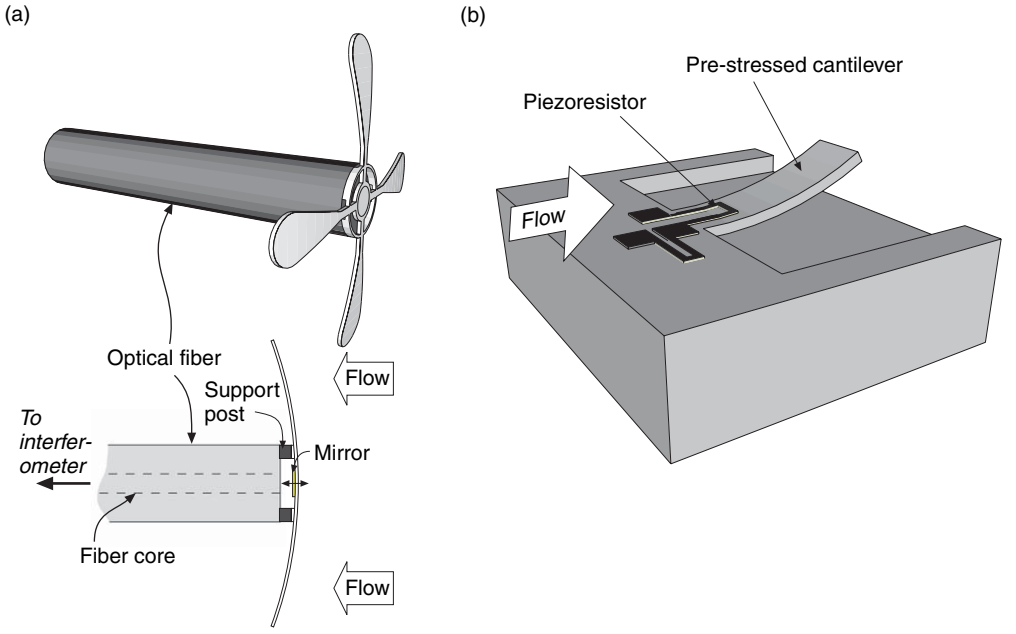

Figure 23 (a) Drag flow sensor with optical readout. (Source: Mireles 2005.) (b) Prestressed cantilever flow sensor. (Source: Kim *et al.* 2003.)

four cantilevers cause the mirror to move away from the fiber, a movement that can be measured interferometrically.

Go *et al.* (2001) and Kim *et al.* (2003) presented prestressed cantilever flow sensors. The flow direction for these is in the length direction of the cantilevers, and the deflection decreases as the flow increases (see **Figure 23(b)**).

While most sensing cantilevers are designed to have resonant frequencies above 10 kHz to avoid environmental excitation, Go *et al.* (2001), Su *et al.* (1996), and Zhang *et al.* (1997) deliberately designed arrays of cantilevers with a natural frequency around 1 kHz. At free-stream flow velocities of 3–6 m s^{-1}, the cantilevers vibrate at this frequency. Although the main objective of the structure is to generate cooling, the magnitude of the vibration turned out to increase with increasing flow and was measurable with the integrated piezoresistors. Radhakrishnan and Lal (2005) (**Figure 24**) used electroplating to form an out-of-plane cantilever that exerts a twisting stress on the substrate, which is measured with piezoresistors.

2.07.3.1.1.(i) Hair-type flow sensors A subclass of the cantilever drag flow sensors are those modeled after animal sensory hairs. Ozaki *et al.* (2000) fabricated a 2D airflow sensor that consisted of a wire manually glued to a cross-shaped beam

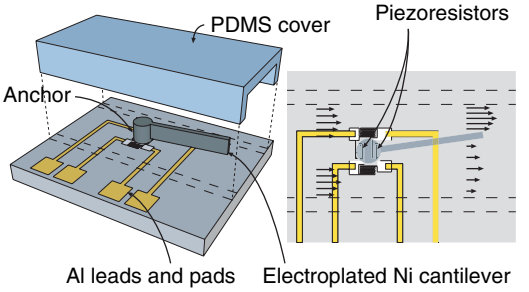

Figure 24 Electroplated beam, twisting when exposed to flow. (Source: Radhakrishnan and Lal 2005.)

structure with integrated piezoresistors (**Figure 25**). Fan *et al.* (2002b) were able to eliminate the manual assembly step by using plastic deformation magnetic assembly (PDMA). With PDMA (Zou *et al.* 2001), a magnetic field is used to fold up a metal cantilever coated with a permalloy. The hinge is plastically deformed causing the cantilever to stay in position after it has been removed from the magnetic field. Water flow is measured by measuring the deflection of a support beam that carries the vertical cantilever. Arrays of such beams oriented in different directions can be used to obtain a full picture of the flow near the surface (Chen *et al.* 2003).

The behavior of cricket sensory hairs has been imitated by van Baar *et al.* (2005) (see **Figure 25**)

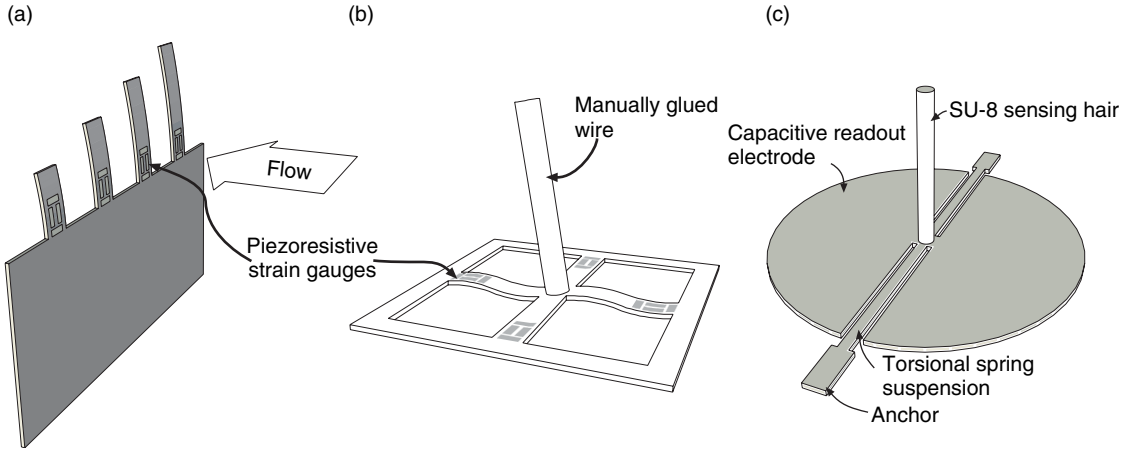

Figure 25 Three variations of hair-type flow sensors: (a) single-axis cantilever beams. who made hairs out of either silicon-rich nitride (van Baar *et al.* 2003, 2005) or SU-8 (van Baar *et al.* 2005, Dijkstra *et al.* 2005), supported by a disc suspended with a gimbal structure. The SU-8 hairs are produced using a surface micromachining process, while the silicon-rich nitride hairs are fabricated using a deep reactive ion-etched silicon wafer as a sacrificial mold. The rotation of the supporting disc is measured capacitively. Single-axis suspended discs have shown a directional sensitivity to flow, and the process allows for dual-axis sensors as well.

Similar hairs have been fabricated by Engel *et al.* (2005) using polyurethane. First, polyurethane is mixed with a conductive filler and molded on a glass substrate with electrodes to form a pressure-conductive rubber pattern (Shida and Yuji 1996). Two types of fillers were used: carbon black and multiwalled carbon nanotubes (MWCNTs), the latter yielding a larger sensitivity. On these force-sensitive resistors, polyurethane hairs are placed using a lost-wax process. The hairs are extremely flexible, making them very robust. A drawback of the method is the large device-to-device variation, requiring the averaging of several hairs to obtain reliable results.

Although many of these solutions can be fabricated in array format, electrical readout becomes a problem as the number of leads out to the array edge rapidly increases. Brücker *et al.* (2005) provided a solution by using an optical readout to measure the deflection of each hair in a sensory array. The hairs are made by a lost-mold process where holes are laser-drilled in a wax sheet to form a mold for polydimethylsiloxane (PDMS) rubber (Schmitz *et al.* 2005). Pattern recognition is employed to identify the deflection of each individual hair and provides a full picture of the liquid flow over the surface. Drawbacks that optical access to the top surface is required, and that vibrations might affect measurements.

A sensor that combines some characteristics of hair-type sensors with the shear sensors described below is shown in **Figure 26** (Dao *et al.* 2002, 2003).

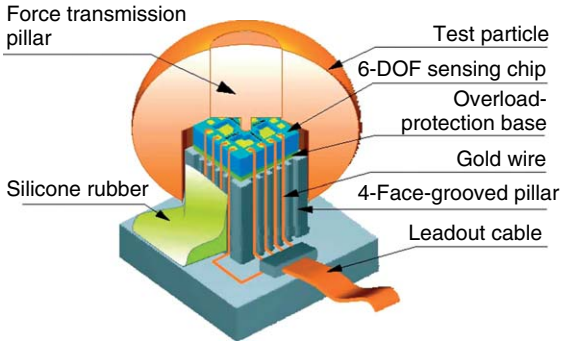

Figure 26 Shear-stress and vortex sensor with six degrees of freedom. (Source: Dao D, Toriyama T, Sugiyama S, Nguyen A, Wells J 2003 A MEMS-based microsensor to measure all six components of force and moment on a near-wall particle in turbulent flow. *TRANSDUCERS '03. 12th Int. Conf. Solid-State Sensors, Actuators and Microsystems. Dig. Tech. Pap.*, Vol. 1, pp. 504–7. © 2003 IEEE.)

It consists of a 8–9-mm-diameter polyethylene-sensing particle mounted on a micromachined force sensor with six degrees of freedom: three translational and three rotation. Polyethylene was chosen because its density lies very close to that of water, resulting in minimum buoyancy. The force sensor uses 18 piezoresistors, out of which 2 are shear piezoresistors, a four-terminal piezoresistor that senses the shear force instead of the normal force on a piezoresistor (Pfann and Thurston 1961). The sensor is placed such that the top half of the sphere protrudes from the surface and measures both the drag and the shear forces in a multiphase liquid flow.

2.07.3.2 Lift-force Flow Sensors

As opposed to the drag flow-based sensors, lift force-based sensing are less common. The only nonturbine sensor was developed by Svedin *et al.* (1998a, b, 2003a, b) who used a pair of airfoil plates attached to a flexible polysilicon beam. By placing this sensor at an angle in the flow, a differential lift force is generated (**Figure 27**). Several improvements were presented on the original design. Use of a Wheatstone bridge to measure the strain difference between the upstream and the downstream plate allowed reduction of common-mode effects such as accelerations and temperature variations (Svedin *et al.* 1998a). By placing strain sensors on detector beams at the edges of the plates (see **Figure 27**), the natural frequency of the device was increased by a factor 3, while the sensitivity was retained or improved. The higher natural frequency implies an improved time response, a parameter that, for mechanical flow sensors, is usually a trade-off against sensitivity. Like all mechanical flow sensors, the lift-force sensor has a low sensitivity at low flow rates. Svedin *et al.* (2003a) added a heating resistor at the center of each wing to exploit the high low-flow sensitivity of thermal sensors. The resistors were thermally isolated from the rest of the wings by polyimide-filled KOH-etched grooves. The resistors were evaluated separately, in CT mode, and in conjunction with each other, as a two-element calorimetric sensor. The thermal anemometry measurements provided a higher flow sensitivity, while the calorimetry-based measurements could indicate the flow direction, but with a lower sensitivity and a nonuniform flow response. The measurements in **Figure 27(c)** illustrate the complementary use of the high sensitivity ranges.

2.07.3.2.1 Turbine flow sensors

A common method of measuring flow in the macroworld is using turbines. Because of stiction and friction problems they are much less popular in microelectromechanical systems (MEMS). Rapoport and Reed (1991) fabricated a surface-micromachined rotor. A microscope with stroboscopic lighting was used to measure the rotation rate of the rotor for water and nitrogen flow. To be able to measure water flow, a glass plate was placed over half the rotor to generate the shear stress required to rotate the rotor. Friction between the rotor and the axle was a serious problem, so a minimum required flow rate before the rotor would start rotating. The intended application of the sensor was blood-flow measurements, but no measurements were presented, and significant deposition of red blood cells on the sensor was observed during attempts.

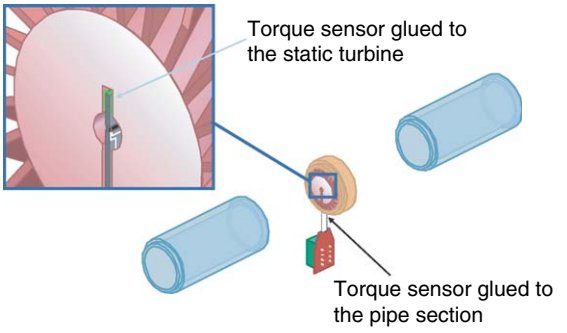

Figure 29 Static turbine flow sensor. (Source: Svedin *et al.* 2003c), courtesy of Niklas Svedin.

Himmelhaus *et al.* (1992) used LIGA (Litografi Galvanisierung Abformung, a combination of deep-etch X-ray lithography, electroforming, and molding techniques) (Becker *et al.* 1986) to fabricate a 250-μm-diameter, 200-μm-high turbine rotor (**Figure 28**). An optical fiber was used both to illuminate and to read out the reflection off the blades. An oscillating signal was obtained as the turbine rotated. This approach also suffered from reliability issues due to friction. The microturbine designed by Holmes *et al.* (2004), intended to generate a flow-dependent power, had similar problems. Despite using ball bearings to facilitate the rotation of the SU-8 rotor, laser-machined to achieve slanted blades, the generated power was only 1% of that predicted by computational fluid dynamics software.

The third optical readout method of turbine rotation used particle image velocimetry (PIV) algorithms to identify the movement of the turbine blades. Han *et al.* (2004) used infrared light to see through the caps of an all-silicon bulk-micromachined microturbine (Frechette *et al.* 2000).

A solution to the friction problems encountered with micromachined turbines has been presented by Svedin *et al.* (2003c). The torque that a fixed turbine wheel exerts on its axle is used as a measure for the flow rate past the blades of the turbine (**Figure 29**). The torque was measured by means of piezoresistors placed at the center of rotation where the silicon chip had been weakened by deep reactive ion etching. The signal of the sensor was shown to be quadratically dependent on the volume flow. Varying the angle and the length of the turbine blades resulted in a trade-off between pressure drop and sensitivity: short turbine blades at a sharp angle to the flow provide not only the highest sensitivity but also the largest pressure drop.

2.07.3.3 Skin-friction Sensors

The third class of mechanical flow sensors is based on the skin-friction effect, also known as wall shear stress. A fluid flowing over a surface exerts a shear stress τ that can be expressed as follows:

$$\tau_0 = \mu \left. \frac{\partial U_x}{\partial y} \right|_{y=0}$$

where μ is the dynamic viscosity of the fluid, x the direction of the flow, and y the direction normal to the surface. Although measuring the wall shear stress can give information on the flow of the fluid near the surface, wall shear stress of itself is also a topic of research in fluid dynamics.

Mechanical skin-friction sensors are sometimes also called direct sensors, as they directly measure the skin friction in contrast to, for example, thermal sensors, which measure a secondary effect. A general trade-off in mechanical skin-friction sensors is sensitivity versus resolution: resolution increases with decreasing measurement surface but results in decreasing force.

Often, the deflection of a spring-suspended element, called the floating element, is measured. Schmidt *et al.* (1987) introduced one of the first micromachined direct skin-friction sensors. It consists of a floating element suspended by four tethers, and the deflection of the floating element is linearly dependent on the shear force upon it. This design has been presented in several variants with different materials and readout methods (Ng *et al.* 1991, Padmanabhan *et al.* 1995, Pan *et al.* 1995a, Schmidt *et al.* 1987). **Figure 30** shows five variants of this type. The device in **Figure 30(b)** consists of a polyimide floating element with an embedded chromium electrode on a silicon surface. The 30-μm-thick polyimide is spun in several steps and is etched using an oxygen plasma,

and the 3-μm capacitor gap is created using aluminum as a sacrificial layer. The displacement, orthogonal to the tethers, is measured using on-chip differential capacitor readout electronics. The size of the element, 0.5 mm × 0.5 mm, is restricted by the stress in the polyimide/metal layer that would cause the floating element to bend more than 1 μm. The device suffered from sensitivity drift as moisture variations caused the polyimide to swell. The high input impedance made it sensitive to electromagnetic noise interference and the air–dielectric interface accumulated charges resulting in drift (Sheplak *et al.* 2004). The same group at MIT presented a variant for measuring skin friction in liquid (see **Figure 30(c)**). Designed to measure much higher shear stresses (1–100 kPa instead of 1 Pa), the floating element is only 120 μm × 160 μm and is suspended by tethers of 10 μm × 30 μm. The moving parts are 5 μm thick and made of monocrystalline silicon bonded to a support wafer to form a silicon-on-insulator (SOI) structure. The sensitivity direction is parallel to the tethers, as two of the tethers are used as piezoresistors in a half bridge. Barlian *et al.* (2006) presented the same basic design for liquid skin-friction measurements, but used side-implanted piezoresistors to achieve higher shear-stress sensitivity and to reduce out-of-plane sensitivity. A further evolution of MIT sensor is shown in **Figure 30(d)** (Padmanabhan *et al.* 1995). For measuring with a resolution of below 1 Pa in air, the piezoresistive readout was not sensitive enough, and the high impedance of the capacitive sensors caused too much drift in the wind tunnel environment. The solution presented by Padmanabhan and coworkers uses two photodiodes to measure the displacement of the floating element. The photodiodes are integrated in the carrier substrate prior to the bonding of the device layer that will form the floating element. By measuring the differential current under illumination by a 7 mW pulsed laser at 1 kHz, shear stress can be measured very precisely. Limitations of this setup lay in the optical setup as vibrations or expansion of the tunnel would cause the light source to move and affect the measurements. A solution to these problems was presented by Horowitz *et al.* (2004). By placing slightly differing aluminum gratings on the floating element and its glass substrate, the displacement of the floating element can be measured by observing the moiré fringes. An advantage of this setup is that the packaged sensor can be mounted on a camera lens (see **Figure 30(e)**), eliminating vibration and thermal expansion effects of the wind tunnel.

An alternative for improving the capacitive readout shear stress sensor was presented by Pan *et al.* (1995b). The use of polysilicon avoids possible problems that polyimide can cause due to viscoelastic effects and absorption of humidity. **Figure 30(f)** also illustrates the use of folded beam suspensions that provide a lower stiffness and fully linear spring behavior. Pan and coworkers also demonstrated the use of force feedback on the floating element to measure the shear stress. For this, a variant of a commercial analog devices accelerometer (ADXL series) was evaluated for its applicability as a shear-stress sensor. Shear stresses up to 5 Pa could be measured before the force required for the feedback became too large to compensate.

Haronian (1999) observed the resonance of a floating element excited at its natural frequency by the flow. The floating element is suspended with a spiral spring (see **Figure 30(g)**), making it sensitive to shear stress in both in-plane directions. At the suspension point of the beam a pair of stress-sensitive diodes is used to differentially measure the stress created by the resonating mass. The amplitude and the frequency of the resonance were observed to increase with increasing flow rates, the latter nearly linearly for flows ranging from 5 to 8 ml s^{-1} in a channel of undisclosed dimensions.

A single-beam shear-stress sensor was presented by Zhe *et al.* (2005). Though electrodes are present for running in force-feedback mode, only the open-loop mode has been demonstrated. Tseng and Lin (2003) fabricated and tested a 2D shear-stress sensor where the floating element is a rectangular SU-8 pillar. The 200-μm-wide sides of the 400-μm-high beam are gold-coated and the bending of the beam is read out using two optical fibers. The cleaved fiber ends are also coated with a metal to form a semitransparent mirror. The cleaved interface and the gold-coated beam form the two reflectors for a Fabry–Perot interferometer.

Figure 31 shows the principle for an extremely small floating-element skin-friction sensor as conceived by Desai and Haque (2004). By designing the sensor so that it needs to be placed perpendicular with respect to the surface, only the floating element is exposed to the flow. This minimizes the interference with the flow and increases the spatial resolution drastically. Fabricated on an SOI wafer with a 20-μm device layer, the floating element's surface is 20 μm × 4 μm. Shear stress on the floating element causes the structure to twist around a central point resulting in measurable capacitance changes at

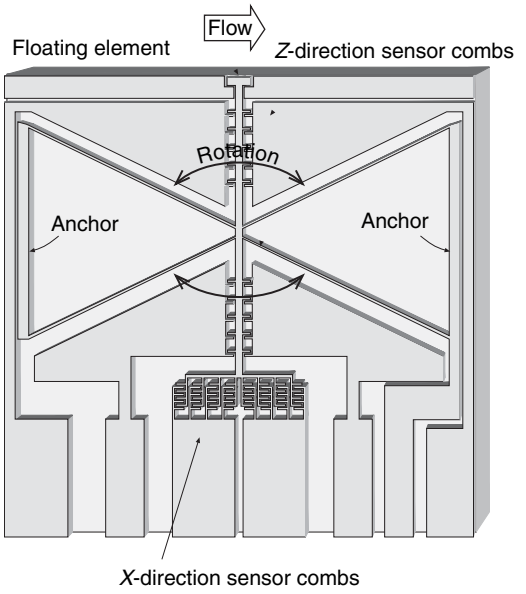

Figure 31 Capacitive floating-element skin-friction sensor by Desai and Haque (2004); the X-shaped spring structure allows rotation only around its center point.

six points. The bottom two capacitors, C_{x1} and C_{x2}, are measured differentially to measure the shear in the x-direction. The sum of the other four capacitances C_{z1-4} provides a measure for the shear in the z-direction. $C_{x1}-C_{x2}$ is not affect by the common mode that a z-shear causes, and the C_z capacitors are placed symmetrically around the point of rotation so that their sum is not affected by shear in the x-direction.

A cantilever-based skin-friction sensor has been introduced by von Papen *et al.* (2002, 2004), illustrated in **Figure 32**. Variants have been designed based on the shape and the number of the attachment points of a low and wide cantilever sticking up from the surface of the wall where the skin friction is to be measured. The variants differ in how they bend when placed in a flow. In variant A, the cantilever is solid, which causes it to bend in the plane perpendicular to both the flow and the wall. Variants B–D bend mainly in the plane perpendicular to the flow but parallel to the wall. For a fixed cantilever area, the sensitivity of the variants increases, variant A being least sensitive and D the most sensitive. The bending of all variants is measured using piezoresistors, strategically placed at the point of maximum bending. More information on micromachined shear-stress sensors can be found in Löfdahl and Gad-el Hak (1999b), Naughton and Sheplak (2002), and Sheplak *et al.* (2004).

2.07.4 Differential-pressure Flow Sensors

A fluid flowing through a channel undergoes a pressure drop that is dependent on the velocity of the fluid. By measuring the drop, one can measure the flow. In contrast to conventional differential-pressure flowmeters, where the flow is turbulent and proportional to the square root of the pressure drop (Bentley 1983a), the volume flow (Q_v) through microchannels is laminar and linearly dependent on the pressure difference, Δp, over the channel. For a no-slip boundary condition, this dependence is as follows (Boillat *et al.* 1995)

$$Q_v = \frac{1}{C}\frac{AD^2\Delta p}{2\mu l} \qquad [1]$$

where A is the channel cross-sectional area, D the equivalent channel hydraulic diameter, equal to $4A$ per wetted perimeter, l the length of the channel, μ the dynamic viscosity, and C a dimensionless friction factor. Caution should be exercised, however, since the Knudsen number reaches values above 0.01 in channel heights less than 8 μm for air at standard ambient pressure and temperature. Below these heights, the no-slip boundary condition and thus eqn [1] do not apply (Arkilic *et al.* 1997, Jang and Wereley 2004). Micromachined differential-pressure flow sensors can be divided into two groups based on whether the pressure difference is measured relatively or as a difference between two absolute pressures.

2.07.4.1 Relative Pressure Measurement

Cho *et al.* (1992) (**Figure 33(a)**) have presented a highly sensitive gas flow sensor whose fabrication is based on a dissolved wafer process. The channel structure and the pressure membrane are defined by p^{++} doped regions and bonded to a glass support before the rest of the wafer is KOH-etched using the p^{++} region as an etch stop. The pressure difference is read out capacitively. The pressure difference is generated by forcing the flow through a channel 60 µm wide, 3.5 µm high, and 8.4 mm long. The sensor is designed to measure process gases in semiconductor manufacturing. The same principle has been used for gas flow sensing by Furuberg *et al.* (2003), where the pressure difference is measured using piezoresistors (see **Figure 33(b)**).

An alternative approach for creating the pressure difference is to force the flow through an orifice in the pressure-sensing membrane as illustrated in **Figure 33(c)** (Nishimoto *et al.* 1994, Richter *et al.* 1999). In this case, the diameter of the orifice can easily become larger than the thickness of the membrane, in which case the flow through it will no longer be laminar, and the pressure difference will become quadratically dependent on the flow (Richter *et al.* 1999). Both Nishimoto *et al.* (1994) and Richter *et al.* (1999) use piezoresistors on the edge of the membrane for readout. An interesting detail is that Richter and coworkers used a commercially available pressure sensor (Honeywell 24PC) and created the orifice with a laser drill.

A differential-pressure sensor that does not require the flow to pass through it has been presented by Berberig *et al.* (1997) (see **Figure 34**). It is a direct miniaturization of the conventional Pitot tube whose operating principle is based on Bernoulli's law:

$$p_{\text{static}} + \rho g h + \frac{\rho U^2}{2} = cst$$

where p_{static} is the static pressure, ρ the fluid's density, h the height, and U the flow velocity. The pressure

difference between the stagnation point at the front of the chip (where $U = 0$) and at the side of the chip (where $U = U_\infty$) becomes as follows:

$$\Delta p = \frac{\rho U^2}{2}$$

(the difference in height between the two points can be ignored). Since the cavity inside the chip is connected to the stagnation point, this pressure difference acts on the boss resulting in a measurable capacitance change. The deflection of the membrane is proportional to the pressure difference over it, and for small deflections, the capacitance changes proportionally to the deflection, resulting in a quadratic flow dependence of the capacitance: $|\Delta C| \sim U^2$. The sensitivity of this device increases linearly with flow and goes to zero as the flow is reduced.

A special type of differential-pressure sensor introduced by Sood and Ghosh (2004) is based on the interplay between the Bernoulli principle and the Seebeck effect. **Figure 35** illustrates how a sensing chip is placed at an angle to the flow to create a flow acceleration over the chip surface. Due to the adiabatic expansion of the gas flow between the stagnation point, at the leading edge of the chip and the far edge of the chip, a pressure difference, and hence a temperature difference, is generated. By using the Seebeck effect of the chip material, a voltage difference can be measured between the two ends of the chip. This voltage difference is shown to be a function of the square of the difference in Mach numbers, defined as the ratio between the fluid velocity, U, and the sound velocity in the fluid, c: $Ma = U/c$. Measuring in argon and nitrogen, two flow regimes were evaluated: incompressible flow $Ma^2 < 0.05$ and compressible flow $0.07 < Ma^2 < 0.20$. In both regimes, the voltage signal was linearly dependent on Ma^2, with a higher sensitivity in the lower range: approximately 300 μV in *n*-Ge at $Ma^2 = 0.05$ and 650 μV at $Ma^2 = 0.20$.

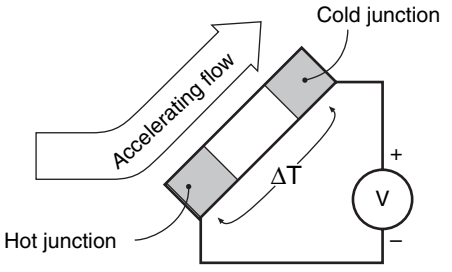

Figure 35 Chip placement in the flow. The shaded areas are the electrical connections. (Source: Sood and Ghosh 2004.)

2.07.4.2 Absolute Pressure Measurement

The pressure difference over a flow constriction can also be measured separately using two absolute pressure measurements. Flow sensors using pressure measurements relative to atmospheric pressure are also included in this category. The principle is illustrated in **Figure 36**. Piezoresistive (Boillat *et al.* 1995, Oosterbroek *et al.* 1999, Van Der Schoot *et al.* 2001) as well as capacitive (Oosterbroek *et al.* 1997) readout pressure sensors have been used. The pressure-sensing membranes in the mentioned devices are defined by wet etching, and the chips are anodically bonded to a glass substrate. An advantage of this type of sensor is that only the back side of the pressure sensor is exposed to the fluid while the electrodes and piezoresistors are placed out of harm's way.

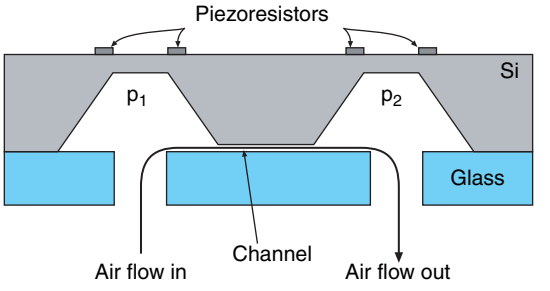

Figure 36 Cross-section of differential-pressure flow sensor based on two pressure measurements relative to atmospheric pressure. (Source: Boillat M, van der Wiel A, Hoogerwerf A, de Rooij N 1995 A differential pressure liquid flow sensor for flow regulation and dosing systems. *Proceedings of the Micro Electro Mechanical Systems, 1995, MEMS '95*. IEEE, pp. 350. © 1995 IEEE.)

The sensor presented by Takahata *et al.* (2004) consists of two capacitive absolute pressure-sensing chips connected to each other with a coil. The coil, the so-called stentenna, is created from a flat structure, fabricated using microelectrodischarge machining. The application is blood-flow measurement, where the stentenna, with a pressure-sensing chip at each end, is inflated in the blood vessel using an angioplasty balloon. The inductive coil, split into two, and the two capacitive sensors are coupled as indicated in **Figure 37**, forming two LC tanks. As the capacitors vary relative to each other due to flow-induced pressure difference, the impedance variation of the circuit can be measured using an external coil. The main advantage of this system is that it contains no active elements and can be powered from outside the body. The device was limited by its quality factor and the low coupling between the internal and the external coil. Continuing on the concept, DeHennis and Wise (2006) from the same group developed a fully integrated differential-pressure sensor with integrated BiCMOS circuitry. The post-BiCMOS process steps include a transfer bond of the circuitry to a glass substrate and a thinning down of both the glass and the silicon substrates to obtain a total device thickness of less than 200 μm. Two epoxy-glued surface-mount capacitors are the only nonintegrated sensor parts. The gold antenna coil is postprocessed on top of the BiCMOS and thinned down to a membrane during the last silicon-thinning step. It is compliant to be able to wrap around the surface of an artery or a stent and not interfere with the blood flow. The circuitry is powered using an RF signal and transmits information back by amplitude-modulating this signal, also known as backscatter modulation. The capacitances, placed at 1 cm distance from each other, are read out using capacitance-to-frequency conversion.

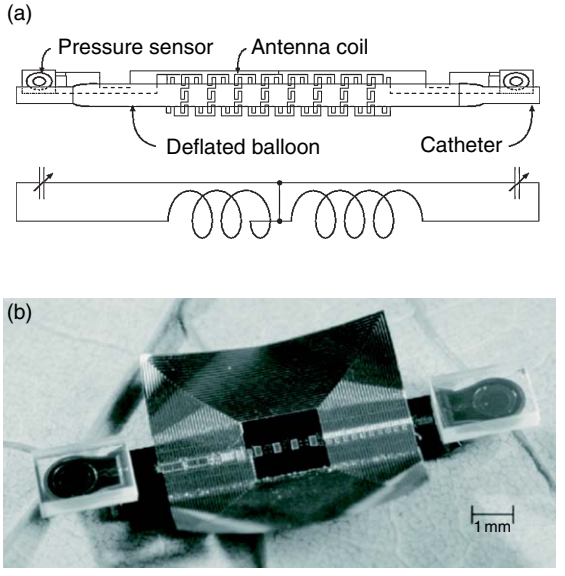

Figure 37 (a) Circuit of the double LC circuit where the variable capacitors are absolute pressure sensors (Source: Takahata K, DeHennis A, Wise K, Gianchandani Y 2004 A wireless microsensor for monitoring flow and pressure in a blood vessel utilizing a dual-inductor antenna stent and two pressure sensors. *17th IEEE Int. Conf. Micro Electro Mechanical Systems,* Maastricht, The Netherlands, pp. 216–19. © 2004 IEEE.) (b) Photograph of a differential-pressure sensor with integrated BiCMOS circuitry and flexible antenna. (Source: DeHennis A, Wise K 2006. A fully integrated multisite pressure sensor for wireless arterial flow characterization. *J. Microelectromech. Syst.* **15(3)**, 678–85. © 2006 IEEE.)

In general, pressure-based flow sensors have the advantage of not needing to heat up the fluid, which enables them to be used in applications that involve fluids that decompose or ignite at elevated temperatures. Also, using capacitive readout, they are able to measure very small flows (Cho *et al.* 1992), whereas thermal-based flow sensors are not practical in very low-flow applications because the gas velocity in those applications is too low to generate any significant convective cooling (Cho *et al.* 1992, Jang and Wereley 2004). A disadvantage of most pressure-based flow sensors is the generated pressure loss, which limits their use to applications that can tolerate this.

2.07.5 Optical Flow Sensors

Micromachined flow sensors that directly measure in the optical domain are few. In order to obtain a signal from the flow, the signal needs to be reflected off an interface that moves along with the flow. Hence, direct optical flow sensors can be used only with multiphase flows.

Flows containing or seeded with many small particles, such as bubbles or beads, can be measured with laser Doppler anemometry (LDA) or PIV. Review articles on these methods can be found in Briers (2001) and Adrian (2005), respectively. The velocity of flows in channels that contain large-area interfaces such as slug flow can also be measured optically by means of the refractive index of the liquid at the edge of the channel (Kraus *et al.* 2004). These methods have all been applied to flows in microchannels, most often with conventional optics. A particular class of optical flow sensors are the cytometers, which count the rate of particles or biological cells

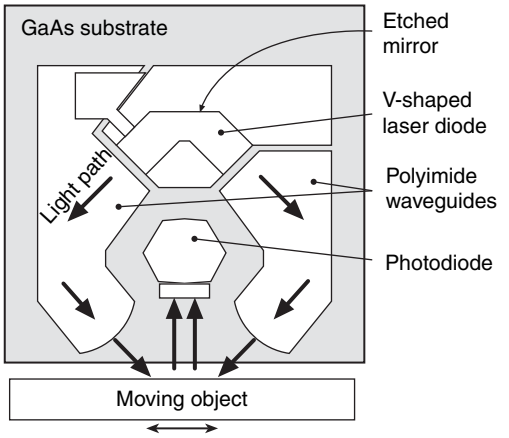

Figure 38 Monolithic laser Doppler anemometry (LDA) chip for near-surface velocity sensing. (Source: Ito T, Sawada R, Higurashi E 1999 Integrated microlaser Doppler velocimeter. *J. Lightwave Technol.* **17(1)**, 30–4. © 1999 IEEE.)

passing the sensor. Although they could be used as flow sensors, they will not be discussed here.

A fully integrated, micromachined laser Doppler anemometer has been developed by Higurashi *et al.* (2003) and Ito *et al.* (1999). The complete LDA system consists of a V-shaped laser diode, fluorinated polyimide waveguides, and a photodiode and was fabricated monolithically on a GaAs substrate (**Figure 38**). The coherent light coming out of the two waveguides reflects off particles moving close to the surface of the sensor, and the difference in Doppler shift can be observed by the photodiode. This sensor provides a nonintrusive measure of the flow velocity of red blood cells just below the skin surface (see also Section 2.07.11.2).

A second application of micromachined LDA was designed by Fourguette *et al.* (2001, 2003). Described in detail in Section 2.07.11, these sensors provide a signal that is linearly dependent on the flow velocity divided by the distance from the wall. In general, these optical methods have a linear response and high-frequency response. Aside from the seed particles, if used, the optical sensors are also nonintrusive.

2.07.6 Ultrasonic Flow Sensors

Ultrasonic transducers can be used in several ways to act as flow sensors (Vass 1997, Hauptman *et al.* 2002). Ultrasonic transit time flowmeters (**Figure 39(a)**) measure the flow-induced time-of-flight difference

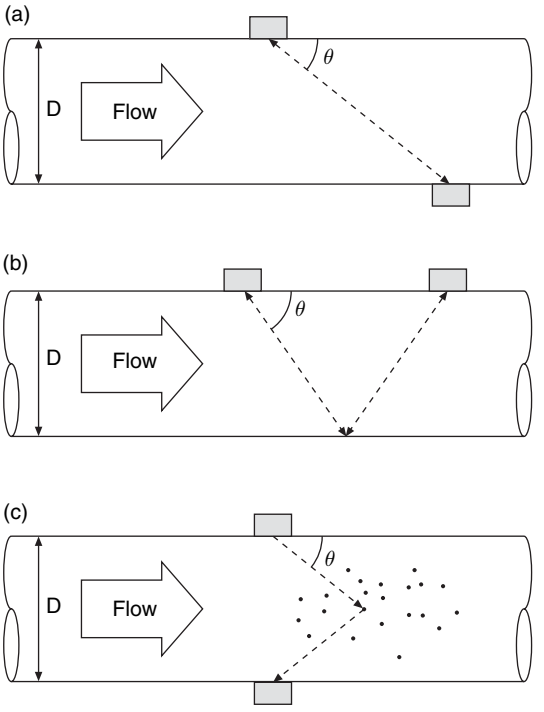

Figure 39 Ultrasonic measurement modes: (a) transit-time flowmeter and (b) Doppler flowmeter.

between an ultrasonic signal traveling upstream and one traveling downstream. This time difference is given as follows:

$$\Delta t = \frac{2D\cot\theta}{c^2} U_{\text{avg}}$$

where D is the pipe diameter, θ the angle of the signal path, c the speed of sound in the medium, and U_{avg} the average flow velocity along the signal path (Bentley 1983b). To increase the path length, detectors can be placed such that the signal is reflected a certain number of times off the pipe wall before it reaches the detector. In multiphase flows (see **Figure 39(b)**), where air bubbles or particles can function as sonic reflectors, the Doppler effect induces a frequency shift in the reflected wave. This shift is as follows (Bentley 1983b):

$$\Delta f = \frac{2f}{c}(\cos\theta) U_{\text{avg}}$$

where f is the frequency of the ultrasonic wave. An alternative to the Doppler effect in multiphase flows is to use the cross-correlation of random attenuation fluctuations measured by two pairs of transducers. The time shift between these fluctuations is directly dependent on the flow velocity.

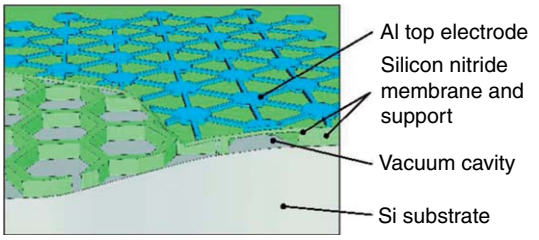

Figure 40 Partial cross-section of an ultrasonic transducer based on a mesh of membranes. (Source: Cittadine 2000.)

The principles employed by conventional ultrasonic transducers can directly be miniaturized by using MEMS technology. Piezoelectric and magnetostrictive transducers (Quandt 1998) can be fabricated using thin-film deposition technology, while sacrificial etching enables producing cavities for capacitive transducers (Cittadine 2000, Jin *et al.* 1998, Ladabaum *et al.* 1998). In air, capacitive ultrasonic MEMS sensors have an acoustic impedance that matches the air significantly better than piezoelectric sensors do; an example is shown in **Figure 40** (Cittadine 2000).

SAW sensors can detect convective cooling as a change in the frequency of a SAW delay line oscillator. They have been described in more detail in Section 2.07.2.

2.07.7 Coriolis Flow Sensors

The principle of Coriolis flow sensors is the apparent force that a fluid experiences when it is moving in a rotating frame of reference. This force is directly proportional to the rotation rate of the frame (ω) and the mass flow rate of the fluid ($\partial m/\partial t$):

$$F_c = 2\frac{\partial m}{\partial t}\omega$$

This relationship implies that, by measuring the effect of the force, Coriolis flow sensors directly measure mass flow, independent of the type of fluid and of whether or not it is single phase. In addition, provided the spring is linear, Coriolis mass flow sensors have a linear response. All electrical connections are outside the flow. One disadvantage is that because the fluid is forced through the tubing, the measurement tubing has to be of the same size as the measured tube to prevent a pressure drop over the instrument.

The practical implementation of Coriolis mass flow sensors consists of bringing the tubing into a vibratory resonance mode that imposes a varying rotation onto the liquid. This is called the primary mode. The Coriolis force then excites another mode, preferably also a resonance mode, called the secondary mode. The amplitude of this mode is a measure for the flow. An important factor when designing Coriolis flow sensors is the trade-off between the relative positions of these two resonance frequencies. On the one hand, one wants the resonance frequencies of the primary and secondary modes to lie close to each other so that the Coriolis force excitation is amplified near the secondary resonance frequency. On the other hand, if the modes lie too close to each other, one risks exciting both modes by asymmetries due to structural imperfections. Although the parasitic secondary mode excitation would still lie at a 90° phase shift with the Coriolis-based excitation, this still generates an increased noise level.

Only a very few Coriolis mass flow sensors have been made using MEMS technology. The first MEMS Coriolis mass flow sensor was presented by Enoksson *et al.* (1997). It is bulk-micromachined, and KOH etching and silicon fusion bonding are used to create a double loop of hexagonal tubes. In one operation mode, illustrated in **Figure 41**, electrostatic actuation is used to drive the sensor into a primary bending mode resonance to achieve a maximum deflection. The secondary torsional mode that is activated by the Coriolis force is read out by detecting the angle of reflection of a laser beam

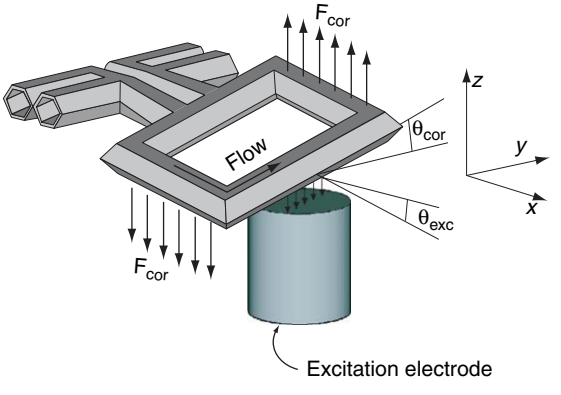

Figure 41 Half of a double-loop device, operated in bending mode, using an external electrode, generating a twisting mode due to mass flow through the tube. (Source: Enoksson P, Stemme G, Stemme E 1997. A silicon resonant sensor structure for Coriolis mass-flow measurements. *J. Microelectromech. Syst.* **6(2)**, 119–25. © 1997 IEEE.)

pointed at the loop. The diameter of the tubes, the distance between the top and the bottom wall of the hexagonal cross-section, is 800 µm. It has a measurement range of $\pm 0.5\,\mathrm{g\,s^{-1}}$ ($1800\,\mathrm{g\,h^{-1}}$) with a relative precision of 0.8%. The torsional mode can also be used as the primary mode, resulting in a secondary bending mode. In the presented sensor, in-phase primary modes result in out-of-phase secondary modes and vice versa (see **Figure 42**).

Another group at Integrated Sensing Systems (ISSYS), Inc., Ypsilanti, MI, USA, introduced a single-loop Coriolis mass flow sensor with surface-micromachined tubes transferred to a support wafer (Tadigadapa *et al.* 2002, Zhang *et al.* 2001) (see **Figure 43**). This process allows more freedom in the tube cross-section design, and cross-sections of 10 and 100 µm have been presented. Both the actuation and the readout are capacitive. The actuating mode is bending and the sensing mode is torsional.

The Industrial Technology Research Institute, Hsinchu Hsien, Taiwan, filed a patent (Fan *et al.* 2002a) describing a readout method for micromachined Coriolis mass flow sensors where the substrate and a mirror addition to the moving part of the loop compose a Fabry–Perot interferometer. This allows miniaturized optical readout, which was not possible with the original sensor presented by Enoksson and coworkers.

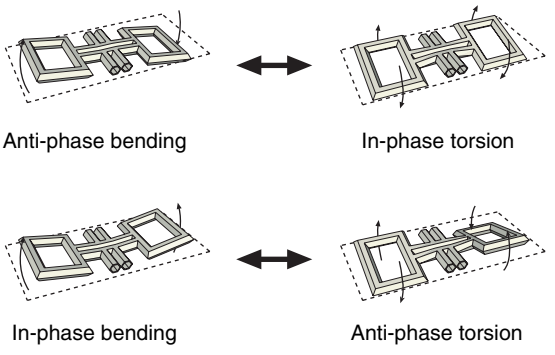

Figure 42 The four resonance modes of the Coriolis sensor presented by Enoksson *et al.* (1997) (Source: Enoksson P, Stemme G, Stemme E 1997 A silicon resonant sensor structure for Coriolis mass-flow measurements. *J. Microelectromech. Syst.* **6(2)**, 119–25. © 1997 IEEE.) Each mode can be used both as a primary as well as a secondary mode.

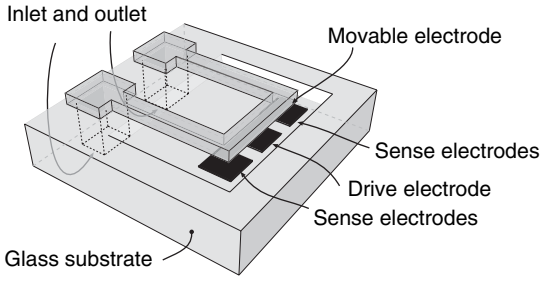

Figure 43 Single-loop Coriolis mass flow sensor with capacitive readout. (Source: Zhang *et al.* 2001.)

An important property of the Coriolis mass flow sensors is that they all can be used as density sensors, since the resonance frequency depends on the mass of the fluid in the tubes:

$$f_0 = 2\pi\sqrt{k_t/m_t + \rho V_t}$$

where k_t is the spring constant of the tube in the resonance mode, m_t the tube wall mass, V_t the volume of the fluid in the tube, and ρ the density of the fluid.

2.07.8 Direct Electrical Flowmeters

2.07.8.1 Electrohydrodynamic

The electrohydrodynamic (EHD) flowmeter is based on measuring the transition behavior of the current when a voltage is applied between two electrodes in a liquid flow. The transient current shows one or more cusps, and the time at which these occur can be correlated with the flow velocity. The dependence is determined by the type of charge carriers in the fluid: for deionized (DI) water at increasing flow rates, an increasing cusp time was noted, while the cusp time decreased for measurements in ethanol. The amount of cusps is defined by how many different types of charge carriers in the fluid are activated. To obtain the ideal situation where only one type of carriers is emitted, the voltage must be adjusted to the fluid.

Richter *et al.* (1991) constructed a micromachined EHD flowmeter by placing two grid electrodes across a channel at distances ranging from 10 to 60 µm from each other (**Figure 44**). The structure is identical to an EHD pump, and since the voltages used for generating the current are the same as those used for EHD pumps, precautions must be taken to avoid the generation of a flow due to the measurement. One solution presented in Richter *et al.* (1991) suggests the use of three electrodes, where the center electrode acts as an emitter, creating an equal in-flow and counterflow pressure.

For an orifice size of $6.25\,\mathrm{mm^2}$ and a voltage of 300 V, flow rates up to $1800\,\mathrm{\mu l\,min^{-1}}$ ($4.8\,\mathrm{mm\,s^{-1}}$) for DI water and $50\,\mathrm{\mu l\,min^{-1}}$ ($0.13\,\mathrm{mm\,s^{-1}}$) for ethanol

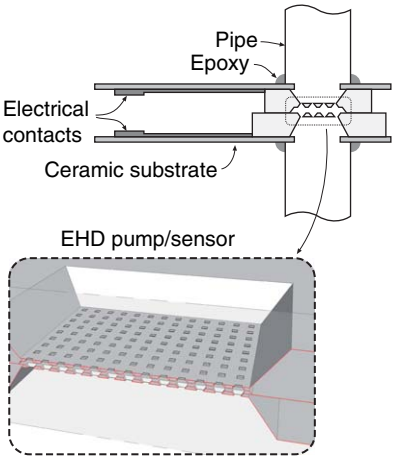

Figure 44 Schematic drawing of a packaged electrohydrodynamic (EHD) pump/flowmeter. (Source: Richter A, Plettner A, Hofmann K, Sandmaier H 1991 Electrohydrodynamic pumping and flow measurement. *Proceedings. IEEE Micro Electro Mechanical Systems. An Investigation of Micro Structures, Sensors, Actuators, Machines and Robots*, pp. 271–6. © 1991 IEEE.)

were measured. The measurements were taken at 1 Hz; the cusp times varied from 50 to 390 µs. These numbers are dependent on the area of the orifice and the distance between the grids.

2.07.8.2 Electrochemical

The time-of-flight principle used for thermal sensors can be straightforwardly applied to the electrochemical domain. Instead of a heater and a temperature sensor, a molecule or an ion generator and a sensor are used.

Wu and Sansen (2002) used the oxygen generated by electrolysis at the anode of an electrochemical cell, and measured the oxygen level with an identical cell 1.5 cm downstream (**Figure 45**). The cells consist of three thin-film electrodes: Pt work and counter electrodes and a Ag reference electrode. The sensing cell can be run in two modes: as an amperometric sensor or as an impedance sensor. In the latter case, only the work and counter electrodes are used.

The use of the sensing electrode in amperometric mode was possible when measuring the flow of phosphate-buffered saline (PBS, a commonly used buffer in biochemistry), where the Cl^- concentration is constant, forming a pseudo Ag/AgCl reference electrode. The amperometric mode can be used even under addition of limited amounts of electroactive species to the buffer. For liquids where the Cl^- concentration is not constant (e.g., tap water), the sensing

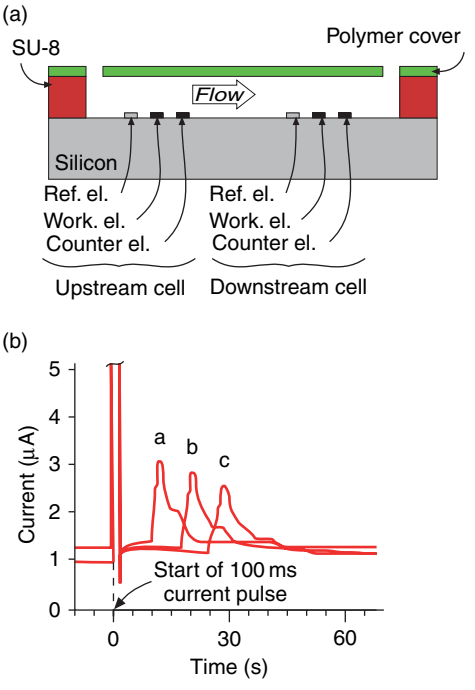

Figure 45 (a) Cross-section of the electrochemical time-of-flight flow sensor with integrated channel. The polymer cover is self-adhesive. (Source: Wu J, Sansen W 2002 Electrochemical time of flight flow sensor. *Sens. Actuators A (Phys.)* **A97–98**, 68–74. © 2002 Elsevier.) (b) Sketch of the current response from the oxygen sensor in amperometric mode. a, b, and c are peaks at 10, 6 and 4 µl min-1 in phosphate-buffered saline (PBS) buffer. The secondary peak on the right flank of each curve is due to oxygen diffusion in the direction orthogonal to the flow. (Source: Wu J, Sansen W 2002 Electrochemical time of flight flow sensor. *Sens. Actuators A (Phys.)* **A97–98**, 68–74. © 2002 Elsevier.)

cell can be used in impedance-sensing mode. A pulse of increased impedance can be sensed, which is speculated to be caused by oxygen microbubbles that are formed at the upstream cell.

The sensor is capable of measuring flow rates ranging from 1 to 15 µl min^{-1}. The range limits for electrochemical flow sensors are imposed by effects similar to those limiting thermal time-of-flight sensors. At flow rates below 1 µl min^{-1}, diffusion becomes too large a factor in comparison to convection, and the oxygen peak cannot be resolved. At flow rates above 15 µl min^{-1}, the current peak measured by the oxygen sensor lies too close in time to the current peak that is caused by the generating cell. This peak is picked up by the sensing cell due to the coupling in the conductive fluid (indicated by A in **Figure 45(b)**).

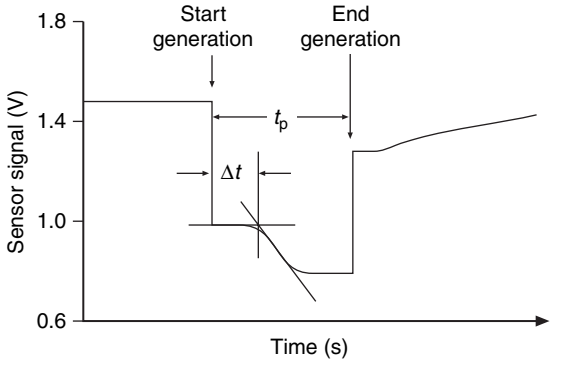

Figure 46 Typical output signal of an ion-sensitive field emission transistor (ISFET)-based flow sensor measuring the generation of OH^- ions with a constant current (CC) of 30 μA. The pulse length t_p lies between 10 and 30 s. Δt is the transit time needed by the OH^- ions to reach the ISFET gate region. (Source: Poghossian A, Berndsen L, Schoening M 2003a Chemical sensor as physical sensor: ISFET-based flow-velocity, flow-direction and diffusion-coefficient sensor. *Sens. Actuators B (Chem.)* **B95(1–3)**, 384–90. © 2003 Elsevier.)

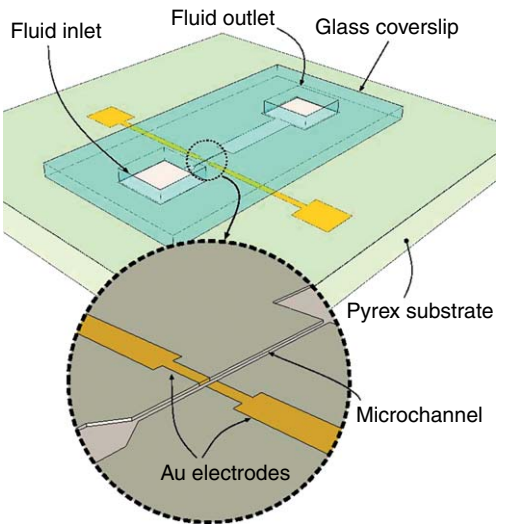

Figure 47 Impedance-based flow sensor. (Source: Ayliffe *et al*. 1999.)

Poghossian *et al.* (2003a) and Schoening *et al.* (2001) employ the H^+ and OH^- groups, respectively, generated during electrolysis of water as tracers to be detected by an ion-sensitive field emission transistor (ISFET). The ISFET used is a field emission transistor where Ta_2O_5 on the gate makes is sensitive to pH levels. The sensor is made direction sensitive by placing an ISFET on either side of the ion generator. Unbuffered 0.1 M KNO_3 water solution (pH ~ 7) was used to measure upon. Flow rates ranging from 0.1 to 0.6 ml min^{-1} were measured in a channel of 2 mm wide and 0.5 mm height. **Figure 46** shows a typical output signal of a sensor of this type. An advantage of using this technique is that it can be combined with other uses of ISFETs, such as sensing pH, penicillin concentration, diffusion coefficient, and temperature (Poghossian *et al.* 2003b).

Besides its use as a time-of-flight sensor, a correlation has been noted between the relaxation time and the flow rate, suggesting a possible application in flow sensing in a way analogous to calorimetric flow sensing.

2.07.8.3 Electrical Impedance

Besides measuring the time of flight of the electrical impedance effect of an electrochemical pulse discussed above (Wu and Sansen 2002), the direct measurement of the electrical impedance change of a liquid due to flow has also been reported; Ayliffe and Rabbitt (2003) describe an electrical impedance sensor integrated in microfluidic channels for bioMEMS applications. The channels are formed by a glass/SU-8/glass sandwich, while electroplated gold electrodes are integrated in the walls (**Figure 47**). A dependence of both the magnitude and the phase of the impedance in a physiologic saline solution is shown.

Observing the impedance using a network analyzer, a magnitude dependence with respect to the flow could be observed at frequencies below 200 kHz with a maximum effect at 350 Hz. The phase profile of the impedance also changed. At frequencies above 200 kHz, no significant flow dependence was observed. The magnitude increase could be reproduced in an electrochemical/convective simulation and was explained by the flow washing out the ion cloud that is formed between the electrodes. On applying a DC bias (50 mV) during the AC interrogation of the impedance, this ion cloud is larger, which increases the flow sensitivity. Flows ranging from 2.4 to 4.8 μl min^{-1} were measured.

Collins and Lee (2004) measured the admittance across a channel to determine the flow rate of a saline solution. With an electrode distance of 100 μm (**Figure 48**), as opposed to 5–10 μm in the set-up of Ayliffe *et al.* (1999), the capacitance is much smaller. Within the range of 10 Hz–5 kHz, an optimal measurement frequency, where the absolute value of the admittance was maximized, was found to lie at around 500 Hz. Besides the frequency dependence,

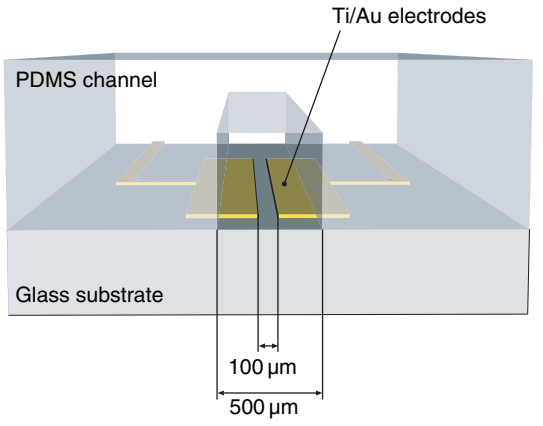

Figure 48 Admittance-based flow sensor integrated in polydimethylsiloxane (PDMS) microchannel. (Source: Collins and Lee 2004.)

an optimal excitation voltage (0.4 V) and a buffer concentration (0.2 M) were observed. Using an AC excitation voltage of 400 mV and measuring the current through a 1-kΩ series resistor, sensitivities ranged from 10^{-4} to 5.2×10^{-4} mA μl^{-1} min depending on the electrolyte or the buffer used. Flows from 35 down to 0.1 μl min^{-1} could be measured. Only the root mean square (RMS) value of the current was taken into account, and no information was given on the observed phase shift.

2.07.8.4 Electromagnetic – Using Faraday's Law

According to Faraday's law, when a conductor moves through a magnetic field, a voltage that is dependent on the relative velocity between the conductor and the field is produced in the conductor. Therefore, a conducting fluid, when flowing through a magnetic field oriented perpendicular to the flow, will induce a flow rate-dependent voltage in the direction perpendicular to the flow and the field (**Figure 49**). For channels with a circular cross section, the voltage between two electrodes placed opposite to each other in the channel wall can be expressed as $E = DBV$, where D is the diameter of the channel, B the magnetic field strength, and V the average flow rate (Thürlemann 1941, 1955).

Yoon *et al.* (2000) presented a microelectromagnetic flow sensor based on anisotropically etched silicon microchannels with metal electrodes (**Figure 50**). Flow rate measurements on a fluid with a conductivity of 100–200 mS cm^{-2} in the range of 9.1–62 ml min^{-1}

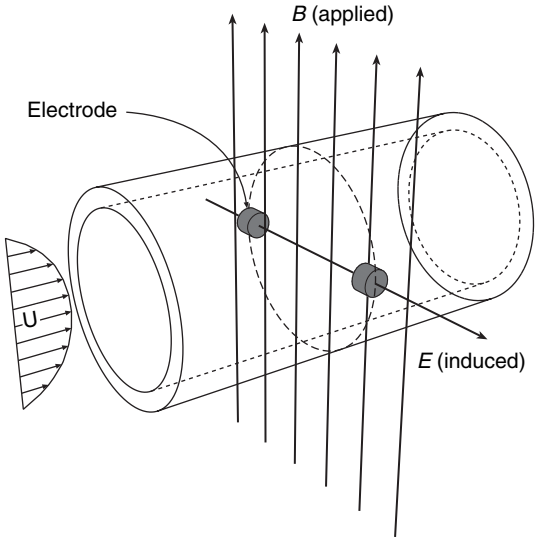

Figure 49 Schematic representation of the electromagnetic flowmeter.

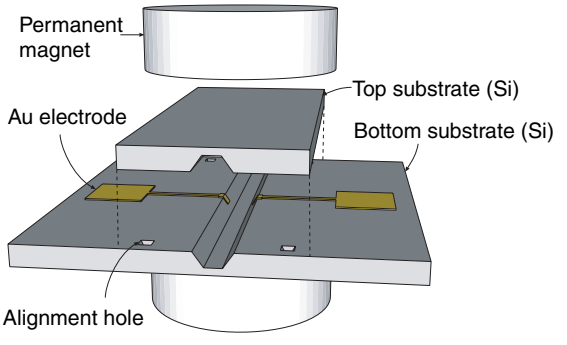

Figure 50 Exploded view of an electromagnetic flowmeter integrated in an anisotropically etched microchannel. (Source: Yoon *et al*. 2000.)

in a magnetic field with flux density of 250 mT resulted in induced voltages of 261 μV to 7.3 mV, respectively. Using microelectric discharge machining, Takahata and Gianchandani (2005) produced a sensor that can be implanted in blood vessels using balloon angioplasty. The implanted sensor consists of three parts: an antenna coil for excitation, a varactor diode to create on oscillator circuit, and a set of cuff electrodes (**Figure 51(a)**). The coil and the electrodes are fabricated in a planar form and threaded on the balloon. The expansion of the balloon plastically deforms the structures; this keeps them in place after the balloon is deflated and removed. The circuit is illustrated in **Figure 51(b)**. An external coil is used to interrogate the system. When a magnetic field is

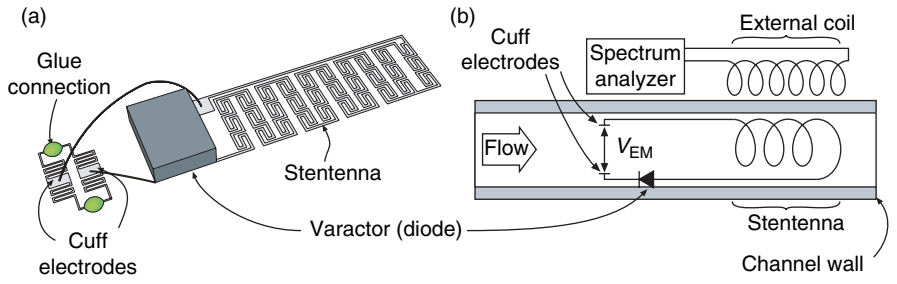

Figure 51 Electromagnetic flowmeter for implantation in blood vessels. (a) Pre-expansion and (b) equivalent circuit. (Source: Takahata K, Gianchandani Y 2005 Micromachined intraluminal devices for active and passive electromagnetic measurements of flow. *18th IEEE Int. Conf. Micro Electro Mechanical Systems 2005 (MEMS 2005)*, pp. 863–6. © 2005 IEEE.)

applied, the flow-dependent DC voltage generated in the cuff electrodes controls the varactor's capacitance. This affects the resonance frequency and the phase response of the system. Flow measurements were simulated but had not yet been performed.

The advantages of electromagnetic flow sensors are that they have a simple structure and generate no heat or pressure loss. For applications where the total flow through the channel is of interest, electromagnetic flow sensors provide a correct value, independent of the flow profile. The limitation is that the liquid needs to be conductive; the level of conductivity, however, does not affect the measurement.

A variant where the electrodes are not in ohmic contact with the fluid has been fabricated by Merkel *et al.* (2000) using microchannels in printed circuit boards (Merkel *et al.* 1999) (**Figure 52**). By varying the magnetic field, the voltage can be detected capacitively (see **Figure 52**). Flow rates ranging from 2 to 14 $\mu l\,min^{-1}$ were measured using a magnetic field intensity with an amplitude of 1200 $A\,m^{-1}$ varying at 65 kHz.

2.07.9 CNT-based Flow Sensors

First discovered by Sumio Iijima in 1991 (Iijima 1991), CNTs are cylindrical carbon molecules with interesting thermal, mechanical, and electrical properties. CNTs can be seen as wrapped graphite sheets that, depending on the orientation, behave like semiconductors or like metals. A distinction is made between single-walled carbon nanotubes (SWCNTs) and MWCNTs, the latter consisting of several concentric cylinders. With the introduction of fabrication techniques that allow CNTs to be integrated with thin-film processes, more properties of CNTs have been discovered and different application areas have arisen, among which is flow sensing.

A truly novel phenomenon was observed by Ghosh *et al.* (2003). The voltage across bundles of randomly oriented SWCNTs exposed to liquid flows (**Figure 53**) was found to be nearly logarithmically dependent on the flow rate over six orders of magnitude (for water: from 10^{-7} to $10^{-1}\,m\,s^{-1}$ free flow velocity in a 3-cm-diameter glass tube). The sensitivity was observed to be dependent on the type of liquid, and it is believed to be dependent on the adsorption properties of the nanotube surfaces with respect to different types of ions (Sood *et al.* 2005). The underlying physics of the phenomenon is not yet fully understood, and several explanations have been suggested. In a review paper, Sood *et al.* (2005) argue for the explanation

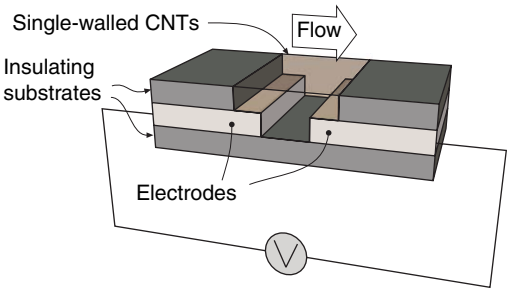

Figure 53 Schematic sketch of the nanotube flow sensor placed along the flow direction. (Source: Sood *et al*. 2005.)

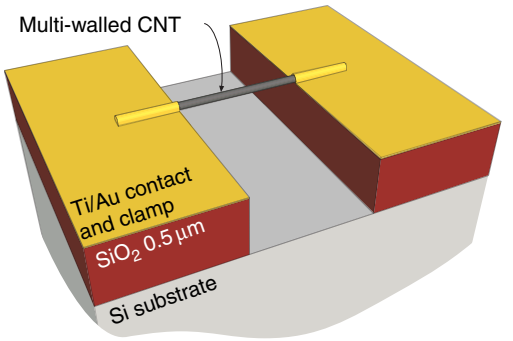

Figure 54 A suspended carbon nanotube (CNT) device. (Source: Chung *et al*. 2003.)

given in Ghosh *et al.* (2003, 2004), rejecting theories proposed by Král and Shapiro (2001) and Persson *et al.* (2004).

The response time of the sensor was reported to be better than a few milliseconds, the measurements being limited by the liquid flow velocity and the rate of data acquisition (Sood *et al.* 2005)

Chung *et al.* (2003) reported a resistance change in a suspended MWCNT subjected to a nitrogen flow (**Figure 54**). The effect is assumed to be a result of drag-induced deformation resulting in a resistance change (Tombler *et al.* 2000). Sood and Ghosh (2004) also presented a CNT gas flow sensor that uses the Seebeck effect in CNTs. This principle is described in Section 2.07.4.

2.07.10 On-chip Electronics

The use of semiconductor substrates for micromachined flow sensors provides the possibility of integrating electronics on the same chip as the sensor. This can reduce fabrication costs as fewer chips need to be combined in a package. The established fabrication facilities for complementary metal oxide semiconductor (CMOS) electronics can also provide low cost and high volume production. From a technical point of view, the output signal can be amplified or digitized before it leaves the chip thereby reducing the effects of noise. However, there are challenges both in fabrication and in operation. The overall majority of flow sensors with on-chip electronics are thermal and therefore require above-ambient, often-varying temperatures or temperature gradients that can affect the behavior of the analog electronics around them. Bruschi *et al.* (2004a), Makinwa and Huijsing (2002b), and Tong and Huang (1987) solved this problem by maintaining the entire chip at a constant, moderately elevated temperature (up to 55°C). Fricke (1994) used GaAs as a substrate material since the MESFET circuit integrated upon it can stand temperatures up to 240°C without its behavior being significantly affected. A more common solution, however, is to thermally isolate the heater from the rest of the chip. To achieve this, usually membranes need to be formed or grooves etched, and the etching methods used for this are often not compatible with, for example, CMOS electronics. One approach concentrates the thermal isolation micromachining steps in the pre- and post-processing stages before and after the CMOS fabrication (e.g., Malcovati *et al.* 1995). Another, more comprehensive, method integrates the MEMS-specific process steps in the CMOS fabrication (e.g., Yoon and Wise 1992).

Thermal flow sensors with on-chip circuitry can be categorized into two groups based on the function of the circuitry. The sensors of the first group are those in which the electronics amplify or digitalize the output signal. Bosman *et al.* (1992) used an on-chip voltage-to-frequency converter to convert the low Seebeck voltage signals, on the order of 0.1 mV, to a more noise-resistant variable-frequency signal. Bruschi *et al.* (2004a) based the function of their circuit on a current source that is proportional to absolute temperature (PTAT). Developed by Meijer (1986), this current source provides a signal linearly dependent on the absolute temperature of the device. This signal is used by Bruschi and coworkers as an input to an off-chip CT controller. Kersjes *et al.* (1993) placed a heater/sensor diode on a membrane to thermally isolate it from the bulk and used a differential amplifier at ambient temperature on the bulk of the chip to measure the temperature difference between the diode on the

membrane and the one on the bulk. A second chip then converted the analog signal into a pulse-width-modulated signal. One step beyond amplification is to digitalize the signal on the chip. Verhoeven and Huijsing (1994) used a PTAT current source and combined it with an on-chip sigma–delta converter to provide a TTL-compatible pulse-rate-modulated signal with a 10-bit resolution. Malcovati *et al.* (1995) based their design on a CMOS sigma–delta converter resulting in a 15-bit resolution.

In the second group are those sensors where the on-chip circuitry provides a feedback signal to operate the sensor in closed loop. The electrothermal oscillator by Stemme (1988), described above, was implemented at the bulk end of the sensor using metal gate CMOS technology with only the heating circuitry at the thermally isolated end. Chen *et al.* (2005) fabricated out-of-plane hot-wire structures starting from a passivated CMOS chip containing a constant temperature anemometry (CTA) circuit with only the contact pads free. (The process is described in Section 2.07.2.3.4.) A fully standard CMOS-processed chip was developed by Tong and Huang (1987). The chip is kept at a CT, and the voltage to the heating resistor is the output signal. This simple process skips any micromachining steps, but the trade-off is a time constant of around 40 s. Makinwa and Huijsing (2002b) also used a standard CMOS chip to make a hot-chip sensor for wind-meter applications. The feedback circuitry is based on three sigma–delta modulators, one to keep the chip at a constant average temperature and two to balance out the flow-induced temperature differences over the chip. This device has a time constant on the order of 10 seconds. The wide-range flow sensor developed by Yoon and Wise (1992) consists of two flow-rate sensors and a flow direction sensor. **Figure 55** shows a block diagram and a chip layout of the multisensor chip that, besides the flow-rate and direction sensors, has a gas-type sensor and a pressure sensor. The flow-rate sensors are driven in CT mode. To build the device, a dedicated process was developed that interleaved the CMOS and the micromachining steps. An analog multiplexer is used to select the desired output.

The demands on the fabrication of on-chip electronics in the differential-pressure blood-flow sensor presented by DeHennis and Wise (2006) are similar to the thermal flow sensors, but for different reasons. No heating is required, but the formation of the pressure membranes by wet etching and, specific for this sensor, the thinning of the substrate require pre- and postprocessing of the BiCMOS electronics used.

In the field of mechanical flow sensors, Schmidt *et al.* (1987) used a matched pair of depletion-mode metal gate positive-channel MOS (PMOS) transistors as the first stage to read out the capacitance variation of the polyimide shear-stress sensor described above (see **Figure 30(b)**). The signal is amplified further off-chip. On-chip feedback has also been demonstrated for mechanical skin-friction sensors. Pan *et al.* (1995a, b) (see **Figure 30(f)**) used

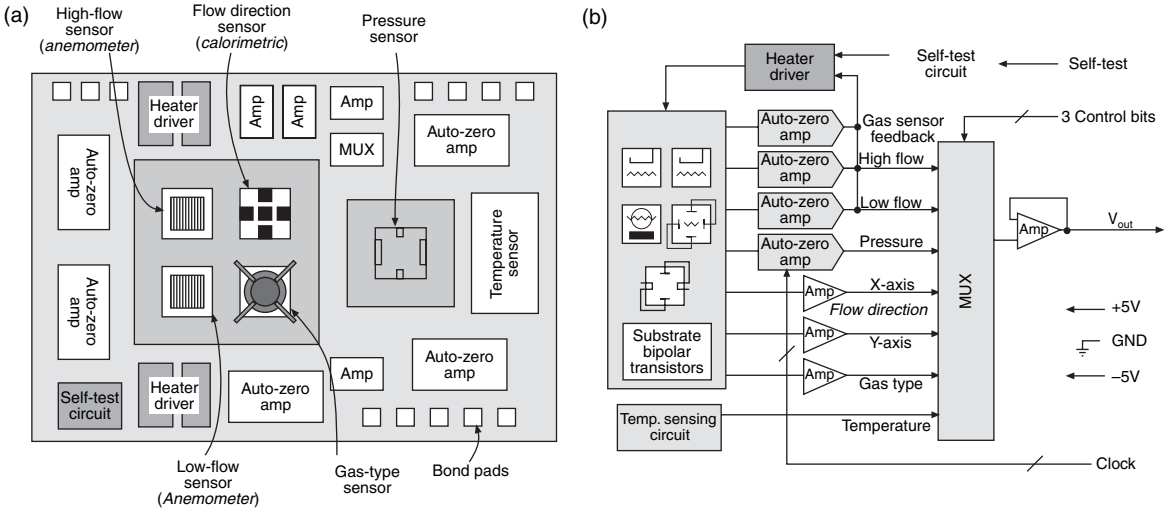

Figure 55 (a) Block diagram and (b) chip layout of the multisensor chip presented by Yoon and Wise (1992). (Source: Yoon E, Wise K 1992 An integrated mass flow sensor with on-chip CMOS interface circuitry. *IEEE Trans. Electron. Devices* **39(6)**, 1376–86. © 1992 IEEE.)

the control circuitry of an analog devices accelerometer (Kuehnel and Sherman 1994) to maintain the floating element at a constant position. Analog to CTA, the feedback signal provides a measure for the skin friction. **Table 6** provides an overview of flow sensors with integrated circuitry.

2.07.11 Applications

2.07.11.1 Skin-friction Measurements

Skin friction, also referred to as wall shear stress, is an important factor in the study of near-wall fluid flows. From a scientific point of view, measuring the skin friction provides information for understanding and modeling the complex behavior of the turbulent boundary layer. From an engineering point of view, this turbulent boundary layer determines the performance of aerodynamic surfaces such as wings or propellers. In flow-control applications, where one needs to control the transition from laminar to turbulent flow or vice versa, feedback from high-resolution skin-friction measurements is essential. The small size and rapid response times of MEMS sensors make them particularly interesting for such applications.

Besides a high bandwidth of up to 10 kHz for high Reynolds numbers and a spatial resolution of 100 μm (Padmanabhan *et al.* 1997, Sheplak *et al.* 2004), skin-friction sensors should interfere as little as possible with the flow. Since an array formation is desirable to obtain a picture of the shear-stress distribution over an area, restraints are placed on the mounting of the sensor and placing of the electrical leads.

Shear-stress-sensing methods can be divided into two categories: direct and indirect. The direct way to measure shear stress is by mechanical means – by means of the skin-friction subset noted above – where the displacement of a spring-suspended element is measured. The spring suspension provides high directional specificity. Care needs to be taken, however, that the mechanical structure does project into the flow or create a recess in the wall that would affect the flow. Of the direct skin-friction sensors presented in the literature, only the devices described in Hyman *et al.* (1999) and Pan *et al.* (1999) have been scaled up to array sensing.

Indirect mechanical shear-stress sensing is also possible. For flows of not too high Reynolds numbers, or if a slight influence of the flow by the sensor can be tolerated, hair-type cantilever flow sensor arrays can be used for shear-stress imaging. A prerequisite for

accuracy is that the hairs are short enough to remain completely within the viscous sublayer. Arrays of hair-type sensors have been presented by Chen *et al.* (2003), van Baar *et al.* (2005) and Brücker *et al.* (2005) using piezoresistive, electrostatic, and optical hair-deflection readout, respectively. Brücker *et al.* (2005) is the only one of this group who has demonstrated full 2D sensitivity but the application is limited by the optical readout system.

In addition to studies on mechanical shear-stress sensing, much research has been performed on thermal shear-stress sensing. Unlike mechanical skin-friction sensors, thermal sensors require no moving parts and can, in most cases, be easily integrated into a flat surface. The output from single hot-element flow sensors can be correlated empirically with the skin friction at the heating element. The spatial resolution of the skin-friction sensor is limited mainly by the size of the heated area, which includes part of the insulating structure (Yoshino *et al.* 2001). Furthermore, as the conductive heat transfer into the supporting structure is frequency-dependent, the relationship between the transferred heat and the skin friction varies with varying flow regimes, which results in a nonunique relationship (Sheplak *et al.* 2004). Therefore, thermal shear-flow sensors need to be calibrated for the situation in which they are used, which is not always possible as with complex flow phenomena.

Figure 56(a) illustrates the principle of the set of thermal shear-stress sensors developed by Tai and Ho and coworkers. A polysilicon heater is placed on a thermally isolating membrane over a 2-μm-deep vacuum cavity. A device based on the same principle was developed by Cain *et al.* (2000) who used platinum as a heater material and a 10-μm-deep vacuum cavity. Yoshino *et al.* (2003) used a more easily fabricated membrane over an air cavity, perforating the membrane to allow wet etchant to form the cavity. Thermally insulating the heated element by means of polyimide around a heated chip area was performed by Kälvesten *et al.* (1995) (see **Figure 56(b)**). **Figure 56(c)** illustrates the principle of Kim and Lee (2006) and Rouhanizadeh *et al.* (2006) where back-side contacting reduces the flow obstruction due to the contacting leads while at the same time isolating them from the fluid.

Löfdahl *et al.* (2003) used a different approach, controlling the heat flow to the substrate instead of trying to minimize it. In incompressible, no-slip turbulent flow, there is a viscous sublayer close by where the velocity profile is linear due to the

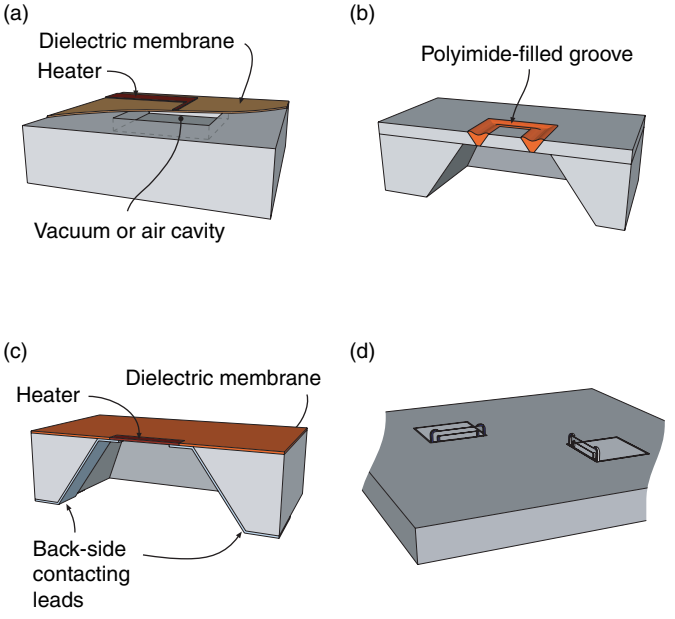

Figure 56 Thermal shear-flow sensors: (a) heater on vacuum cavity by Tai and Ho and coworkers (Huang *et al*. 1995, 1996, 1999, Jiang *et al*. 1995, 1996, 1997, Li *et al*. 2000, Lin *et al*. 2000, 2004, Liu *et al*. 1994, 1999, Tung *et al*. 2004, Xu *et al*. 2005a, b), alternatively on an air cavity. (Source: Yoshino *et al*. 2003.) (b) Groove-isolated membrane. (Source: Kälvesten *et al*. 1995.) (c) Thermally insulating membrane with back-side contacting. (Sources: Kim and Lee 2006, Rouhanizadeh *et al*. 2006.) (d) Prong-suspended hot wires. (Source: Löfdahl *et al*. 2003.)

dominance of the viscous forces (see **Figure 1**). The thickness of the viscous sublayer, λ_0, can be approximated as a function of the wall shear stress, the density of the fluid (ρ), and its kinematic viscosity (ν) (Löfdahl and Gad-el Hak 1999a):

$$\lambda_0 = 5\nu\sqrt{\frac{\rho}{\tau_0}}$$

By measuring the flow at a fixed distance from the wall, the wall shear stress can be derived from the following equation:

$$\tau_0 = \mu \left.\frac{\partial U}{\partial y}\right|_{y=0} = \mu\frac{U_d}{d}$$

where U_d is the velocity at a distance d from the wall (within the viscous sublayer). Micromachined aluminum hot wires at distances ranging from 50 to 250 μm were used (see **Figure 56(d)**). At greater distances from the wall, the shear-stress sensitivity increased and fluid temperature sensitivity decreased. However, the measurable range is decreased as the viscous sublayer becomes thinner with increasing wall shear stress. The heat flow to the substrate is controlled because the supports and the wall are thermally conductive and so remain at a CT (Haasl 2005).

van Oudheusden and Huijsing (1988) presented a direction-sensitive thermal shear-stress sensor in hot-chip mode using a thermopile to measure the temperature difference between the upstream and downstream ends of the chip. The set-up, in which the chip and the ceramic base are heated, had very large time constants (2–20 min), thus rendering it useless for dynamic applications.

Uncompensated thermal shear-stress sensors are extremely sensitive to fluid temperature changes; variations of 0.1°C have been reported to significantly affect the output signal (Löfdahl *et al.* 2003). Attempts to compensate for this by means of separate temperature sensors on-chip have been moderately successful within ranges of 0.7°C (Huang *et al.* 1999 and Jiang *et al.* 1996), which is acceptable for wind tunnel set-ups with tight temperature control. In general, for all thermal shear-stress sensors, increasing the overheat ratio $((T_{\text{wire}} - T_{\text{ambient}})/T_{\text{ambient}})$ increases the shear-stress sensitivity and decreases the fluid temperature sensitivity. At high overheat ratios, however, buoyancy effects caused by the heating of the flow by the wire start to affect the measurements (Appukuttan *et al.* 2003).

Despite these issues in accurately obtaining quantitative values for wall shear stress, flow control has been achieved with flexible arrays of shear-stress sensors held together by a polyimide film (Ho and Tai 1998). The shear-stress sensor arrays were attached to the leading edge of an unmanned aerial vehicle and provided feedback to micromachined balloon actuators to control its flight.

A micromachined optical shear-stress-sensing method has been presented by Fourguette *et al.* (2001). The principle, first developed with conventional optical components by Naqwi and Reynolds (1987), is derived from LDA. In LDA, two phase-shifted laser beams are crossed at a slight angle to generate an ellipsoid region with parallel interference fringes. As particles pass through this region, they scatter light with the intensity varying at a frequency $f = U/d_f$ where U is the velocity of the particles orthogonal to the fringes and d_f is the distance between the fringes. Naqwi and Reynolds (1987) instead used a diverging set of fringes (**Figure 57(a)**) and measured in a region within the viscous sublayer where the flow velocity is linearly dependent on the distance to the wall, $U_d = \tau_0 d/\mu$. As the distance between the fringes increases linearly with the distance from the wall (y), $d_f = k_f y$ (k_f is a constant), the frequency of refracted light off the particles becomes dependent only on the wall shear stress, $f = \tau_0/\mu k_f$. The micromachined optical interface between the laser and the photodetector is shown in **Figure 57(b)**. A 500-μm-thick fused silica or quartz substrate is used. A chromium pattern on the front side defines a pair of slits to create diffraction and a collecting window for the photodiode. On the back side, there are two polymethylmethacrylate (PMMA) diffractive lenses, which were fabricated by analog direct-write electron beam lithography followed by acetone development (Mouroulis *et al.* 1998, Wilson *et al.* 1996). The measuring volume was 15 μm × 20 μm × 90 μm, centered at 66 μm from the surface. As the viscous sublayer becomes thinner with increasing Reynolds numbers, the measurements were limited to Reynolds numbers up to 3×10^6 at 1 m downstream from a leading edge, at which the accuracy of a single-point measurement becomes 90%. Fourguette *et al.* (2003) presented a second generation of this sensor that uses three diffractive optical elements (DOEs): one transmitting DOE to split the incoming laser light into two beams and two receiver DOEs to measure the velocity at two different heights by means of photodetectors (**Figure 58**). The measurement volumes consist of a pair of 75-μm-long elongated light spots at 13.75 μm from each other, positioned at 65 and 110 μm from the surface. Using this set-up, and fitting the results to Spalding's formula

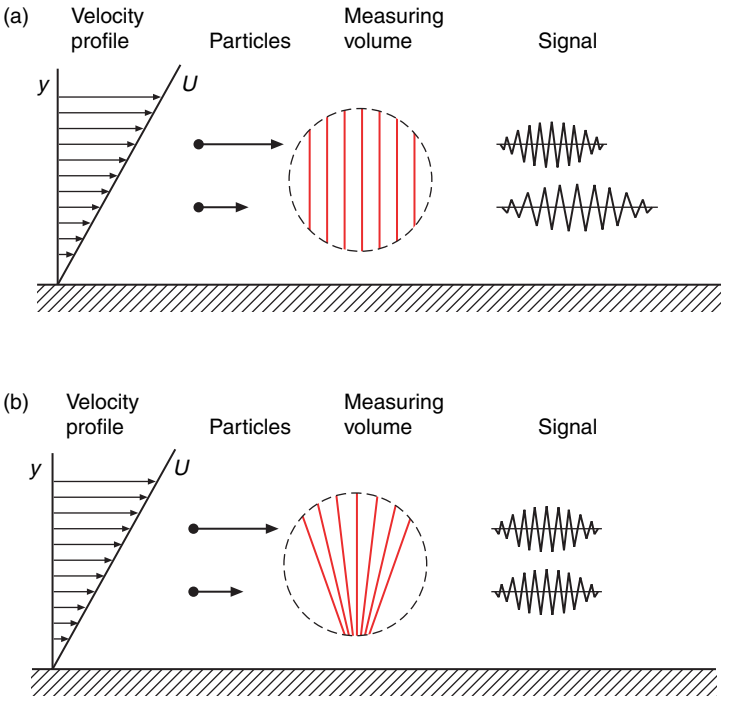

Figure 57 (a) Standard laser Doppler anemometry (LDA): parallel fringes result in a flow velocity-dependent signal as particles pass through the measuring volume. (b) LDA adapted for shear-stress sensing. The linearly diverging fringes result in a shear-stress-dependent signal. (Spalding 1961) that describes the mean velocity profile in a turbulent boundary layer up to a much larger distance than the viscous sublayer, 90% reliable results could be obtained up to a Reynolds number of 1.5×10^7.

The advantages of these optical methods are their nonintrusiveness (except for the seed particles), their linear response, and their high-frequency response. Their main drawback is the performance degradation

at large and unsteady velocity gradients because of the lack of near-wall seed particles (Naqwi and Reynolds 1991).

2.07.11.2 Medical Applications of Micromachined Flow Sensors

Micromachined flow sensors have been developed for use in three main areas of medicine: respiratory control, blood-flow measurements, and microdosing. Instruments that come in contact with the patient are often used only once to avoid contamination since disposing of them can be cheaper than disinfecting them. Microsystem technology with its low cost at high volumes, therefore, offers appealing prospects. The increasing use of implanted devices and minimally invasive surgery (MIS) has also created a need for miniature sensors that can be introduced with minimal tissue damage.

For respiratory control applications, the size requirement is not very stringent, the most important factor being low flow resistance, especially in situations where the patient can breathe partially or completely autonomously. Complicating aspects are the humidity and temperature variations in the breathing air and particles that may be carried with it and deposited on the sensor. Thermal flow sensors themselves do not generate pressure differences and generally have high sensitivity at low flow rates. However, because they usually measure flow only at one point, care must be taken of the varying ways in which the sensors are connected to the rest of the system as they might affect the flow profile. Respiratory flow sensors of the direction-insensitive thermal anemometer-type sensors have been presented (Bu *et al.* 1996, Svedin *et al.* 1998a), but an ability to distinguish inspiration from expiration is required if more than just the respiration frequency is to be reliably measured. Sensors based on both the double Wheatstone bridge thermal anemometry principle used by van Putten *et al.* (1997) and the calorimetric principle used by Bracio *et al.* (2000), Kaltsas and Nassiopoulou (2004), and Steurer and Kohl (1998) were developed with ventilator applications in mind, but many other thermal flow sensors would meet these specifications. Svedin *et al.* (2003a–c) developed two types of mechanical flow sensors based on lift-force measurement to obtain low pressure-drop measurements. As described in Section 2.07.3, Svedin *et al.* (2003a) combines a calorimetric flow sensor with the mechanical lift-force sensor to achieve high sensitivity over a large range. The main advantage of mechanical flow sensors is that they are less sensitive to particles and humidity variations.

The demands on blood-flow sensors are stringent. Those used in MIS have to be small enough to fit in the catheter that is used for introducing instruments. The packaged sensor should have a smooth surface to avoid blood clotting, and for thermal sensors, the allowed temperature variations are limited to about 5 K above ambient to avoid platelet and protein deposition as well as damage to the blood constituents (Kersjes *et al.* 1996, Tabata *et al.* 1987). The biocompatibility of the materials must be assured and the sensor has to be able to withstand standard sterilization procedures (Kotzar *et al.* 2002). As the entire sensor is placed in the liquid, care needs to be taken with packaging to prevent short circuits. Limited reverse flow can occur in blood vessels, which makes directional sensitivity desirable. Because of the size limitation, nearly all invasive blood-flow sensors are either thermal- or differential pressure-based. Kersjes *et al.* (1993, 1996) and Perichon *et al.* (2000) developed anemometer-type flow sensors with temperature compensation. Tanase *et al.* (2002) integrated a calorimetric flow sensor together with sensors for pressure and oxygen saturation into a single chip (**Figure 59(a)**). By integrating the sensor into the catheter, flow measurement can be performed online, while other surgical instruments or sensors are inserted with the guide wire. A significant disadvantage of anemometric and calorimetric flow sensing in blood vessels is that the dimensions of the blood vessels differ, which results in differing flow profiles within the vessel. The difficulty of controlling the lateral position of the sensor in the vessel adds further uncertainty to the volumetric blood-flow measurement. Differential-pressure measurement provides a partial solution, as the pressure does not vary much in the lateral direction of a blood vessel. Radi Medical Systems (Uppsala, Sweden) has developed a pressure sensor for measuring the pressure difference in the coronary arteries and hence to derive the volumetric flow and identify possible restrictions in the flow (stenoses). **Figure 60** illustrates how the sensor, mounted near the end of a guidewire, is inserted in the coronary vessels.

De Bruyne *et al.* (2001) and Pijls *et al.* (2002) used the resistive temperature compensation sensor on Radi's chip as the sensing part of a time-of-flight flow sensor. A small amount (3 ml) of saline at room temperature is quickly injected to cause a

temperature drop first at the tip of the catheter and then at the tip of the guide wire, 3 cm downstream. The injection time is measured by using the catheter tip as a thermistor. The small injection volume sufficed for accurate measurement and did not significantly affect the flow rate.

Micromachined flow sensors for blood perfusion measurements of the blood supply to tissue have been devised for both invasive and noninvasive applications. Kuttner *et al.* (1991) incorporated Ge thermistor arrays into the tip of a needle in order to probe the cerebral cortex of rabbits. Higurashi *et al.* (2003) and Ito *et al.* (1999) integrated a laser Doppler velocimetry system onto a substrate with an area less than 1 mm^2. A miniaturization of existing, bulky solutions can measure skin perfusion by observing the Doppler shift of red blood cells flowing just under the skin surface. Takahata and Gianchandani (2005) and Takahata *et al.* (2004) used a stent-like structure as an antenna to power differential-pressure and electromagnetic luminal flow sensors. DeHennis and Wise (2006) used a gold coil to provide power to a monolithic differential-pressure luminal flow sensor with integrated circuitry.

Blood shear stress has been found to be useful for monitoring blood clotting in cardiopulmonary bypass machines and implanted heart pumps. Luminal shear stress, i.e., the shear stress in blood vessels, has been shown to predict plaque formation in specific situations. For measuring shear stress, Rouhanizadeh *et al.* (2006) developed a sensor based on a back-side-contacted anemometer (see **Figure 56(c)**) that has been demonstrated in walls of artificial arteries (**Figure 61**).

Li *et al.* (2005) and Papageorgiou *et al.* (2001) designed flow sensors integrated in the base of neural microprobes, illustrated in **Figure 62**. The probes have electrodes integrated on the needle shaft to measure the electrical response of the neurons to electrical stimuli and a hollow shaft to allow drug injection. The flow sensor is used to control the

dosage and to ensure that no blockage has occurred. The heating budget for probes in the central nervous system is even more stringent than for blood sensors as the temperature rise must be kept below 2°C to avoid neural damage. Since the entire sensor is in a liquid environment, the outside is thermally insulated by an air cavity to reduce unnecessary heat loss.

Göran Stemme was born in 1958 in Stockholm, Sweden. He received the M.Sc. degree in Electrical Engineering in 1981 and the Ph.D. degree in Solid State Electronics in 1987, both from the Chalmers University of Technology, Gothenburg, Sweden. In 1981, he joined the Department of Solid State Electronics, Chalmers University of Technology, Gothenburg, Sweden. There, in 1990, he became an associate professor heading the silicon sensor research group. In 1991, Dr. Stemme was appointed Professor at The Royal Institute of Technology, Stockholm, Sweden, where he heads the Microsystem Technology group at the School of Electrical Engineering. His research is devoted to microsystem technology based on micromachining of silicon. His work spans over a broad range of technological and application fields such as medical technology, biochemistry, biotechnology, microfluidics, optical applications, wafer-level packaging, and device integration. Some of the results have successfully been commercialized. Dr. Stemme is a member of the Editorial Board of the IEEE/ASME *Journal of Microelectromechanical Systems* since 1997 and was a member of the Editorial Board of the Royal Society of Chemistry journal *Lab On A Chip* between 2000 and 2005. He has published more than 150 research journals and conference papers and has more than 12 patent proposals or granted patents. Dr. Stemme is a member of the Royal Swedish Academy of Sciences (KVA) and he is an IEEE fellow.

Sjoerd Haasl was born in 1976 in Leuven, Belgium. He received the M.Sc. degree with high honors in Electrotechnical Engineering, specialization Automation and Computer Systems at the University of Leuven, Belgium, in 1999. He received the Ph.D. degree in Microsystem Technology at the Royal Institute of Technology, Stockholm, Sweden, in 2005. At present, he is employed as Research Scientist and Project Leader at IMEGO AB, Gothenburg, Sweden. His current research interests lie in the fields of inertial sensors, flow sensors, and chemical sensors. Dr. Haasl is a member of the IEEE.

2.08 Gas Micropumps

2.08.1 Introduction

A gas micropump is a small-volume device that can pump compressible gaseous fluids at different flow rates and pressures. The development of gas micropumps has been facilitated through the use of microelectromechanical systems (MEMS) technology that allows high-precision manufacturing of microdomain structures. Gas micropumps have several significant advantages, such as small size, low power consumption, and portability, that are highly desirable in many emerging applications, including health and environmental monitoring (Zellers *et al.* 2004, Kim *et al.* 2006c, Watson 1997), microelectronics cooling (Chou *et al.* 2002, Gromoll 1994, Jiang *et al.* 2002, Kim *et al.* 2006b, Rodgers *et al.* 2005, Tuckerman and Pease 1981, Zhang *et al.* 2002), micropropulsion (Chou *et al.* 2001, Kim *et al.* 2006b, Kwon *et al.* 2005, Wang *et al.* 2006, Yu and Kim 2003), and power generation (Arana *et al.* 2003, Seo and Cho 2004). They can fit in a small volume (<0.1 cc) and consume little power (<100 mW) (Kim *et al.* 2006a); in contrast,

conventional mesoscale pumping systems, such a gas tanks or mechanical pumps, take up much space, consume high power, and have limited precision to be used for controlling small doses of fluids in the microscale, as illustrated in **Figure 1**.

The development of gas micropumps has lagged behind liquid micropumps (Laser and Santiago 2004), primarily due to gas compressibility (Stehr *et al.* 1996), sealing challenges, and small actuation forces and amplitudes that are achievable in the microdomain. As of 2006, there have been only about more than 20 conference and journal papers reported in the literature on gas micropumps fabricated using MEMS technology (**Figure 2**). This is a small number compared with more than 200 archival papers published on liquid micropumps.

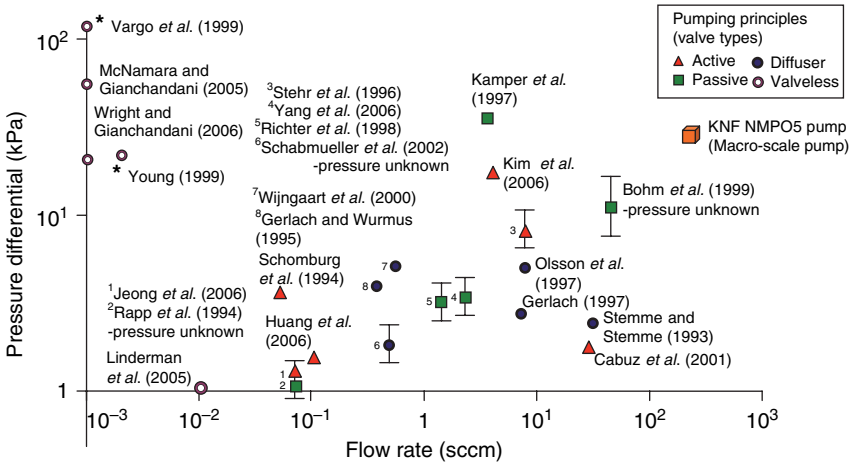

Figure 2 Flow rate and pressure differential of past gas micropumps with different pumping principles (asterisk indicates theoretical values). (Source: Kim H 2006 An integrated electrostatic peristaltic gas micropump with active microvalves. Ph.D. thesis, University of Michigan.)

The earliest MEMS-fabricated liquid micropumps were developed by van Lintel (van Lintel *et al.* 1988), then by Esashi (Esashi *et al.* 1989), and Smits (Smits 1989). The first MEMS gas micropumps were reported in the mid-1990s. The first reported micromachined pump that was targeted for gas pumping was the surface micromachined pump developed by Judy *et al.* (1991), but no flow data were available or reported in that paper. The first experimental measurements in a gas micropump were reported by Stemme in 1993 (Stemme and Stemme 1993). Since then, significant progress has been made in the development of gas micropumps due to better understanding of the relationship between flow resonances and pumping in the microdomain, and because of improved fabrication technologies and device structures. Stehr utilized the gas resonance effect to develop a bidirectional pump that produces reverse flow at high frequency (Stehr *et al.* 1996). Astle developed a theory to analyze the effect of gas compressibility and its use in a resonance-based micropump (Astle *et al.* 2007). Industry has also played an important role in the development of gas micropumps. Westinghouse developed a piezoelectric peristaltic gas micropump (Young *et al.* 1995), and Honeywell introduced a dual-membrane structure to minimize gas leakage and reported a high flow rate and efficient gas pumping (Cabuz *et al.* 2001). **Figure 2** shows the performance of past gas micropumps in terms of differential pressure generation and flow rate capabilities. It is noted that these parameters alone do not provide complete information on the performance of a particular micropump, because other performance metrics, such as size or power consumption that are not shown in the graph, are also important in many applications (**Table 1**).

This chapter will provide a systematic review of gas micropumps. Section 2.08.2 discusses the basic operation and structure of gas pumps and identifies important components, such as valves, that characterize gas micropumps. Section 2.08.3 provides a review of past gas micropumps based on four different pumping structures (valve types): passive, active, diffuser, and valveless pumps. Section 2.08.4 reviews gas micropumps based on their actuation techniques and fabrication technologies. Section 2.08.5 concludes the chapter with a design road map that summarizes all past efforts in developing gas micropumps based on some specific metrics and briefly discusses the remaining challenges and future directions in the development of gas micropumps.

2.08.2 Fundamental Characteristics

Gas micropumps have used different structures based on various working principles and have produced a wide range of performance specifications. This section discusses the general structure and important performance metrics, and design of gas micropumps.

2.08.2.1 General Pump Structure

A gas micropump can be simply described as a closed cavity with two fluidic paths, as illustrated in **Figure 3**. It consists of an inlet, an inlet control (usually an inlet valve), a main pumping cavity, an outlet control (outlet valve), and an outlet. The inlet is a passage through which gas is introduced into the main pumping cavity. Gas flow through the inlet into the main pumping cavity is often controlled by a valve. The inlet valve also minimizes flow loss in the unwanted reverse direction and plays an important role in defining pumping efficiency. The main pumping cavity is where gas goes through the pumping action to generate gas flow. In most cases, the pumping action involves a physical volume change of the cavity that is often performed by a compliant wall or membrane. In other cases, the pumping action involves a change in some properties of gas inside the cavity. For example, a change in temperature leads to thermal expansion in the volume, which in turn results in a higher pressure inside the cavity. By such pumping actions, gas is pumped out of the cavity and is directed to the outlet through the outlet valve. In the microdomain, the pumping action is generally limited due to the limited volume displacement or force.

Gas pumps operate based on the pressure change in the pumping cavity caused by gas compression or expansion. Because gases are compressible fluids, the inlet and outlet valves play an important role in regulating the pressure changes in gas pumps. The valves control the leak rate and limit the reverse flow through the pump, and adjust the valve timing that determines how much the gas is compressed before it is allowed to flow out of the main pumping chamber. Furthermore, the valves are an integral part of the pumping process because they can be used to modulate the phase between gas compression and flow cycles. In liquid pumps, where the liquid is incompressible, the primary role of the inlet and outlet valves is simply to minimize reverse flows in the

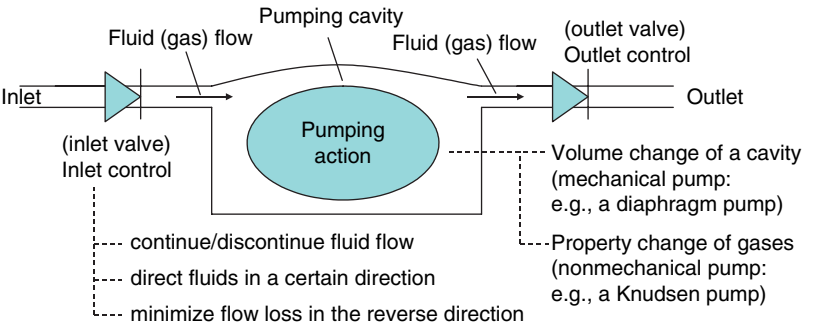

Figure 3 The general structure of a gas micropump. (Source: Kim H 2006 An integrated electrostatic peristaltic gas micropump with active microvalves. Ph.D. thesis, University of Michigan.)

pump. In these liquid pumps, the pumping process is mainly controlled by the pumping action in the cavity.

2.08.2.2 Performance Metrics

Before proceeding further, it is informative to define a set of performance metrics for gas micropumps. These metrics are useful in comparing different pumping mechanisms and fabrication technologies. The most important performance metrics are summarized below:

- Pressure differential
- Flow rate
- Pumping efficiency
- Size
- Power consumption
- Cost

Pressure differential is the pressure difference created between the inlet and the outlet and indicates how much pressure a micropump can work against. Flow rate is the volume (or mass) of gas that is transferred per unit time from the inlet to the outlet. Generally, pressure differential and flow rate are good indicators of the quality of the pump. Pumping efficiency is defined as the ratio between the ideal stroke volume per unit time in a diaphragm pump and the real flow rate. It indicates how much of the compressed gas is actually pumped out. In gas pumps, pumping efficiency is typically less than 20% because gases are compressible; in liquid pumps, most of the compressed liquid can be pumped out. Device size, power consumption, and cost are all obvious but important parameters and all need to be minimized. Among the five performance metrics, the three most critical metrics are (1) pressure differential, (2) flow rate, and (3) pumping efficiency. Figure 4 shows typical performance curves for a gas micropump illustrating these features.

2.08.2.2.1 Pressure differential

One distinctive feature of a gas micropump is the maximum pressure differential or the maximum back pressure it can produce. Figure 4 illustrates a typical performance curve of a gas pump, which shows that the pressure differential created by the pump decreases as the pump flow rate is increased. The maximum back pressure is the pressure at which the pump flow rate is zero. It indicates the maximum pressure that the micropump can work against while avoiding negative flow rates.

In a gas micropump, thermodynamic considerations show that the maximum pressure differential is determined by the compression ratio (CR) of the pump, as described in Figure 5. Here the compression ratio is defined as the change in volume divided by the original volume of the pumping chamber

$$\mathrm{CR} = \frac{\Delta p}{p_{\mathrm{in}}} = \frac{\Delta V}{V_1} \qquad [1]$$

where Δp is the maximum back pressure, p_{in} is the absolute inlet pressure, ΔV is the volume change of the pumping chamber, and V_1 is the pumping cavity volume. Here isothermal compression is assumed. For example, if the pump is compressed by 20% of its original volume, the pressure inside the chamber increases by 20%. Thus, a high pressure differential can be achieved by obtaining a high compression ratio, which could result from either by directly compressing the gas by moving a pumping membrane or by expanding the volume of the gas thermally in the pumping cavity. The pump by Rapp *et al.* (1994) employs a flexible polyimide membrane to create a large deflection to compress the

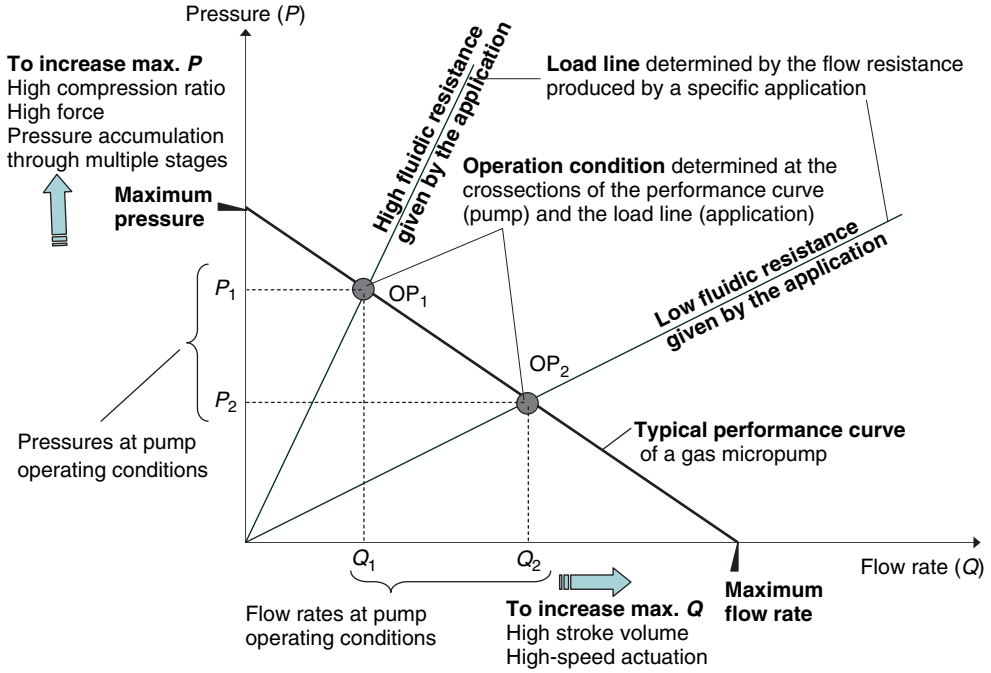

Figure 4 Typical performance curves including important performance metrics (pressure differential, flow rate, and operation modes) observed in a gas micropump.

pumping chamber with a high compression ratio, whereas the pump reported by Cabuz *et al.* (2001) produces only a small pressure differential of 2 kPa because it transfers gas without compression cycles. Other researchers have taken advantage of the high thermal expansion of gas to achieve higher effective compression ratio than typical diaphragm pumps (McNamara and Gianchandani 2005, Vargo *et al.* 1999, Young 1999). In practice, the compression ratio is lower than predicted by theory due to imperfect valves and leakage.

Pressure differential can be accumulated using multiple pumping chambers connected in series, each with a certain compression ratio. **Figure 5** shows the increase in pressure when multiple pumping chambers are used. If the compression ratio is large (CR = 0.5), the pressure differential in the last few stages is much larger than that in the first few stages. However, when the compression ratio is small (CR = 0.02), the differential pressures across all the stages are approximately equal (Astle *et al.* 2002, 2007). This feature of the multiple-chamber configuration is very attractive for MEMS micropumps because it allows to distribute the required pumping actuation force uniformly across many pumping chambers. A high overall pressure differential can be achieved while limiting the compression ratio and the pressure differential for each stage. For example, Kim *et al.* cascaded several micropumps and reported the first functional peristaltic configuration achieving a high pressure differential (>17 kPa) for the whole pump. The compression ratio for each stage in this pump was less than 5% (Kim *et al.* 2006a).

2.08.2.2.2 Flow rate

Another important feature of a gas micropump is the maximum gas flow rate, which represents the maximum volume/mass of gas transferred per unit time, often defined in standard cubic centimeter per minute (sccm) or milliliters per minute. As discussed earlier the maximum gas flow rate for a typical gas pump is achieved when the pressure differential is zero.

Thermodynamic analysis shows that the maximum gas flow rate, Q_{max}, is determined by the product of the volume displacement of a moving membrane, its frequency of oscillation, and the pumping efficiency, as shown in eqn [2], where ΔV indicates the volume displacement per stroke, f the actuation frequency, and α the pumping efficiency. In gas micropumps that do not utilize moving parts such as a moving membrane, flow rate is typically small because the effective volume displacement is small. In diaphragm-based gas micropumps, a high

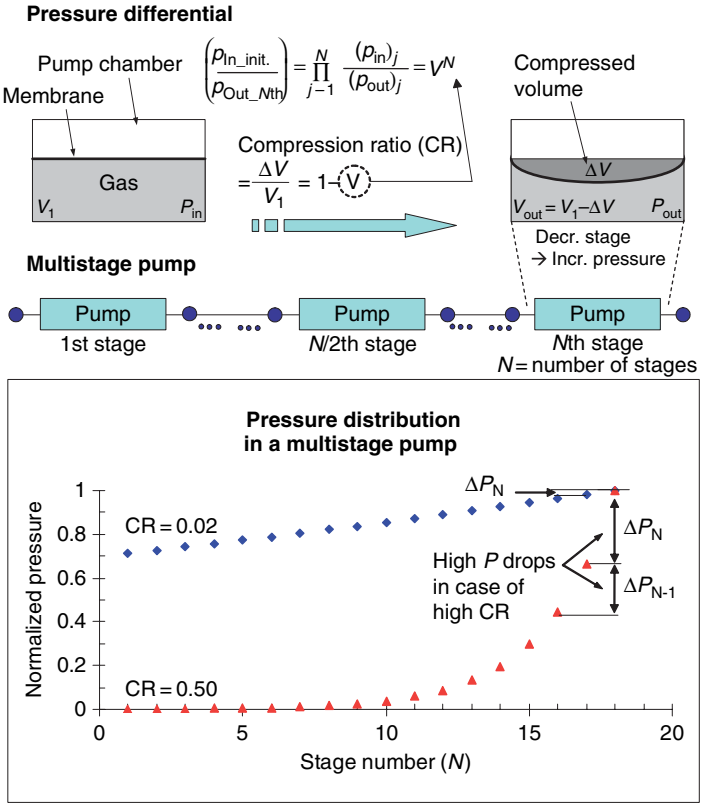

Figure 5 Pressure differential is determined by the compression ratio of each stage. In a multistage pump, the compression ratio is low for each stage, but a high total pressure differential is achieved. (Source: Astle A, Paige A, Bernal L P, Munfakh J, Kim H, Najafi K 2002 Analysis and design of multistage electrostatically-actuated micro vacuum pumps. *Proc. ASME Int. Mechanical Engineering Congress and Exposition (ASME '02).* New Orleans, LA, USA, IMECE 2002-39308.)

gas flow rate can be achieved by operating the micropump at a high frequency.

$$Q_{max} = \Delta V_{pump\_membrane} * f * \alpha \qquad [2]$$

Typically, the flow rate in gas pumps has a peak at a certain operating frequency, as shown in **Figure 6**,

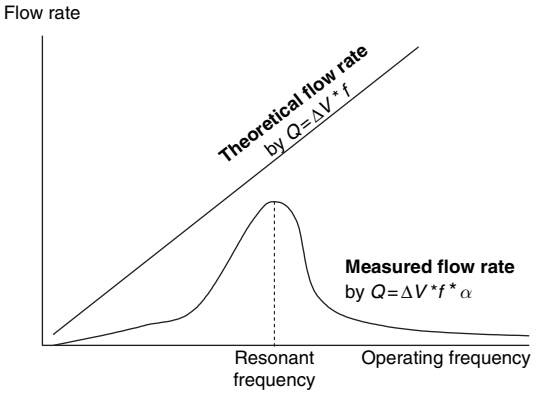

Figure 6 Output flow rate shows a resonance behavior caused by the compressibility of gas.

which is not often observed in liquid pumps. Flow rate increases with frequency and peaks at the resonant frequency, showing the maximum gas transfer, and then decreases as frequency increases despite the higher volume displacement per unit time. Such a resonant behavior in gas flow could be the result of gas dynamics resonance, structural resonance, or actuator resonance. Muller *et al.* provided an insightful analysis of gas flow resonance effects in the microdomain for a pumping membrane operated at a high frequency based on Helmholtz theory (Eckart 1948, Filippi *et al.* 1999, Muller *et al.* 2002, Rayleigh 1916). This analysis shows that an optimum frequency exists where gas transfer is maximized given by

$$f_o = \frac{a}{2\pi}\sqrt{\frac{A_t}{L_t V_c}} \qquad [3]$$

where a is the speed of sound, A_t the effective cross-sectional area, L_t the effective length of small flow passages in the pump, and V_c the pumping cavity

volume. At the optimum frequency, the flow rate is a maximum. At higher frequencies, the flow rate decreases rapidly because the phase shift between membrane compression and gas motion leads to inefficient pumping. It is worth noting that the fluidic resonance and the associated highest flow rate occur at a high frequency in micropumps due to their small dimensions, as shown in eqn [3].

The flow rate in a gas micropump can be improved by increasing the volume displacement (ΔV), operating frequency (f) of the pumping membrane, or pumping efficiency (α). Volume displacement is maximized by compressing gas by using high-force and large-deflection actuation mechanisms and by making the membrane using high-elongation flexible materials, such as polymers. The operating frequency, often the resonance frequency of the device, as shown in eqn [3], is optimized through proper scaling of the pump geometry. It follows that the high operation frequency compensates for the small volume displacement in the microdomain gas pumps. Pumping efficiency is enhanced by operating the gas pump at the fluidic resonance where gas volume transfer becomes highly efficient and by minimizing gas leakage by using appropriate microvalve structures, as explained in detail in the next section.

2.08.2.2.3 Pumping efficiency

Pumping efficiency (α) is defined as the ratio of the actual gas flow rate to the ideal gas flow rate. The ideal gas flow rate can be calculated from the product of stroke volume of the membrane and the operating frequency, as described earlier in eqn [2]. Pumping efficiency is typically lower than 20% even at fluidic resonance and is determined by gas leakage through imperfect microvalves and by the volume transfer efficiency of the compressible gas caused by the phase difference between the actual membrane deflection and microvalve timing.

Pumping efficiency is influenced by different microvalve designs used in micropumps: passive valves, diffuser valves, and active valves. Generally, pumping with passive valves provides the highest pumping efficiency, whereas diffuser-based micropumps provide the lowest pumping efficiency of less than a few percent. Active pumps provide a pumping efficiency between those of passive pumps and diffuser pumps. For example, a pumping efficiency of $\geq$10% can be estimated from the parameters reported in the passive valve pump reported by Rapp *et al.* (1994) where a flow rate of 0.086 sccm for a 5-mm diameter membrane was reported at an operating frequency of 5 Hz. The diffuser pump reported by Stehr *et al.* (1996) provided a measured flow rate of 8.0 sccm for a 5.3-mm membrane deflected over $\sim$20 μm at a frequency of 16.5 kHz, which results in an estimated efficiency of 1.44%. Active pumps have demonstrated pumping efficiencies of 2.2% and 9.8%, respectively, in the dual-membrane pump by Cabuz (Cabuz *et al.* 2001) and the 18-stage pump by Kim (Kim *et al.* 2006a). While Cabuz's dual-membrane pump provided a flow rate of 30 sccm using a 15-mm diameter membrane at an operation frequency of 100 Hz, Kim's pump demonstrated a flow rate of 4 sccm using a 2-mm square membrane at an operation frequency of 17.5 kHz.

2.08.3 Review of Pumping Techniques

Pumping techniques play an important role in producing the desired pressure differential, flow rate, and pumping efficiency. They include passive, diffuser, active, and valveless pumping. In this section, we briefly review several types of common pumping techniques used in micropumps, with an emphasis on their operation principle, basic structure, and advantages and disadvantages. **Figure 7** summarizes the types of micropumps and categorizes them by their pumping technique and actuation mechanism. This latter categorization will be discussed in more detail in Section 2.08.4.

2.08.3.1 Passive Pumping

Passive pumping is the most basic and traditional pumping technique that has been widely used in most macroscale pumps and some microscale pumps. It restricts gas flow passively by using the pressure changes in the pumping chamber. The pressure change is caused by the pumping action primarily through the membrane motion. Passive pumping typically uses a unidirectional normally-closed valve located over the inlet and the outlet paths. The valve remains closed until the pressure difference across it becomes sufficiently large to force it open and to allow gas to flow (Zengerle *et al.* 1995), as illustrated in **Figure 8**. Because the valve normally closes the flow path, passive pumping minimizes reverse flows or leakage, which results in a high pumping efficiency. It is notable that gas can be pumped only in one direction because the valve opens only in one direction. Passive pumping does not work at high frequencies because it is governed by the geometry and mechanical

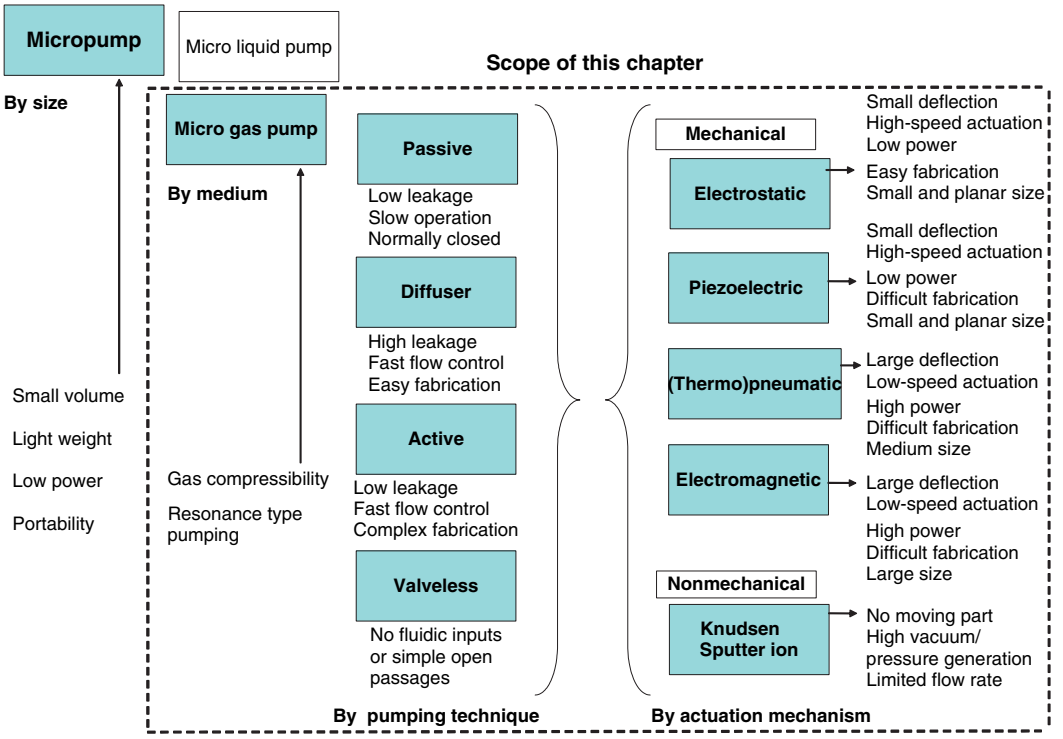

Figure 7 Gas micropumps categorized by pumping technique (valve types) and actuation mechanism. (Source: Kim H 2006 An integrated electrostatic peristaltic gas micropump with active microvalves. Ph.D. thesis, University of Michigan.)

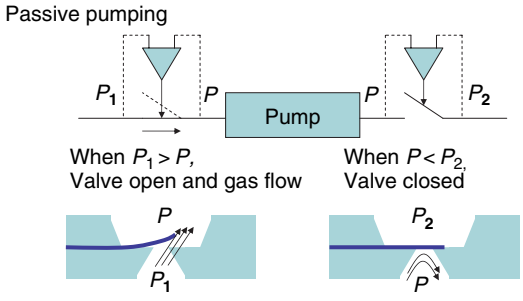

Figure 8 Simplified diagram for a passive pump (*top*) and operation principle of a passive valve (*bottom*).

characteristics of the valve, which limit the response time to the changes of pressure at high frequencies.

Passive pumps have used two different valve configurations: a single cantilever valve and a dual-diaphragm check valve, as shown in **Figure 9**. The cantilever valve, the most common valve used in passive pumping, is deflected to open or close the fluidic path depending on the pressure change across it. Using the cantilever valve Richter investigated the relationship between the required gas compression ratio to actuate the passive valve and the resultant flow rate from passive pumping (Richter *et al.* 1998). In his work, he formed a cantilever valve made of silicon under pumping cavities with various heights from the pumping membrane in piezoelectric and electrostatic gas micropumps. Passive pumping using the cantilever valve produced higher flow rates at higher compression ratio of above ~2% but some flow was observed when compression ratio was higher than 1.7%. Additionally, a gas flow rate of up to 1.4 sccm was measured when the compression ratio was 8.5% and the membrane was operating at 300 Hz. For efficient passive pumping, the cantilever valve has typically been used together with electromagnetic (Bohm *et al.* 1999) and thermopneumatic actuation (Bustgens *et al.* 1994, Schomburg *et al.* 1994). These actuation techniques produce a larger deflection and thus a higher compression than piezoelectric and electrostatic actuation. Bohm developed an electromagnetic pump that deflects the membrane using a high electromagnetic force of 0.11 N. To further facilitate the motion of the valve, the cantilever valve was made of a flexible polymer, Mylar, with a thickness of 7 μm. This passive pump produced a measured gas flow rate of 40 sccm, while consuming a power of 0.5 W (5 V and 100 mA) in a packaged volume of 10 mm × 10 mm × 10 mm.

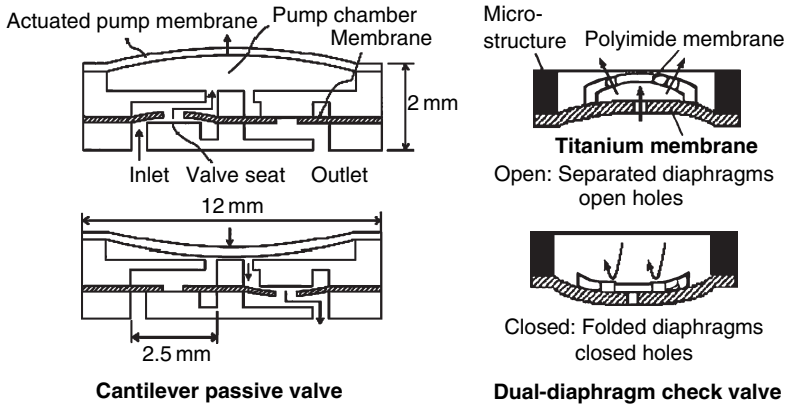

Figure 9 *Left*: Typical cantilever passive valve in an electromagnetic pump. (Source: Bohm S, Olthuis W, Bergveld P 1999 A plastic micropump constructed with conventional techniques and materials. *Sens. Actuators A* **77**, 223–8.) *Right*: Dual-diaphragm check valve. (Source: Rapp R, Schomburg W K, Maas D, Schulz J, Stark W 1994 LIGA micropump for gases and liquids. *Sens. Actuators A* **40**, 57–61.)

Bustgens used thermopneumatic actuation to achieve a high compression ratio of 10% by deflecting a 70-mm^2 membrane over a 100-μm distance. This thermopneumatic passive pump produced a flow rate of 0.044 sccm and a pressure of 3.8 kPa at a pumping efficiency of ~2.1%.

The dual-diaphragm check valve, the second valve design used in passive pumps, consisted of two separate membranes that were mounted on top of each other with valve holes staggered relative to each other, as shown in **Figure 9** (*right*). Because the top membrane was made of a flexible polyimide film, it could be moved above the bottom titanium membrane, thus opening the holes to allow gas flow when gas was pumped out of the pumping chamber in the forward direction. The top polyimide membrane collapsed down to the bottom titanium membrane closing the holes in the reverse direction, thus preventing any gas flow (Rapp *et al.* 1994). Rapp reported a high pumping efficiency of 14.6% using the passive check valve using a high-force (>50 kPa of external pressure) pneumatic action. This passive pumping produced a flow rate of 0.086 sccm and a pressure of 4.7 kPa at a frequency of 10 Hz. Rapp also reported that when the passive check valve is larger in dimension or thinner in thickness, it reacts in a more responsive way by allowing higher gas flows under some specific conditions.

2.08.3.2 Diffuser Pumping

Diffuser pumping was first used by Stemme (Stemme and Stemme 1993) in the microdomain to take advantage of the high-frequency stroke of a piezoelectric pumping membrane to provide a high stroke volume per unit time (high flow rate). It directs gas flow using different flow resistance in the forward and the reverse directions through tapered inlet and outlet passages, as shown in **Figure 10**. Its tapered passages work as a diffuser valve where the flow resistance is much smaller in the forward direction than in the reverse direction. The basic operation of the pump is quite straightforward, as illustrated in **Figure 11**. In the supply cycle, where gas is pumped into the chamber

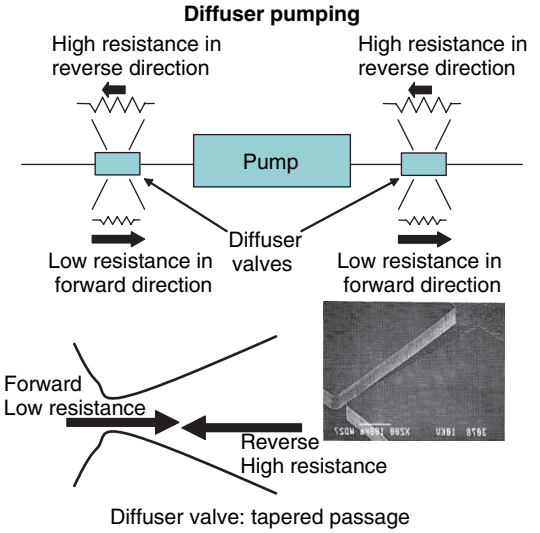

Figure 10 Basic structure of a diffuser pump (*top*) and operation principle of a diffuser valve and a SEM of a fabricated diffuser valve (*bottom*). (Source: Olsson A, Enoksson P, Stemme G, Stemme E 1996 An improved valve-less pump fabricated using deep reactive ion etching. *Proc. 9th Int. Conf. Micro Electro Mechanical Systems (MEMS '96)*, San Diego, CA, USA, pp. 479–84.)

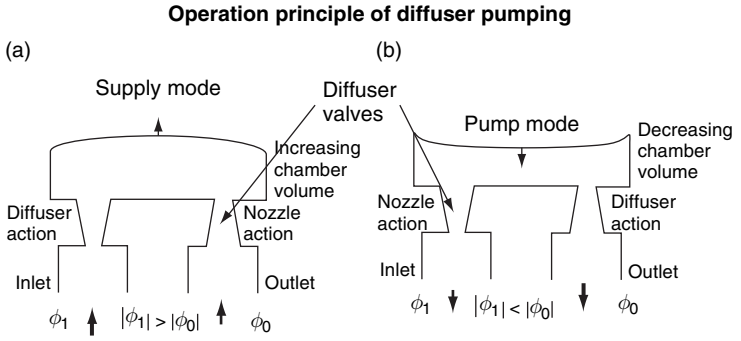

Figure 11 Operation principle of diffuser pump. (Source: Stemme E, Stemme G 1993 Valveless diffuser/nozzle-based fluid pump. *Sens. Actuators A* **A39(2)**, 159–67.)

from the inlet, the pumping membrane moves up, thus expanding the chamber volume. Because flow resistance is smaller from outside to inside for the inlet diffuser than for the outlet diffuser, more gas flows into the chamber from the inlet than through the outlet. In the pump cycle, the membrane is deflected downward, thus compressing the pumping chamber. Because flow resistance is smaller from inside to outside through the outlet diffuser than through the inlet diffuser, more gas is pumped out through the outlet than through the inlet. Therefore, during a complete pumping cycle, there is a net flow of gas from the inlet to the outlet. The theory for deriving pumping flow rate and pressure as well as efficiency has been developed by several investigators. While Stemme developed a theory for generic diffuser pumping for both gas and liquid, Olsson investigated a theory for gas pumping considering the compressibility of gases through an analogy to electrical circuits (Olsson *et al.* 1996). Olsson *et al.* derived a two-resonance frequency equation where the higher resonance frequency represents the operation frequency for gas pumping, whereas the lower resonance frequency represents that for liquid pumping.

Because diffuser pumping does not require moving valves, it responds to gas pressure changes at high frequency and allows high-speed pumping. In contrast, in passive pumping the frequency of operation is limited by the material property of the moving valve and its resonant frequency. Additionally, diffuser pumping does not suffer from wear or fatigue. However, diffuser pumping has a relatively low pumping efficiency of less than a few percent because it has flow losses in the unwanted direction through the always-open passages. It is notable that diffuser pumping has been realized only in piezoelectrically actuated pumps.

Stemme reported a flow rate of 35 sccm and a pressure of 2.3 kPa in his earliest diffuser pump, while Olsson generated a flow rate of 8 sccm and a pressure of 5 kPa in his diffuser pump designed only for gas pumping. Olsson's diffuser pump operated a 12-mm diameter membrane at a frequency of 11 kHz with a pumping efficiency of ~0.36%. Gerlach investigated a 3D diffuser (out-of-plane) and investigated the dynamic changes in fluid resistance at high flux velocity (Gerlach 1997, Gerlach and Wurmus 1995), as shown in **Figure 12**. The 3D diffuser pumping solved a

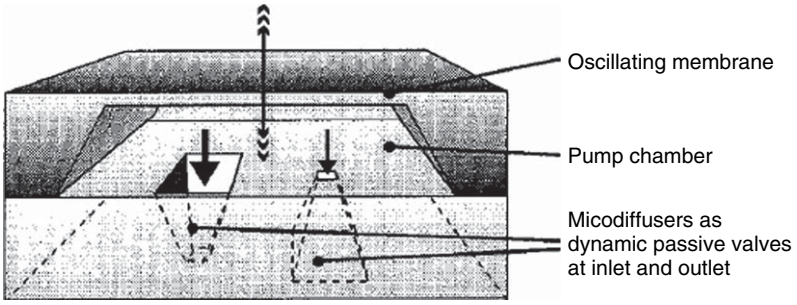

Figure 12 The structure of a 3D diffuser pump. (Source: Gerlach T 1997 Pumping gases by a silicon micro pump with dynamic passive valves. *Proc. Int. Conf. Solid-State Sensors and Actuators (Transducers '03)*, Chicago, IL, USA, pp. 357–60.)

limitation in the typical planar diffusers by providing a large area to obtain necessary flow rectification capability. Gerlach's theoretical model precisely predicted the passive pumping flow rate of 7.8 sccm from a microfabricated prototype within 4% error (measured flow rate 7.5 sccm), while it over-predicted the gas pressure differential of 4.8 kPa by 60% (measured pressure differential 2.8 kPa). The 3D diffuser pumps actuated a 11-mm diameter membrane at a frequency of 12.1 kHz and the resulting pumping efficiency was ~0.56%. Later, a high operation frequency of up to 33 kHz was reported by Wijngaart (Wijngaart *et al.* 2002). This diffuser pump actuated 4 mm × 4 mm membrane producing a flow rate of 0.545 sccm and a pressure of 5 kPa with a pumping efficiency of ~0.86%.

2.08.3.3 Active Pumping

Active pumping is intended to combine the advantages of passive and diffuser pumping by compressing gas in a confined chamber for high and efficient pressure rise and releasing it only during a certain period for minimized reverse flow. For such operation, active pumping controls individual valves independently using external signals, as shown in **Figure 13**. Active pumping controls the timing and the duration of opening and closing of microvalves to reduce flow leakage and operate the pump at high frequency, and create various output gas flows. Active pumping generally requires a more complex structure and fabrication process than other pumping techniques.

Active pumping has been pursued in various configurations, among which four commonly used configurations are discussed here: (1) single membrane pumping (valve and micropump (VAMP)) (Stehr *et al.* 1996), (2) dual-membrane pumping (Cabuz *et al.* 2001), (3) serial (peristaltic) pumping (Huang *et al.* 2006), and (4) independent valve pumping (Kim 2006).

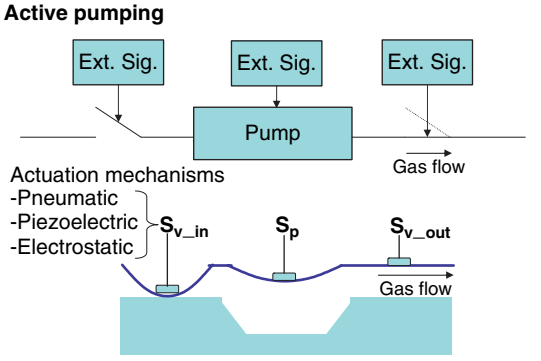

Figure 13 General structure of active pumping (*top*) and an active micropump (*bottom*).

Stehr introduced a single-membrane valve in a diffuser pump called VAMP to minimize unwanted flow losses while maintaining a high-frequency operation. VAMP uses one active membrane that works as a valve and as a pump membrane and another passive membrane that compresses the gas (**Figure 14**, *left*) (Stehr *et al.* 1996). In VAMP, gas is inhaled as the active membrane moves up and down, then it is compressed as the passive membrane moves with the delay from the motion of the active membrane, and finally it is pumped out through the outlet. The VAMP operated a 6-mm diameter membrane piezoelectrically at a frequency of 16.5 kHz producing a flow rate of 8 sccm. The pumping efficiency is estimated to be between 1.45% and 3.4%.

Another active pumping structure using dual membranes was reported by Cabuz *et al.* (2001). The pump consists of two polymer membranes (metallized Kapton) containing gas transfer holes to form a check valve. It transfers a certain volume of gas without compressing it by folding and moving the two membranes with closed gas transfer holes on each membrane (**Figure 14**, *right*). It completes a cycle by separating the dual membranes and returning them separately to their original position while letting gas leak through the open transfer holes. This dual-membrane pumping generated a gas flow rate of 30 sccm and a pressure of 2 kPa by actuating the two membranes electrostatically at a frequency of 100 Hz with an operation voltage of 200 V while consuming a power of 8 mW, which resulted in an efficiency of 1.85% (Cabuz *et al.* 2001). Note that, as explained in the earlier sections, pressure rise is produced by gas compression, and because the dual-membrane pump does not compress gas during its cycle, it produces a low pressure differential of only 2 kPa. Also note that the operation frequency of the dual-membrane pumping is relatively low (100 Hz).

Serial (peristaltic) pumps, which have been popular in liquid pumping, have also been used in active gas pumping. Serial pumps squeeze gas from one side to the other by moving membranes in a sequential order (**Figure 15**). Such sequential motion is especially useful in transferring incompressible fluids, such as liquid, while minimizing leakage. In compressible gas pumping, the minimization of dead volume between chambers or under the incompletely deflected membrane is critical to high-performance

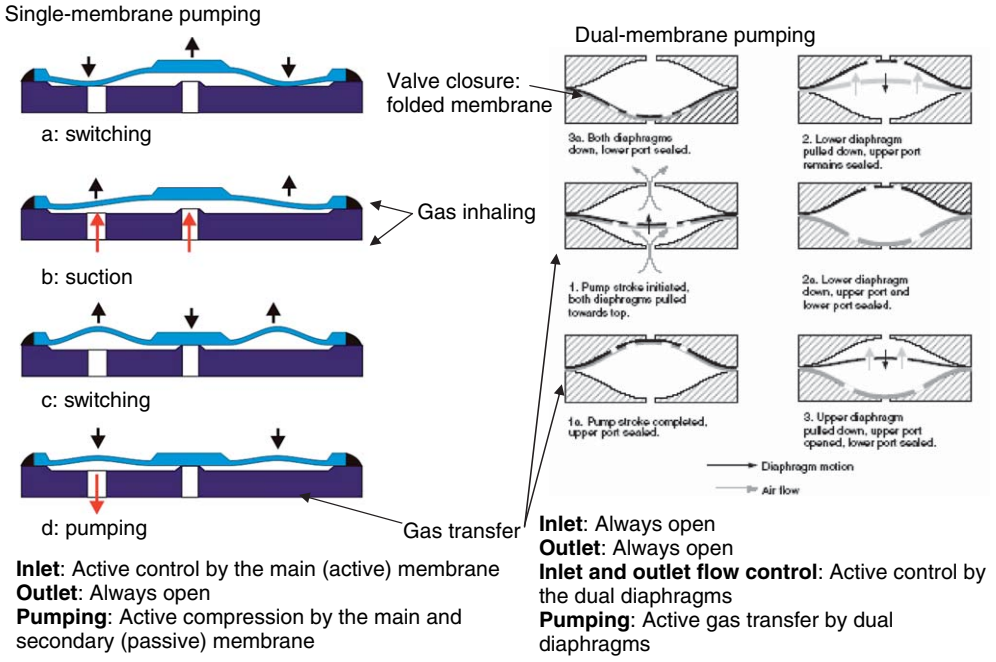

Figure 14 *Left*: Operation principle of active pumping using a single (active) membrane structure. Micro Electro Mechanical Systems (MEMS '06)*, Istanbul, Turkey, pp. 782–5.)

operation. Thus, serial pumping is used frequently with high compression actuation, such as thermo-pneumatic and pneumatic actuation. Serial pumping was first used in the first gas micropump by Judy in 1991 (Judy *et al.* 1991) where the successful sequential electrostatic actuation of three membranes was reported, but no measured gas flow was observed. This was most likely because the employed surface micromachining technology limited the maximum size (0.4 mm × 0.4 mm) of the pumping membrane, which resulted in a small volume displacement and a gas flow that was too small to be monitored. Measured flow rates of 0.086 and 0.108 sccm were reported in later pneumatic micropumps reported by Jeong (Jeong *et al.* 2006) and Huang (Huang *et al.* 2006), respectively. They formed three serially connected pumping chambers with polydimethylsiloxane (PDMS) membranes in each chamber. The

PDMS membranes were actuated pneumatically using 60 and 172 kPa of external pressure, respectively, at an operating frequency of 10 Hz. Huang's pump generated a pressure of 1.6 kPa. It is notable that the serial pumping process does not involve active gas compression in its cycle, thus resulting in a low pressure rise.

The most advanced configuration of active pumping requires independent valve and membrane operation to optimize pumping performance, as shown in **Figure 16** (Kim 2006). Individual microvalves (inlet and outlet) operate independently from each other and from the pump membrane. An inlet valve signal governs the movement of the inlet valves and the gas flow from top chambers to bottom chambers. An outlet valve signal governs the movement of the outlet valves and the gas flow from the bottom chambers to the top chambers. The timing of the two electrical signals for inlet and outlet microvalves can be adjusted to control micropump performance variables such as flow rate and pressure generation. Different from the pump membrane signal, each valve signal can be delayed or shortened within a cycle, allowing the pressure to build up longer or the flow to transfer faster. The flow rate and pressure rise of the pump are determined by the adjusted duration of the valve opening (gas transfer), as shown in **Figure 16**. When the opening duration is long (close to half the cycle: 0.5 T), the pump flow rate is maximized and the pressure rise is very small because most gases transfer without being confined and compressed. When the opening duration is short (e.g., 0.25 T), the duration of the membrane compression is increased so that the pressure increases and the flow rate decreases. Kim applied independent valve control to an 18-stage peristaltic gas micropump. This pump consists of 18 pumping stages and 19 microvalves, as shown in **Figure 17** (Kim *et al.* 2006a). By independently controlling the individual valves, they (1) proved that gas pressure could be controlled and accumulated using multiple stages by confining the gas during compression, (2) generated gas flows using fluidic resonance at a high frequency by controlling individual pumping membrane, and (3) demonstrated multiple pumping modes by modulating the duration of gas compression. Independent valve pumping produced a high pressure of 17.5 kPa and a high flow rate of 4.0 sccm with a high pumping efficiency of 9.8% while consuming 57 mW. Each membrane was 2 mm × 2 mm and was operated at a frequency of ~15 kHz. It also demonstrated pumping mode control (high flow rate or high pressure generation) by adjusting the valve opening duration.

2.08.3.4 Valveless Pumping

Valveless pumping uses a nonmechanical approach (no moving parts) to generate high pressure differential in the pumping chamber. In the macroscale, several mechanisms have been used, including thermal transpiration (Knudsen pump), ion capturing using chemisorption (electrostatic ion pump (ESP)), physisorption (sputter ion pump (SIP)), and particle implantation on pumping surfaces (getter pump). In

the microdomain, only Knudsen pumping and SIPs have been realized.

Thermal transpiration pumping was originally discovered by Knudsen in 1910 and was theoretically demonstrated in a microdomain Knudsen pump by Vargo and Young in 1999 (Vargo *et al.* 1999, Young 1999). A Knudsen pump consists of several cascaded chambers, each of which is connected to very tiny diameter channels, as shown in **Figure 18**. One side of a given chamber is connected to the adjoining chamber using several microchannels, whereas the other side of the chamber is connected to another adjoining chamber using fewer channels. Because the diameter of these channels is very small, gas flow (through these channels) is minimized because gas flows in these channels in the free molecular regime instead of the continuum regime and leads to a pressure rise proportional to the temperature difference, $\frac{P_H}{P_C} = \sqrt{\frac{T_H}{T_C}}$. A theoretical estimation suggested that a cavity would be evacuated from 152 torr (~20.26 kPa) down to 3 torr (~0.4 kPa) using 16 stages of cold and hot chambers at 300 and 600 K, respectively (Young 1999). Later, a microfabricated Knudsen pump was reported to have evacuated a cavity down to 0.46 atm (~45 kPa) using a power of only 80 mW (McNamara and Gianchandani 2005). This microfabricated version used a single stage of cold, hot, and cold chambers where hot chambers were heated up to 600°C. It is notable that the Knudsen pumps had only minimal flow rate (less than 0.010 sccm).

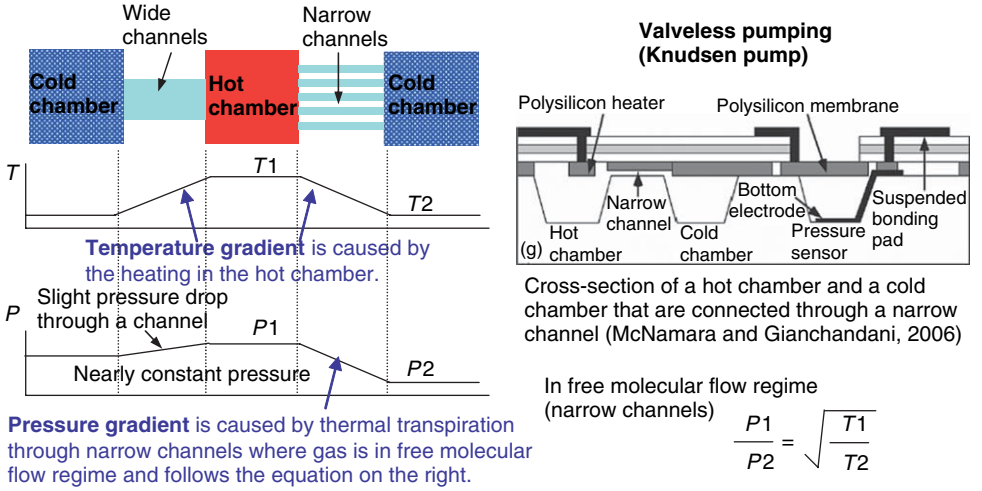

Figure 18 *Left*: Operation principle of a Knudsen pump where pressure differential is generated up by heating of gas. (Source: Kim H 2006 An integrated electrostatic peristaltic gas micropump with active microvalves. Ph.D. thesis, University of Michigan.) *Right*: Cross-sectional view of a Knudsen micropump. (Source: McNamara S, Gianchandani Y B 2005 On-chip vacuum generated by micromachined Knudsen pump. *J. Microelectromech. Syst.* **14(4)**, 741–6.)

An SIP was also recently realized in the micro-domain (Wright and Gianchandani 2006). This pump captures gas molecules and creates a vacuum in an isolated chamber. The developed micro SIP used a high voltage (500–1000 V) to create discharges in the closed chamber. The discharges, in turn, caused the sputtering of titanium, which was previously deposited in the chamber. The sputtered titanium would capture gas ions in the chamber, thus lowering the pressure inside. It was reported that a vacuum of 168 torr (~22.4 kPa) could be produced in a volume of 6.33 cc.

2.08.3.5 Summary and Comparison

Table 2 summarizes the performance and characteristics of these four pumping techniques. Passive pumps have low reverse flow and leakage but cannot operate at high frequencies. Diffuser pumps provide the simplest flow control method as well as easier fabrication. Although they can operate at high frequency, they suffer from reverse flow and leakage. Active pumps combine the advantages of passive and diffuser pumps, allowing gas pumping at high frequency with minimized reverse flow and leakage. Valveless pumps are easy to fabricate in the micro-scale, can generate high pressure differential, but produce very low flow rates.

2.08.4 Review of Pump Actuation Mechanisms

The selection of the actuation mechanism plays an important role in determining the performance of a gas micropump because it influences the speed, force, and deflection distance of the pumping membrane and the microvalve. Gas micropumps can be divided into two categories based on their actuation mechanism: mechanical and nonmechanical. Mechanical pumps need actuators to move the membrane and valves, whereas nonmechanical pumps rely on gas

heating or other interactions to pump gas or create a vacuum. Clearly, the actuator plays an important role in mechanical pumps, and so different actuation mechanisms and their use in gas micropumps will be reviewed in this section.

2.08.4.1 Electrostatic Actuation

Electrostatic actuation uses the attractive electrostatic force between two oppositely charged electrodes to move a membrane that is one of the two electrodes, as shown in **Figure 19**. When a voltage is applied across the electrodes, electrostatic actuation moves the membrane against the other fixed electrode, resulting in the compression of the space enclosed under the membrane. When the applied voltage is removed, the movable membrane returns to its original position because of its mechanical stiffness.

Electrostatic actuation is easy to apply in microdevices because of its compatible fabrication process, the ability to form small air gaps (10 μm), low power consumption, high speed operation, and easy electrical control of various components. An additional advantage is resistance to temperature and humidity changes. However, electrostatic actuation is susceptible to particulates, although particulates could be filtered using an inlet filter, and it requires high operation voltages (>80 V).

In the design of an electrostatic pump, the fundamental challenge lies in the fact that the maximum out-of-plane (vertical) deflection is physically limited by the small gap separation between the two electrodes. The small gap limits the maximum volume displacement and thus the flow rate. Increasing the gap separation would require much higher operating voltages. For most electrostatic micropumps with a membrane size less than 3 mm × 3 mm, a gap distance larger than 10 μm becomes impractical requiring high operating voltages (>500 V).

To overcome these issues (limited volume displacement and high operating voltage), several techniques have been developed, including the use of polymer membranes, dual drive electrodes, and curved electrodes (Cabuz *et al.* 2001, Kim *et al.* 2006a). A polymer membrane can deflect over a relatively large distance due to its high elongation rates; however, its use was limited in electrostatic gas micropumps due to its limited stiffness and restoring force. This can be overcome by using dual electrostatic electrodes to pull the compliant membrane in two directions as needed. The dual electrodes also increase (double) the volume displacement of the membrane. The curved electrode decreases the operating voltages compared with conventional flat electrodes (Legtenberg *et al.* 1997). It provides larger electrostatic forces, due to smaller air gap at the edges. Thus, the membrane is moved to a much larger vertical deflection with a lower voltage because a large force is created around the edges where the two electrodes are closest.

2.08.4.2 Piezoelectric Actuation

Piezoelectric actuation uses the deformation of piezoelectric materials, such as polyvinylidene fluoride (PVDF), zinc oxide (ZnO), and lead zirconate titanate (PZT), under an electric field, to vibrate a thin membrane that the materials are attached to, as shown in **Figure 20**. Piezoelectric actuation is the most commonly used actuation technique in both macro- and micropumps, thanks to its high-frequency operation,

(Source: Schabmueller C, Koch M, Mokhtari M, Evans A G R, Brunnschweiler A, Sehr H 2002 Self-aligning gas/liquid micropump. *J. Micromech. Microeng.* **12**, 420–4.)

precise motion control, low power consumption, high stroke force, and operation at cryogenic temperatures (Yang and Wiberg 2003). However, piezoelectric actuators have limited deflection and require high operating voltages (>80 V).

The main challenge in realizing a piezoelectric micropump is the fabrication process that is complex, is hard to integrate and often requires manual assembly (gluing), and is limited in making small-size actuators. Some researchers have developed precision machining technology. For example, Kamper combined injection molding with precision assembly to build a piezoelectric gas micropump with a 10-mm diameter pumping membrane and predicted a cost of only ~$3 (Kamper *et al.* 1998). In the pump, the piezoelectric material (piezoceramic disk) was attached to and used to actuate a 200-μm-thick polycarbonate diaphragm at a frequency of 100 Hz, resulting in a gas flow rate of 3.5 sccm and a pressure differential of 35 kPa.

Another challenge is the limited deflection of piezoelectric membrane actuators. Although a stack of piezoelectric layers can increase the deflection amplitude, it generally cannot operate at a higher frequency (>10 kHz). Thus, researchers have used a single piezoelectric layer for high-frequency operation (~33 kHz) while enlarging the size of the pumping membrane to obtain a high mass flow rate of 8 sccm (Olsson *et al.* 1997).

2.08.4.3 Thermopneumatic and Pneumatic Actuation

Thermopneumatic or pneumatic actuation uses the volume expansion of a material or a pumping membrane when heated or inflated by external sources, as shown in **Figure 21**. This volume expansion is often generated by microheaters built on top of the membrane in a thermopneumatic pump (Bustgens *et al.* 1994) and by external pressure in a pneumatic pump (Huang *et al.* 2006, Jeong *et al.* 2006, Rapp *et al.* 1994). Thermopneumatic actuation provides a large deflection and a high force but responds slowly (less than

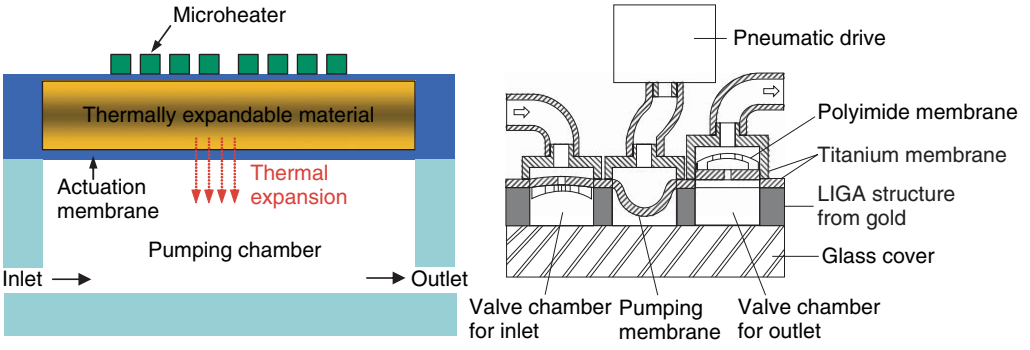

Figure 21 *Left*: Basic structure of a thermopneumatic micropump. LIGA, an acronym from German words for lithography, electroplating, and molding. 10 Hz, often decided by the thermal time constant), requires high power consumption, and produces a low flow rate (<0.1 sccm). Pneumatic micropumps use external gas pressures to actuate the membrane. By applying the external pressure (as high as >100 kPa), the membrane is forced into large deflection. The requirement for an external pressure source generally prevents the use of pneumatic pumps in integrated microsystems.

2.08.4.4 Electromagnetic Actuation

Electromagnetic actuation is based on an electromagnetic field generated by either magnets or microcoils. The most common structure for an electromagnetic actuator in the microdomain uses a permanent magnet above a fixed coil, as shown in **Figure 22** (*top*). Depending on the direction of current flow through the coil, the direction of the electromagnetic field changes, causing the magnets to realign along the field. Such realignment of magnets leads to the up and the down motion of the membrane. Another common structure for an electromagnetic actuator has a slightly modified design: a permanent magnet is placed inside a fixed coil, as shown in **Figure 22** (*bottom*). Depending on the direction of current flow in the coil, the magnet moves up or down, thus actuating the attached pumping membrane.

Electromagnetic actuation has not been used widely for gas pumping in the microscale because of the difficulty in scaling and integrating magnets. Instead, it has been applied in a few mesoscale micropumps (Bohm *et al.* 1999). Electromagnetic actuation does have some advantages in the microdomain because it provides bidirectional (push-pull) actuation, thus larger volume displacement, and can operate at high frequencies. It is functional over a relatively large displacement and is especially desirable for use in dust-filled environments or in conductive fluids. Because it requires a large current (more than a few amperes) to obtain a reasonable amount of force, it often consumes a large power of more than a few watts.

Bohm developed a mesoscale electromagnetic pump using the magnet-coil configuration in a volume of 11 mm × 11 mm × 11 mm, as shown in **Figure 22** (*bottom*). The membrane was attached to a small permanent magnet that was actuated using a 1000-turn coil formed around the pump package. When the permanent magnetic material (NdFeB, 5 mm diameter) moves out-of-plane by the Lorentz force generated from the current-carrying microcoils, the pumping membrane is deflected and compresses the pumping chamber. Such movements generated a large

force of 0.1 N and a large deflection of several hundred microns, which resulted in large flow rate of 50 sccm.

2.08.4.5 Summary and Comparison

Gas micropumps have employed different actuation techniques to pump compressible gases, as summarized in Table 3. The selection of the actuation mechanism depends on the goals of a particular application. Electrostatic actuation would be the best choice for low power consumption, high-speed operation, and easy microfabrication without material restrictions, despite its high operating voltage and susceptibility to particulates. Piezoelectric actuation offers low power consumption, high-speed operation, and operation at a low temperature, but it requires a more complex fabrication process. Thermopneumatic actuation provides high force and large deflection. Electromagnetic actuation offers high force and immunity to dust.

2.08.5 Conclusions and Discussion

Figure 23 shows the design road map of past gas micropumps and the design choices and performance achievements in the evolution of past gas micropumps. All of the key components and characteristics required in gas pumps are listed in the figure, along with the citation to the paper that addresses that requirement or utilizes a particular technology to achieve a specific requirement. Despite recent successes and remarkable improvements in performance, several challenges and issues remain for gas micropumps. The primary

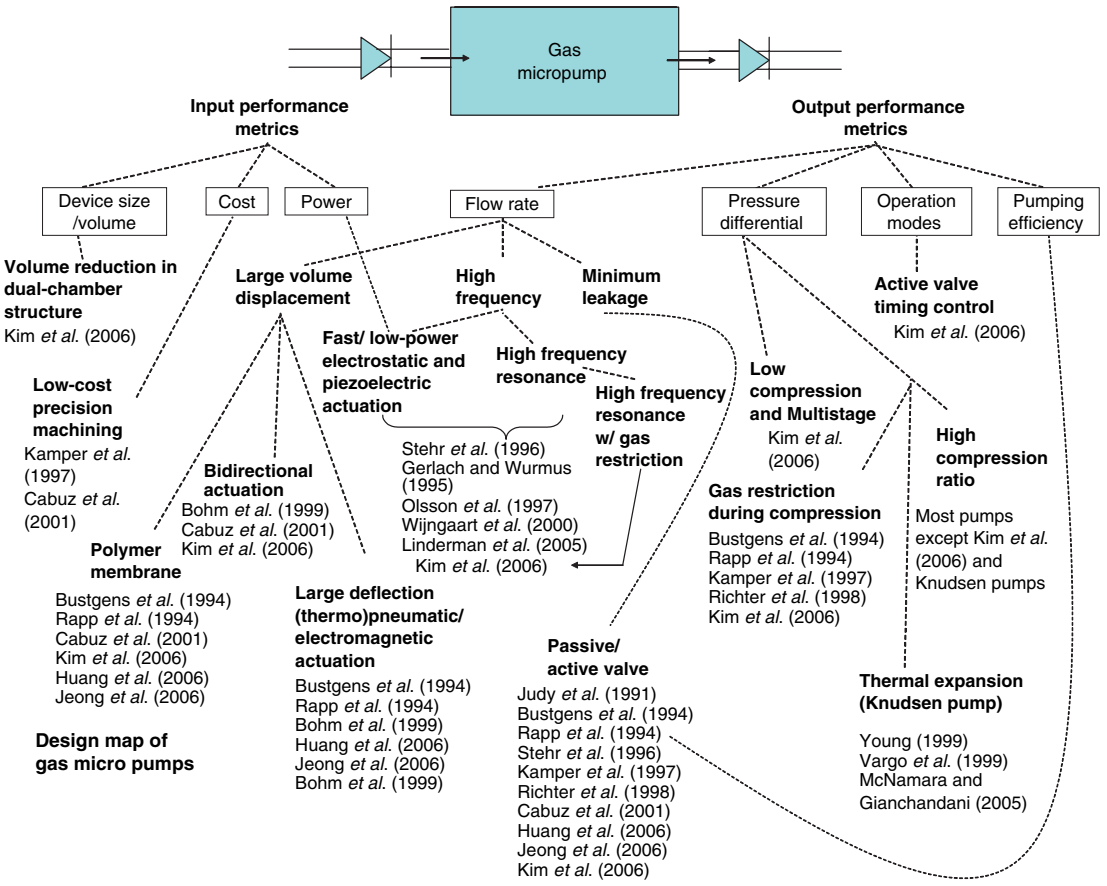

Figure 23 Design road map for gas micropumps.

shortcoming of most gas micropumps is the limited pressure difference they can produce. This is because of the limited actuation force and deflection amplitude, which are due to the limits imposed on actuators by the fabrication technology and size. Therefore, the major future developments in gas micropumps will involve better and more flexible fabrication processes.

The fabrication of a gas micropump requires three key manufacturing steps: (1) formation of a movable membrane, (2) formation of pumping chambers, and (3) assembly of the membrane and pumping chambers. The construction of thin membranes over a pumping chamber has been performed using three major manufacturing technologies: (1) bulk and surface micromachining and wafer bonding, (2) membrane transfer, and (3) mechanical machining of commercial thin films, as listed in **Table 4**. The fabrication processes used to form the pumping chambers has been relatively straightforward and include techniques such as conventional surface and bulk micromachining, injection (thermoplastic) molding, and LIGA (an acronym from German words for lithography, electroplating, and molding), as listed in **Table 5**. Gas micropumps also require suitable packaging and assembly techniques. Packaging has been typically performed by using wafer bonding and mechanical assembly, as listed in **Table 6**. Wafer bonding can be performed at either a high or a low temperature. Among high-temperature bonding techniques, anodic bonding has been frequently used. Low-temperature bonding approaches have used parylene, PDMS, and epoxy, all of which can be performed at less than 300°C. Mechanical assembly has used laser welding and screws. Although the mechanical assembly is appropriate in some applications for mass production, it does not really fit in manufacturing of gas micropumps due to the lack of precise alignment required in the microdomain.

Clearly, these and other fabrication technologies will continue to improve, and new techniques will be developed to further improve the performance of gas micropumps. Many emerging applications require further miniaturization of gas micropumps that can produce high pressure and high flow rate and consume low power (Agah *et al.* 2003, Chen *et al.* 2003,

Disadvantages	Relatively expensive process; requirements of high temperature, high voltage, or special surface quality in some cases				Noncompatibility with conventional microfabrication	

PDMS, polydimethylsiloxane.

Elwenspoek 1994, Lambertus *et al.* 2004, Lu *et al.* 2005, de Rooij 1995). Based on the rapid development of past gas micropumps over a short period of time, it is clear that these goals can and will be achieved in future micropumps.

Acknowledgments

The authors are grateful to Professor Peter Washabaugh and Dr. Aaron Astle for their valuable contributions to the development of the multistage peristaltic gas micropump reported in this chapter. The research on the multistage pump reported was supported by the Engineering Research Center Program of the National Science Foundation under Award Number EEC-9986866.

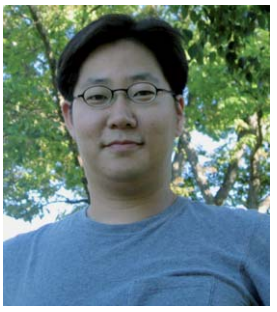
Biographies



Hanseup Kim received his BS degree in 1997 in Electrical Engineering from the Seoul National University, Korea, and his MS and Ph.D. degree in 2003 and 2006, respectively, in Electrical Engineering from the Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor. Since 2006, he has been employed as a research fellow in the Center for Wireless Integrated MicroSystems (WIMS), the Department of Electrical Engineering and Computer Science, University of Michigan. His research interests include MEMS, bio-microsystems, lab-on-a-chips, microfluidics, microsensors and actuators, micro/nano-fabrication, and polymer technology development.

He was the recipient of the 2001 Best Paper and the 1st place award in the 38th Student Design Contest of Design Automation Conference (DAC 2001) with four other coauthors. To date, he has authored and coauthored over 20 papers in refereed journals and conferences, held one patent, and served as a technical reviewer for the IEEE *Journal of Micro Electromechanical Systems (JMEMS)*, IEEE *Transactions on Electron Devices (TED)*, and *Sensors and Actuators Journal (SNA)*.

Khalil Najafi received his BS, MS, and Ph.D. degree in 1980, 1981, and 1986 respectively, all in Electrical Engineering from the University of Michigan, Ann Arbor. From 1986 to 1988 he was employed as a research fellow, from 1988 to 1990 as an assistant research scientist, from 1990 to 1993 as an assistant professor, from 1993 to 1998 as an associate professor, and since September 1998 as a professor in the Solid-State Electronics Laboratory, Department of Electrical Engineering and Computer Science, University of Michigan. His research interests include micromachining technologies, micromachined sensors, actuators, and MEMS; analog integrated circuits; implantable biomedical microsystems; micropackaging; and low-power wireless sensing/actuating systems.

Dr. Najafi was awarded a National Science Foundation Young Investigator Award from 1992 to 1997 and has been active in the field of solid-state sensors and actuators for more than 20 years. He has been involved in several conferences and workshops dealing with micro sensors, actuators, and microsystems, including the International Conference on Solid-State Sensors and Actuators, the Hilton-Head Solid-State Sensors and Actuators Workshop, and the IEEE/ASME Micro Electromechanical Systems (MEMS) Conference. Dr. Najafi has served as the editor for several journals, including the IEEE *Transaction on Electron Devices*, *Journal of Solid-State Circuits*, *Transactions on Biomedical Engineering*, and is currently an associate editor for the IEEE *Journal of Micro Electromechanical Systems*, the *Journal of Micromechanics and Microengineering*, Institute of Physics Publishing, and an editor for the *Journal of Sensors and Materials*. He is a Fellow of the IEEE and the AIBME.

Luis P. Bernal received an Aeronautical Engineering Degree in 1971 from the School of Aeronautics at the Polytechnical University of Madrid, Spain, and a Ph.D. in Aeronautics in 1981 from the California Institute of Technology. He also has a Doctorate in Aeronautical Engineering from the Polytechnic University of Madrid which he received in 1983. From 1981 to 1983, he was Member of Technical Staff in the Experimental Fluid Mechanics group at Jet Propulsion Laboratory (now JPL). In 1984 he joined the Faculty of Aerospace Engineering Department at the University of Michigan as an assistant professor, and he was promoted to his current position in 1992. Professor Bernal's research interests span a wide range of topics in Gas Dynamics, Aerodynamics, and Propulsion including the development of microsystems for propulsion, actuation, and flow control applications.

Dr. Bernal has served in numerous scientific panels from NSF, NASA, and AFOSR. He has served as a reviewer for the *Journal of Fluid Mechanics*, *Experiments in Fluids*, the *AIAA Journal*, and the *Journal of Fluids Engineering*, among other journals. He teaches undergraduate and graduate courses in Gas Dynamics and Aerodynamics.

2.09 Liquid Micropumps

Shuichi Shoji,[1] Hironobu Sato,[1] and Roland Zengerle[2], [1]Waseda University, Tokyo, Japan, [2]Department of Microsystems Engineering – IMTEK, University of Freiburg, Freiburg, Germany

Glossary

Electrohydrodynamic Fluid flow are generated by interaction of electric field and charges in the fluid. Due to the viscosity, liquid molecules around the charges are dragged; as a result, pumping force was induced. There are two types of EHD micropumps, EHD injection micropump, and traveling-wave EHD micropump.

Traveling wave Waves that are moving are called traveling waves. In the traveling-wave EHD micropumps, the electric field waves are produced by applying the phase-shifted rectangular pulses on the arrayed planar electrodes formed on the bottom of the pump channel.

Magnetohydrodynmic Lorentz force was utilized to pump the fluid. The pumping force was generated when an electric currents is applied across a channel filled with conducting solution in the presence of a perpendicular magnetic field. Both DC and AC current can be used to achieve the pumping of the liquid.

Electroosmosis The electric double layer was formed at the interface between the channel wall and the fluid. When a voltage is applied between two ends of the microchannel, the ions of the double layer are moved by the influence of the electric field. Due to the viscosity, the ions force the bulk liquid to move through the channel.

2.09.1 Introduction

Microfabrication technologies based on the photolithography have been applied to miniaturize the conventional chemical and biochemical analysis systems. A new field called micrototal analysis systems (μTAS) or lab-on-a-chip (LOC) started in the 1980s and was established in the 1990s. μTAS is now one of the most practical microelectromechanical systems (MEMS) for chemical and biochemical applications. μTAS realize very small necessary sample volume, fast response, and reduction of reagents, which are very useful for the chemical, biochemical, and medical analysis. Now this field includes chemical synthesis also, which enables efficient chemical reactions in the small-scale reactors. One of the features of μTAS is to use the efficiencies of microfluidics, which represents the behaviors of fluids in micrometer-scale channels (Gravenson *et al.* 1993). Since precise flow control on the order of microliters per minute or nanoliters per minute is required in this area, microflow devices of microvalves, micropumps, and microflow sensors play very important roles (Shoji 1998, Shoji and Esashi 1994). Many kinds of microfluidic devices have been developed over the past 20 years. Precision of the device structures has been improved with the remarkable progresses of MEMS technologies. The materials of the flow devices show large diversity. Si and glass were used in early stage while plastic is one of the trends considering the actual biochemical and medical applications. Simulation tools for microfluidic behaviors of these devices, computational fluid dynamics (CFD) software, are currently developing and are used to achieve the optimum design of the microflow devices.

Micropumps are one of the essential devices to realize precise flow control in microscale channels. Micropumps that have been developed so far are categorized into mechanical pumps and nonmechanical pumps. Mechanical micropumps have the electrically driven actuators and the mechanical structure to generate pressure and flow. Conventional pumps have been miniaturized with MEMS technologies using miniaturized or microfabricated actuators. Diaphragm-type and peristaltic-type micropumps have been developed from the early stage. On the other hand, various methods for pressure generation or flow generation that take into account the flow behaviors in microchannels have been proposed. Physical phenomena, for example, electrohydrodynamic (EHD) behavior, magnetohydrodynamic (MHD) behavior, electroosmosis, and chemical phenomena, for example, chemical and electrochemical gas generations, are used for the flow generations. Structures, principles, and features of various types of micropumps are categorized and described below.

2.09.2 Mechanical Pumps

Micropumps are one of the frontier MEMS devices and were fabricated by Si and glass micromachining in the 1980s (Shoji *et al.* 1989, Smits 1989, Van Lintel *et al.* 1988). Small disk-type and stack-type piezoelectric actuators were used to drive the pump in the early stage. Over the past 20 years, various actuators have been developed and used for driving the micropumps and active microvalves. Piezoelectric, electrostatic, electromagnetic, and thermopneumatic actuators are commonly used for these purposes. The performances of the mechanical micropump, such as maximum flow rate and output pressure, depend strongly on the features of the actuator. The actuator must be chosen considering the characteristics of the generated pressure, displacement and response time, etc. In fact, the sizes of the micropump are determined by the actuator used. Typical mechanical micropumps are a diaphragm-type (reciprocating) pump and a peristaltic-type pump (Shoji 1998). In the 1980s and the first half of the 1990s, micropumps consisting of Si and glass stacks were fabricated by anisotropic Si etching and anodic Si glass bonding. From the mid-1990s, plastic micropumps fabricated by molding have been developed considering the fabrication cost. First, the features of the actuators used for the micropump are described. Then structures and principles of the mechanical micropumps developed so far are reviewed.

2.09.2.1 Actuators

Many kinds of small-sized or microfabricated actuators have been developed since the MEMS field was established in the mid-1980s. The newly developed actuators have been applied for microflow control devices of microvalves and micropumps. Almost all possible principles of the actuators are proposed for these purposes. The performances of mechanical micropumps depend strongly on the features of the actuator. In fact, the sizes of these devices are determined by the actuator. The actuators used

for micropumps are classified into two categories: miniaturized conventional actuators and batch-fabricated microactuators (Shoji 1998, Shoji and Esashi 1994). Typical and realistic miniaturized actuators and batch-fabricated microactuators are described below.

2.09.2.1.1 Miniaturized conventional actuators

Miniaturized conventional actuators are fabricated individually and assembled on the microfabricated pump body. The pump body has to be designed considering the structure of the actuator. Assembly method of the actuator is one of the problems to obtain mass production of the micropumps or to realize the integration with other micro fluidic components.

2.09.2.1.1.(i) Piezoelectric Actuators using piezoelectric effect have been widely used from very early stage. Some kinds of miniaturized piezoelectric actuators of disk type (**Figure 1(a)**) and stack type (**Figure 1(b)**) are commercialized. Piezoelectric actuators consist of piezoelectric plates and metal electrodes. Since disk-type actuators are easily glued with resin to the pump body, the disk-type actuators of piezoelectric unimorph and piezoelectric bimorph are most commonly used. They show large deformation and fast response and reasonable generated pressure. High applied voltage of over 100 V, small necessary current, and small power consumption are the features of this actuator.

To generate large pressure, a stack structure of many piezoelectric plates and metal electrodes is proposed. Very large pressure greater than 3.5×10^5 hPa is obtained. The stroke to length of the actuator is smaller than 10^{-3}, which means that the stroke is on the order of 10 μm for the small-sized stack actuator.

2.09.2.1.1.(ii) Electromagnetic Electromagnetic actuator was realized with solenoid plunger as shown in **Figure 1(c)**. The force generated by this actuator depends on the applied current to the solenoid coil and on the number of turns. A large stroke is one of the advantages of this actuator. Since high current is necessary to generate high pressure, power consumption must be considered. A miniaturized electromagnetic actuator consists of a soft magnetic mass suspended by a spring beam, and an external coil is also fabricated. The generated pressure P_{em} is calculated using the following equation:

$$P_{em} = \frac{M_m}{A} \int \frac{\partial H_x}{\partial x}\, dx$$

where A, M_m, and H_x are the area, the magnetization of the mass, and the vertical component of the magnetic field produced by the external coil, respectively.

The other type of electromagnetic actuator is also possible as shown in **Figure 1(d)**. It consists of a deflectable membrane having a metal conductor and an external permanent magnet. A current applied to the conductor perpendicular to the magnetic field generates Lorentz force.

2.09.2.1.2 Batch-fabricated actuators

2.09.2.1.2.(i) Electrostatic Electrostatic actuators are the most widely used MEMS actuators. The principle of the electrostatic actuator is very simple as shown in **Figure 1(e)**. The electrostatically generated pressure P_{el} is calculated using the following equation:

$$P_{el} = 1/2\varepsilon_0 \left\{ \frac{V}{d_0 + \varepsilon_{0x} d_{0x}} \right\}^2$$

where ε_0, ε_{0x}, d_0, d_{0x}, and V are the dielectric constant of vacuum, relative dielectric constant of the isolating layer, gap between the electrode and isolating layer, the isolating layer thickness, and the applied voltage, respectively. The generated force is inversely proportional to the second power of the distance d_0. In actual uses, the displacement of the actuator is limited if large generated pressure is required.

2.09.2.1.2.(ii) Thermopneumatic A typical thermopneumatic actuator has a sealed pressure chamber and a movable diaphragm as shown in **Figure 1(f)**. The pressure chamber is filled with a gas or a liquid. The inner pressure is increased by electrical dissipation in a heater resistor incorporated into the chamber. Generated pressure P_{tp} in the chamber is given by the following equation:

$$P_{tp} = P_0 \exp\left(\frac{-L_0}{RT}\right)$$

where P_0, L_0, R, and T are the initial pressure, the latent heat of vaporization, a gas constant and the temperature, respectively. Large volume expansion in liquid phase to gas phase transfer is sometimes utilized for this actuator. The rising time of the actuator depends on the heat capacitance and the available power of the heater, while the relaxation time is determined by the

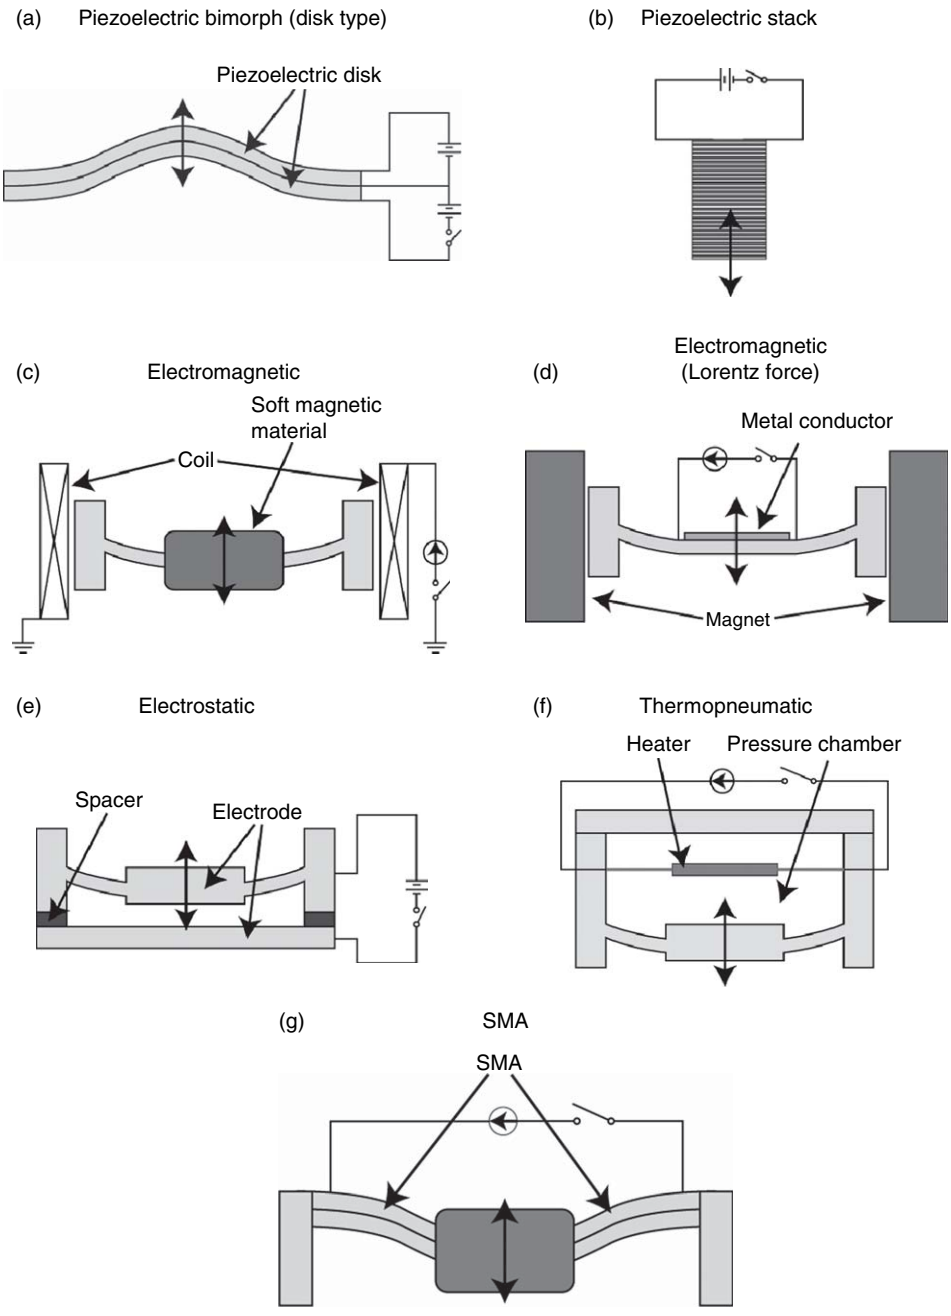


Figure 1 Schematic structure of the actuators used for the micropumps. (Source: Shoji S 1998 Topics in current chemistry. 194. Microsystem technology in chemistry and life science. In: Manz A, Becker H (eds.) *Fluids for Sensor Systems*. Springer-Verlag, Berlin, pp. 163–88.)

heat transfer to the outside. Since the small chamber volume has small heat capacitance, miniaturization of the actuator enables faster response time.

2.09.2.1.2.(iii) Shape memory alloy Small actuators are obtained by using a shape memory alloy (SMA) memorizing the expanded state. **Figure 1(g)** is the schematic of SMA actuators consisting of a SMA thin film and a diaphragm. The SMA regains its original shape when it is heated above the critical temperature. The critical temperature of Ti–Ni SMA is 40–50°C, which is achieved by the Joule

Table 1 Features of miniaturized conventional and batch-fabricated actuators

Actuators	*Pressure*	*Displacement*	*Response time*	*Figures*
Piezoelectric disk	Large	Medium	Fast	**Figure 1(a)**
Piezoelectric stack	Very large	Very small	Fast	**Figure 1(b)**
Electromagnetic (external coil)	Medium	Large	Medium	**Figure 1(c)**
Electromagnetic (Lorentz force)	Small	Medium	Medium	**Figure 1(d)**
Electrostatic	Very small	Very small	Very fast	**Figure 1(e)**
Thermopneumatic	Large	Large	Medium	**Figure 1(f)**
Shape memory alloy	Small	Large	Slow	**Figure 1(g)**

effect. To obtain a reasonable response time, a large current is required so that the power consumption should be considered. The general features of the miniaturized conventional actuators and the batch-fabricated microactuators are listed in **Table 1**.

2.09.2.2 Diaphragm-Type Micropump

2.09.2.2.1 Principle

The principle of the diaphragm-type micropump is illustrated in **Figure 2**. It consists of a thin flexible membrane (diaphragm) driven by an actuator, a pump chamber, and two passive check valves. Reciprocating the pump mode (**Figure 2(a)**) and the supply mode (**Figure 2(b)**) realizes continuous pumping. The actuator is driven by a sinusoidal wave or a rectangular wave AC voltage source. The displacement of the membrane (valuable volume, V_{dif}) causes the volume flow through the check valve (Zengerle *et al.* 1993). A pump chamber has a dead volume (V_{dead}). An important parameter that determines the pumping behavior is the ratio of dead volume to valuable volume (V_{dead}/V_{dif}) as shown in **Figure 3**. Small V_{dead}/V_{dif} realizes a self-priming and high bubble-tolerant micropump. The high-performance micropumps are obtained by minimizing the dead volume and maximizing the valuable volume (Kämper *et al.* 1998, Linnemann *et al.* 1998). The output pressure depends on the generated power of the actuator. The leakage flow of the check valve under reverse pressure applied state is also a factor for the maximum pump pressure. The flow rate of the micropump is determined by the frequency of the AC voltage as well as the displacement of the diaphragm. Usually, the flow rate is saturated with the increment of the frequency under the same applied voltage. The saturation is caused by not only the action of the diaphragm driven by the actuator but also the action of the check valve. If the dead volume exists around the check valve, it also affects the pumping behaviors.

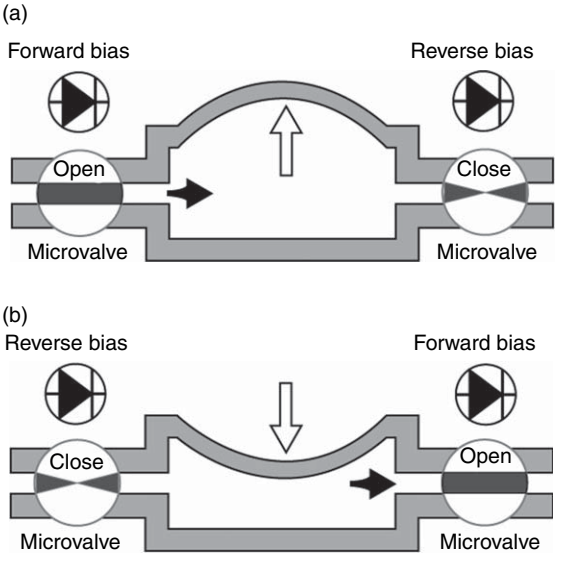

Figure 2 Principle of a diaphragm-type micropump.

2.09.2.2.2 Quasistatic simulation

One of the most common ways to model the performance of microdisplacement pumps with passive check valves is the quasistatic approach published in Zengerle *et al.* (1993) and Zengerle and Richter (1994). The approach allows the calculation of the

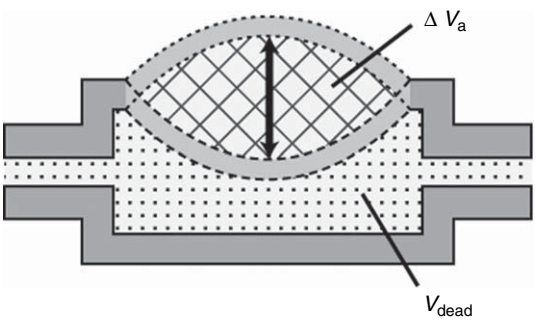

Figure 3 Schematic view of a variable pump chamber.

frequency dependence or back pressure dependence of the pump rate from the static characteristics of its building blocks, namely the displacement characteristics of the actuated membrane and the flow characteristics of the check valves. The result can be used not only to gain valuable insights for the optimization of microdisplacement pumps but also to understand malfunctions of it caused, e.g., by enclosed gas bubbles (Zengerle and Richter 1994) or potential leakage of the valves. A generalized schematic view of a microdisplacement pump with passive check vales is given in **Figure 4**. The pump consists of a flexible membrane, displaced periodically, and two passive check valves. When the membrane is displaced to enlarge the volume of the pump chamber, fluid is sucked in through the inlet valve. When the displacement decreases the chamber volume, fluid is pushed out through the outlet valve. The diode-like characteristics of the valves direct the fluid flow from the inlet to the outlet and prevent backflow.

At first sight these microdisplacement pumps just seem to be miniaturized versions of their macroscopic equivalents. Therefore, it is quite surprising that their characteristics in terms of frequency or back pressure–dependent pump rate are quite different. For instance, it is quite common for microdisplacement pumps that the pump rate is reduced linearly with the back pressure applied, a feature that is not known from macroscopic displacement pumps. The reason is that in most cases there is a strong coupling between the actuation of the displaced membrane, the back pressure between the outlet and the inlet, and the performance of the valves of miniaturized displacement pumps. Typically that is not the case in macroscopic pumps under standard operating conditions.

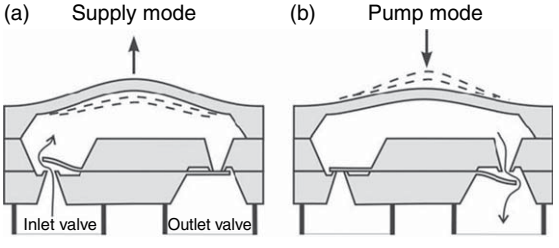

Figure 4 Schematic principle of a microdisplacement pump of the reciprocating type. (Source: Zengerle R, Richter M, Brosinger F, Richter A, Sandmaier H 1993 Performance simulation of microminiaturized membrane pumps. *7th Int. Conf. Solid-State Sensors and Actuators*, Yokohama, Japan, pp. 106–9; reproduced with permission.)

Many different designs of microdisplacement pumps have been presented so far. They differ in the actuation principle of the membrane and in the design of the valves. Flap valves (Oh and Ahn 2006), diaphragm valves (Shoji 1998), and even diffuser/nozzle elements without any movable parts (Oh and Ahn 2006) are typically used as flow-directing elements. On the other hand, piezoelectric actuation (Laser and Santiago 2004, Van Lintel *et al.* 1988), electrostatic actuation (Laser and Santiago 2004, Zengerle *et al.* 1992, 1995a, b), pneumatic actuation (Laser and Santiago 2004), or more specifically thermopneumatic actuation (Laser and Santiago 2004, van de Pol *et al.* 1989) have been reported among others (Laser and Santiago 2004) to drive the membrane. For generalization purpose, all actuation principles in the following are described by a characteristic actuation parameter A. The actuation parameter A could be a voltage, e.g., for electrostatic or piezoelectric actuation, a pressure in case of pneumatic or thermopneumatic actuation, or other physical parameters for other actuation principles. The parameter is in the next sections to deduce the dynamics of a microdisplacement pump in a generalized way.

2.09.2.2.2.(i) Calculation of the transient pressure within the pump chamber The time-dependent mass flow density $j(t)$ into the pump chamber is connected with the time-dependent change of the mass content $m(t)$ inside the pump chamber via the continuity in eqn [1].

$$-\int \vec{j}\,\vec{d}A = \frac{\mathrm{d}m}{\mathrm{d}t} \qquad [1]$$

The transient mass flow density can also be expressed as the difference in the rate of inlet and outlet flow through the check valves, which depend only on the time-dependent pressure drop $(p_1 - p(t))$ and $(p(t) - p_2)$ across the inlet and the outlet valve.

$$-\int \vec{j}\,\vec{d}A = \rho(\Phi_{\mathrm{inlet}}(p_1 - p(t)) - \Phi_{\mathrm{outlet}}(p(t) - p_2)) \qquad [2]$$

where p_1, p_2 are the hydrostatic pressure at the inlet/outlet side of the pump, $p(t)$ is the time-dependent hydrostatic pressure inside the pump chamber, and ρ is the density of the fluid.

On the right-hand side of eqn [1] the total mass m inside the pump chamber is given by the fluid mass m_{fluid} and the gas mass m_{gas}. If only fluid flows

through the valves and no degassing of the fluid occurs, time-dependent change in gas mass is zero.

$$\frac{\mathrm{d}m}{\mathrm{d}t} = \frac{\mathrm{d}m_{\mathrm{fluid}}}{\mathrm{d}t} + \frac{\mathrm{d}m_{\mathrm{gas}}}{\mathrm{d}t} = \frac{\mathrm{d}m_{\mathrm{fluid}}}{\mathrm{d}t} \qquad [3]$$

Therefore in the case of incompressible fluids, the time-dependent change in the fluid mass inside the pump chamber can be expressed as a corresponding volume change of the movable parts (**Figure 5**). This results in eqn [4]

$$\frac{\mathrm{d}m_{\mathrm{fluid}}}{\mathrm{d}t} = \rho\frac{d}{dt}(V_0 + V_{\mathrm{mem}}(p, A(t)) - V_{\mathrm{inlet}}(p, p_1) + V_{\mathrm{outlet}}(p, p_2) - V_{\mathrm{gas}}(p)) \qquad [4]$$

where V_0 is a constant offset, given by the total volume of the pump chamber, V_{inlet} and V_{outlet} are related with the volume displacements of the movable parts of the valves, and V_{gas} denotes the volume of a potential gas bubble inside the pump chamber.

The most important part of eqn [4] is given by the actuation characteristic $V_{\mathrm{mem}}(p, A)$ of the pump. $V_{\mathrm{mem}}(p, A)$ describes the coupling between the volume displacement of the membrane and the resulting pressure p inside the pump chamber at a specified actuation condition A. This function has to be derived considering a static equilibrium between all forces acting on the membrane (quasistatic model).

Combining eqns [4], [2], and [1] results in the basic differential equation [5] for the calculation of the time-dependent pressure p inside the pump chamber

$$\frac{\mathrm{d}p}{\mathrm{d}t} = \frac{(\Phi_{\mathrm{inlet}}(p_1 - p) - \Phi_{\mathrm{outlet}}(p - p_2)) - \frac{\partial V_{\mathrm{mem}}}{\partial A}\Big|_p \frac{\mathrm{d}A}{\mathrm{d}t}}{\frac{\partial V_{\mathrm{mem}}}{\partial p}\Big|_A - \frac{\mathrm{d}V_{\mathrm{inlet}}}{\mathrm{d}p} + \frac{\mathrm{d}V_{\mathrm{outlet}}}{\mathrm{d}p} - \frac{\mathrm{d}V_{\mathrm{gas}}}{\mathrm{d}p}} \qquad [5]$$

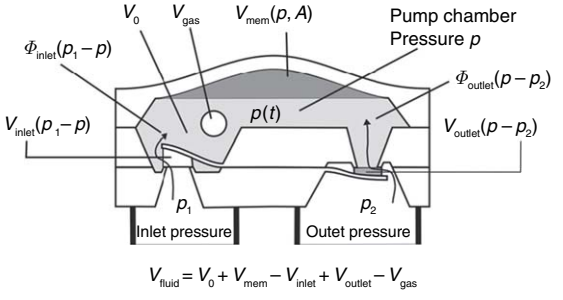

Figure 5 Schematic view of a microdisplacement pump. The characteristic functions of its building blocks are illustrated. (Source: Zengerle R, Richter M, Brosinger F, Richter A, Sandmaier H 1993 Performance simulation of microminiaturized membrane pumps. *7th Int. Conf. Solid-State Sensors and Actuators*, Yokohama, Japan, pp. 106–9; reproduced with permission.)

The characteristic functions of the basic building blocks of the microdisplacement pump can be determined by measurements or simulations, whichever is easier. For instance, the valve characteristics $\Phi_{\mathrm{inlet}}(p_1 - p)$, $\Phi_{\mathrm{outlet}}(p - p_2)$ typically can be easily determined by static measurements, whereas the actuation characteristic $V_{\mathrm{mem}}(p, A)$, the volume displacement of the valves $V_{\mathrm{inlet}}(p_1 - p)$, $V_{\mathrm{outlet}}(p - p_2)$, and the expansion characteristic of a gas bubble are more easily calculated.

The derivation of eqn [5] does not allow for compressibility and inertia of fluids. A more detailed study can be done within the same formalism, considering both effects that are important only at high pump frequencies (Zengerle and Richter 1994).

Eqn [5] can be easily integrated numerically by standard mathematical tools like Mathematica (Mathematica®, Wolfram Research, Inc., Champaign, IL). Once the transient pressure inside a pump chamber is known, all other physical parameters can be easily calculated. For instance, the transient volume flow through the inlet or the outlet valve can be easily calculated from the corresponding valve characteristics. The net flow can be calculated from the difference of outlet flow and inlet flow according to eqn [2], and the pumped fluid volume per pump stroke can be derived by numerical integration of the flow through one of the check valves during one pump cycle.

An alternative to the quasistatic approach presented before is the use of common tools for network analysis such as Saber (Saber®, Synopsys Inc., Mountain View, CA). In general, these tools are ideal to understand the behavior of complex machines that consist of several subsystems, which interact with each other. The basic principle behind network simulation is not very different from the quasistatic approach discussed before, but the differential equations should not be derived by hand. In contrast, a network model is set up just by combining different building blocks in a logical way. All the building blocks are represented by numerical functions – similar to the characteristic functions discussed before – and the network simulator creates the differential equation internally on its own. Once a model is implemented for a building block, it can be connected with other building blocks to build more complex systems. A fluidic channel, for instance, can be modeled as a flow resistance and a membrane can be modeled as a fluidic capacitance. All these building blocks can be connected to each other and the behavior of the total system (Litterst *et al.* 2005,

Voigt 2002) can be simulated without the need of the user to explicitly set up differential equations.

2.09.2.2.2.(ii) Example of a pneumatically actuated micropump The performance of the quasistatic approach can most easily be demonstrated by modeling the pneumatically operated microdisplacement pump depicted in **Figure 6**. In **Figure 7(a)** a typical measurement of the flow characteristic of passive check valves is depicted. The forward flow rate is much higher compared to the backward flow rate (leakage). The pressure-dependent volume displacement of the valve (**Figure 7(b)**) is assumed to be zero for the backward direction and increases linearly with the pressure difference in the forward direction.

The most important term is the actuation characteristic $V_{\text{mem}}(p, A)$. For pneumatic pumping the actuation parameter A is given by the time-dependent pneumatic pressure $p_a(t)$ used to actuate the membrane. In case of small displacements, the volume displacement of the membrane depends only on the net pressure $(p - p_a)$ acting on the membrane.

$$V_{\text{mem}}(p, A(t)) = C(p - p_a(t)) \qquad [6]$$

The constant factor C includes elastic and geometrical parameters of the membrane. **Figure 7(c)** shows the actuation characteristic for a pneumatically actuated microdisplacement pump, with a lateral membrane dimension of $5 \times 5\,\text{mm}^2$ and a thickness of a silicon membrane of 40 µm. An external system generates pressure pulses with an amplitude of $p_a^0 = -20\,000$ Pa (e.g., vacuum) relative to the atmosphere. Now, there are two characteristic functions specifying the equilibrium at the membrane. A first function when the external pressure is applied ($p_a(t) = p_a^0$) and a second function when it is not ($p_a(t) = 0$).

Starting at any pressure p_{start} within the pump chamber and at any volume displacement $V_{\text{mem}}(p_{\text{start}})$, $V_{\text{inlet}}(p_{\text{start}})$, ..., with a user-defined time characteristic of $p_a(t)$, solving the eqn [5] results in the time-dependent pump chamber pressure $p(t)$ after some cycles of iteration (**Figure 8**). As mentioned before, when $p(t)$ is known, other transient quantities can be easily derived.

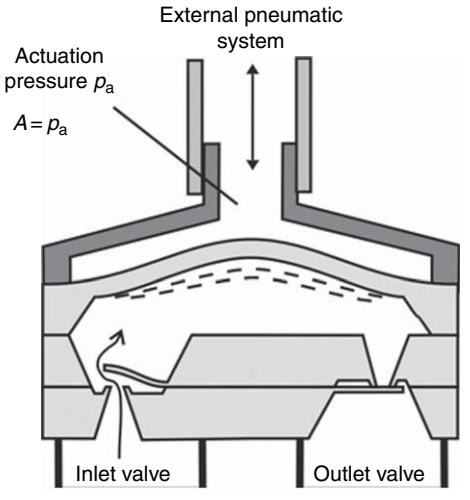

Figure 6 Schematic of a pneumatically actuated microdisplacement pump. The external pneumatic system applies a pneumatic pressure (here a vacuum) on top of the membrane. (Source: Zengerle R, Richter M, Brosinger F, Richter A, Sandmaier H 1993 Performance simulation of microminiaturized membrane pumps. *7th Int. Conf. Solid-State Sensors and Actuators*, Yokohama, Japan, pp. 106–9; reproduced with permission.)

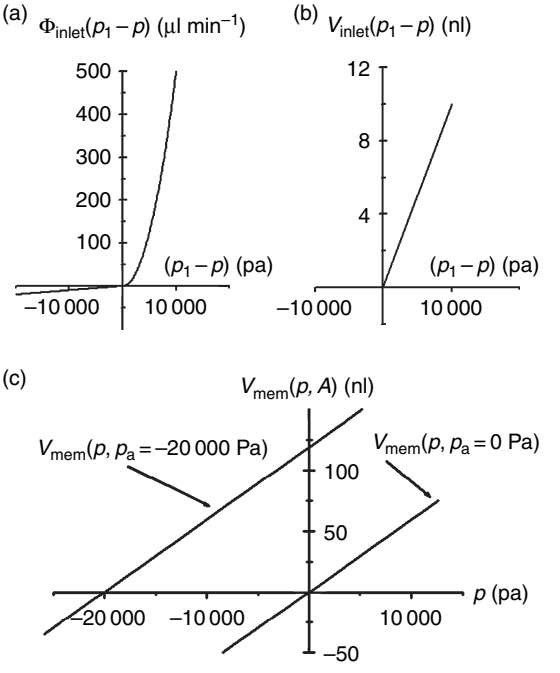

Figure 7 Characteristic functions of the building blocks of a pneumatically actuated microdisplacement pump: (a) characteristic function of the flow rate through a check valve; (b) characteristic function of the volume displacement of a check valve; (c) characteristic function of the actuated membrane. (Source: Zengerle R, Richter M, Brosinger F, Richter A, Sandmaier H 1993 Performance simulation of microminiaturized membrane pumps. *7th Int. Conf. Solid-State Sensors and Actuators*, Yokohama, Japan, pp. 106–9; reproduced with permission.)

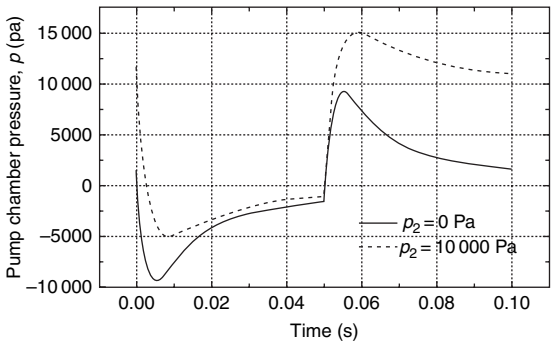

Figure 8 Transient simulation of the pump chamber pressure p for pneumatic actuation. (Source: Zengerle R, Richter M, Brosinger F, Richter A, Sandmaier H 1993 Performance simulation of microminiaturized membrane pumps. *7th Int. Conf. Solid-State Sensors and Actuators*, Yokohama, Japan, pp. 106–9; reproduced with permission.)

Very interesting features of the pump cycles can be understood by the diagram of the volume displacement of the membrane via the pump chamber pressure p (**Figure 9**). A parallelogram (graph a) encloses the possible states of the system. Two significant points of the parallelogram are given by the volume displacement of the nonactuated membrane at the outlet pressure p_2 ($V_{\mathrm{mem}}(p_2, A=0)$) and the volume displacement of the actuated membrane at the inlet pressure p_1 ($V_{\mathrm{mem}}(p_1, A=p_{\mathrm{a}}^0)$).

First, the easiest case (negligible volume displacement of the valves and low pump frequencies) is explained in order to demonstrate the usefulness of this diagram. The pump cycle starts with a nonactuated membrane at a point $V_{\mathrm{mem}}(p_2, A=0)$. Switching on the actuation pressure p_{a}^0 within a very short time constant ε ($\Delta V_{\mathrm{mem}}=0$) the system changes to a point α at the actuated membrane characteristic resulting in a low pressure $p=-p_{\mathrm{a}}^0$. Now the supply mode (**Figure 4(a)**) of the pump starts. Fluid flows through the inlet valve according to the valve characteristic until the inlet pressure p_1 is reached (point $V_{\mathrm{mem}}(p_1, A=p_{\mathrm{a}}^0)$). If the actuation is switched off the restoring force in the deflected membrane drives the system to a point β resulting in an overpressure in the pump chamber. The pump mode (**Figure 4(b)**) starts and fluid flows through the outlet valve until outlet pressure p_2 is reached (point $V_{\mathrm{mem}}(p_2, A=0)$). The volume stroke of the membrane within one cycle can be easily determined from the curve by $V_{\mathrm{mem}}(p_1, p_{\mathrm{a}}^0) - V_{\mathrm{mem}}(p_2, 0)$. From the same diagram the amplitudes of the pump chamber pressure p can also be extracted (see also **Figure 8**).

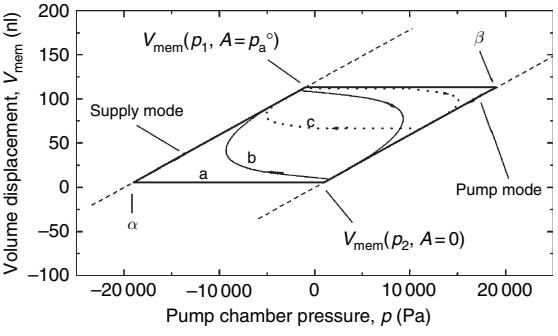

Figure 9 Pressure-dependent volume displacement curves of the pump membrane for pneumatic actuation: (a) simulation for negligible volume displacement of the valves, low pump frequencies and zero back pressure; (b) volume displacement of the valves are switched on; (c) back pressure increased to 10 000 Pa. (Source: Zengerle R, Richter M, Brosinger F, Richter A, Sandmaier H 1993 Performance simulation of microminiaturized membrane pumps. *7th Int. Conf. Solid-State Sensors and Actuators*, Yokohama, Japan, pp. 106–9; reproduced with permission.)

Operating with more realistic volume displacements of the valves and time-dependent actuation pressure $p_{\mathrm{a}}(t)$ the pump cycle is represented by the graph b, resulting especially in smaller amplitudes of pump chamber pressure p. By varying the outlet pressure p_2 from 0 to 10 000 Pa the trajectory changes to graph c, which corresponds to a displacement of the significant point $V_{\mathrm{mem}}(p_2, 0)$. It can easily be deduced from the diagram that the volume stroke of the membrane becomes smaller. This way the linear reduction of the volume stroke or the pump rate with the increasing back pressure, a feature that is quite common with micro displacement pumps, can be easily understood.

A comparison between the simulated- and the measured frequency-dependent pump rates is shown in **Figure 10**. The pneumatic actuated microdisplacement pump had outer dimensions of 7 mm × 7 mm × 2 mm, an active membrane with the lateral dimension of 4 mm × 4 mm, and a thickness of 30 µm. The pressure pulses for the actuation of the membrane had an amplitude of $p_{\mathrm{a}}^0 = -12\,500$ Pa (vacuum) relative to atmosphere. The time constant for switching on and off the external actuation pressure was in the range of 3 ms. Very good agreement between measurement and simulation is given for actuation frequencies of up to 50 Hz. At higher frequencies, the above-mentioned effects of inertia of the fluid have to be considered. The same formalism can also be applied to other actuation principles. For instance, it has been done for electrostatic actuation in Zengerle *et al.* (1993).

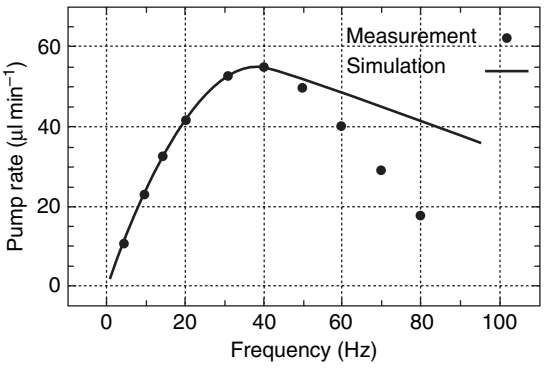

Figure 10 Pump rate of a pneumatically operated microdisplacement pump as a function of the driving frequency: simulation and experimental results according to Zengerle *et al.* (1993). At frequencies above 50 Hz, inertial effects result in divergences between experiments and simulation that are studied by an adopted model in more details in Zengerle and Richter (1994); reproduced with permission.

In summary, the performance of microdisplacement pumps can be easily derived by the quasistatic approach described here. All building blocks of the pumps (actuation unit, valves, etc.) are modeled by characteristic functions (V_{mem}, V_{inlet}, Φ_{inlet}, ...) measured or simulated in the case of its static equilibrium. The dynamic interaction of the building blocks can easily be modeled by applying the continuity equation [1]. A more detailed study as described here has to be used when the compressibility of the fluid plays a major role, and the inertia of the fluid cannot be neglected anymore at frequencies above 50 Hz (Zengerle and Richter 1994). In that case network simulation tools are more adequate to simulate the performance of microdisplacement pumps due to the fact that they are more user-friendly (Litterst *et al.* 2005, Voigt 2002).

2.09.2.2.3 Check valves

2.09.2.2.3.(i) Mechanical check valve Pumping behaviors are determined by the action of the check valves. Behavior of the check valve has symmetry of that of the semiconductor diode. Many types of mechanical check valves have been developed over the past 20 years. **Figure 11** illustrates the structure and the principle of the typical microcheck valves. Small leakage under reverse applied pressure and large reverse-to-forward flow resistance ratio are required for high-performance check valves. Tangent time during open-to-close or close-to-open is also an important factor of the check valve (Shoji 1998). **Figure 11(a)** shows a bulk Si ring-type check valve, which is the first developed check valve for the diaphragm micropump (Van Lintel *et al.* 1988). This check valve has a complicated structure and some dead volumes. The response time is slow compared to the other valves. A bulk Si cantilever is also used as the check valve (**Figure 11(d)**) (Zengerle *et al.* 1992, 1995a). A square ridge structure is formed under the cantilever. This valve shows high performance in large reverse-to-forward flow resistance ratio and short response time. This type of check valve has been widely used due to its simple structure and easy fabrication. A disk suspended by four thin beams made of poly-Si or SU-8 photoresist as shown in **Figure 11(b)** is the other commonly used microvalve (Shoji *et al.* 1989, Truong and Nguyen 2004). Stable actions by the symmetrical structure are the feature of this type. For simplifying the valve structure, polymer membrane–type check valve as shown in **Figure 11(e)** was developed (Rapp *et al.* 1994). This type of valve has been used for plastic micropumps. Reasonable performances are obtained even for its simple structure. Mass production is available with the plastic molding. A ball valve as shown in **Figure 11(c)** is also utilized as a check valve (Yamahata *et al.* 2004, 2005a). A freestanding ball is used as a plug for the through-hole. All micropumps using mechanical check valves are free from the backflows to the inlet and from the outlet. For high-pressure micropump, active microvalves are used instead of the passive check valve (Bodén *et al.* 2005). Thermopneumatic actuators are used for two active check valves and one valuable chamber. This type of micropump has similar flow behaviors to those of the peristaltic micropumps and are sometimes categorized to the peristaltic micropump.

2.09.2.2.3.(ii) Nonmechanical check valve A microfabricated nozzle/diffuser element is used instead of the mechanical check valves used in some micropumps (Stemme and Stemme 1993). A small-angle 2D flow channel, a diffuser (**Figure 12(a)**), and a large-angle 2D flow channel, a nozzle (**Figure 12(b)**), are used as the check valves. One-way motion of this valve is obtained only under the dynamic fluidic actuations. The geometry of these elements is simple but their flow behaviors are very complicated. Simulation studies are carried out for optimizing the nozzle/diffuser design (Olsson *et al.* 2000). Forward flow (small flow resistance) and reverse flow (large flow resistance) of the diffuser element and the nozzle element are opposite as

shown in **Figure 12**. For a microfabricated diffuser element, typical optimum angle realizing high performances is around 7°, while that of a nozzle element is around 70° for a microfabricated nozzle element.

Liquid viscosity change in narrow microchannels, orifices, caused by the temperature change is also used for the micropump (Matsumoto *et al.* 1999). Low viscosity at a high temperature generates larger flow as illustrated in **Figure 13**. Microheaters are formed at the inlet and outlet orifices of the variable pressure chamber of the micropump.

2.09.2.2.4 Examples of the diaphragm micropumps

2.09.2.2.4.(i) Piezoelectric actuators In practice, piezoelectric actuators have been used in high-performance micropumps. A disk-type piezoactuator is commonly used for its easy assembly and large displacement. Structures of the self-priming and bubble-tolerant micropumps using piezoelectric disk as the actuator are illustrated in **Figure 14** (Linnemann *et al.* 1998). The stacked silicon-type micropump (**Figure 14(a)**) has silicon cantilever-type check valves. A maximum pump rate of 1 ml min^{-1} under high-frequency operation of up to 200 Hz and a large back pressure of 1000 hPa are obtained. Its simple structure enables wafer-level batch fabrication, which is suitable for mass production (Richter *et al.* 2001). A low-cost plastic micropump (**Figure 14(b)**) is also realized by a molding process (Kämper *et al.* 1998). The use of polycarbonate membrane check valves enables a very simple structure, which is suitable for mass

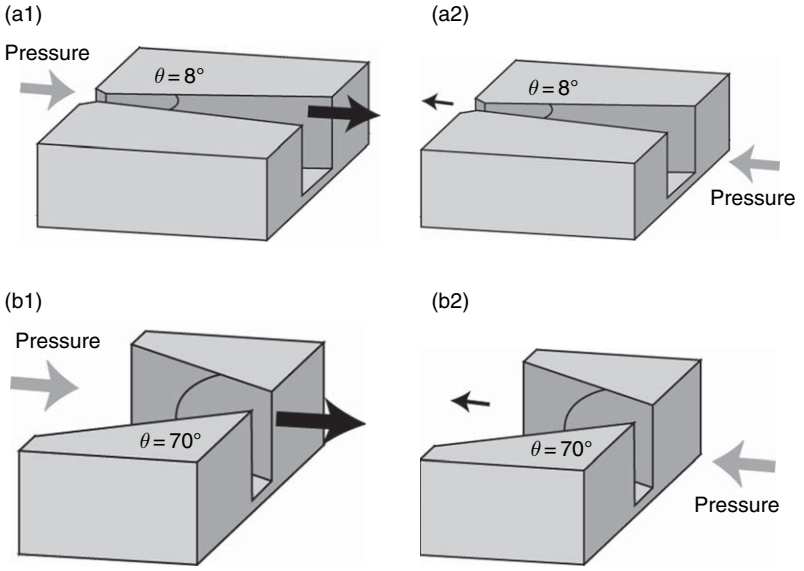

Figure 12 Flow behaviors of the diffuser element and the nozzle element. (Sources: Stemme E, Stemme G 1993 A novel piezoelectric valve-less fluid pump. *7th Int. Conf. Solid-State Sensors and Actuators*, Yokohama, Japan, pp. 110–13; Olsson A, Stemme G, Stemme E 2000 Numerical and experimental studies of flat-walled diffuser elements for valve-less micropumps. *Sens. Actuators A* **84**, 165–75.)

production. The ratio of low dead volume to valuable volume enables self-priming pumping. A maximum pump rate of 400 µl min^{-1} and a maximum back pressure of 2100 hPa are obtained at a driving frequency of 70 Hz. Fully polymeric micropumps use SU-8 disk-type check valves and poly(methyl methacrylate) PMMA stacks (Nguyen and Truong 2004). This structure was designed to achieve easy assembly and integration with other fluidic devices. Parylene dome diaphragm driven by a sputter-deposited piezoelectric ZnO film actuator is also applied to the micropump (Feng and Kim 2005). In this case, the piezoelectric actuator is fabricated by sputter deposition. Maximum output pressure of 120 Pa and maximum flow rate of 1 µl/min was obtained under driving frequency of 30 kHz.

Many types of valveless micropumps utilizing micro diffuser/nozzles have been developed. These types of micropumps using diffuser elements were fabricated by Si–glass micromachining and thermoplastic molding in the mid-1990s (Olsson *et al.* 1998, van der Wijngaart *et al.* 2000). A valveless structure prevents stacking of the particles observed at the mechanical check valve, and a double chamber–type micropump as shown in **Figure 15** was also reported. These micropumps use the 2D diffuser/nozzle structure. Precise numerical and experimental studies for these types of micropumps were reported (Olsson *et al.* 2000). A maximum back pressure of 160 hPa and a maximum pump rate of 1.2 ml min^{-1} were obtained. Truncated, pyramid through-holes realized by Si anisotropic wet etching are also used for the nozzle elements (Gerlach *et al.* 1995). These nozzle structures are easily fabricated by silicon anisotropic wet etching. The angle of the nozzle structure in this case is around 35.3°. A maximum pump rate of 1.5 ml min^{-1} is realized. A micropump consists of a screen-printed PZT actuator and these nozzle elements are fabricated (Schabmueller *et al.* 2002). A pump rate of 155 µl min^{-1} and a maximum back pressure of 10 hPa were obtained at a driving voltage of 600 V.

2.09.2.2.4.(ii) Thermopneumatic actuators

Thermo-pneumatic actuators are also commonly used in micropumps. Silicon and glass stacks having a hermetically sealed chamber with microheater and bulk were fabricated (Mathematica, Wolfram Research, Inc., Champaign, IL). Plastic micropumps using membrane-type check valves were also reported (Büstgens *et al.* 1994). A low-voltage and high-current power supply is required compared to the piezoelectric actuators. A maximum back pressure of 38 hPa and a maximum pump rate of 44 µl min^{-1} were realized under an average power consumption of 0.45 W. A high-performance stacked silicon micropump fabricated by sophisticated

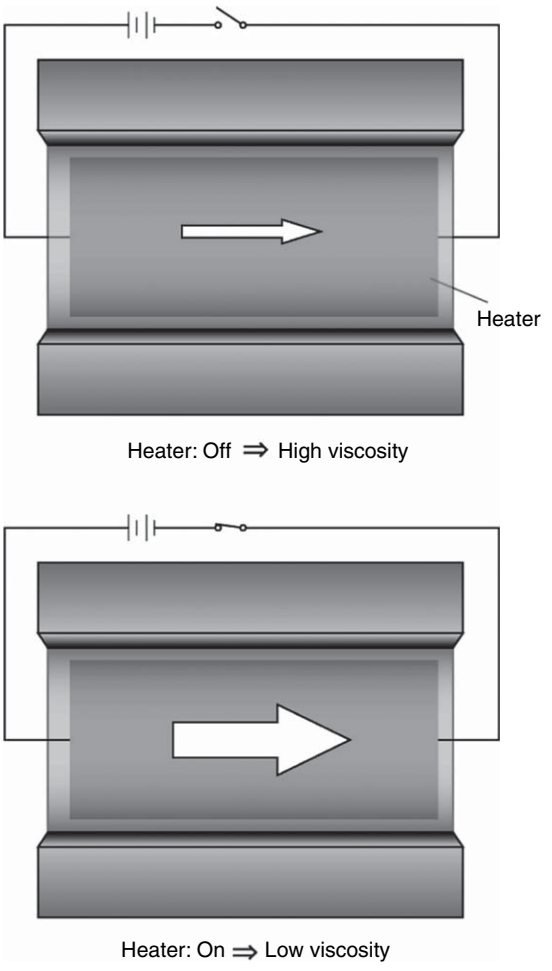

Figure 13 Flow behaviors of the thermal viscosity change. (Source: Matsumoto S, Klein A, Maeda R 1999 Development of bi-directional valve-less micropump for liquid. *12th IEEE Int. Conf. Micro Electro Mechanical Systems*, Orlando, FL, USA, pp. 141–6.)

MEMS processes with silicon-on-insulator (SOI) substrates was reported (Maillefer *et al.* 2001). Precisely fabricated microstructure enables linear and accurate pumping characteristics. The pumping behaviors are insensitive to external conditions. High reliability of this micropump will satisfy the specifications required in a drug delivery system. A valveless micropump using diffuser element was fabricated with a polydimethylsiloxane (PDMS) structure (Kim *et al.* 2005). A simple structure and a low-cost fabrication are suitable for disposable uses. Thermal bubble generation in a pump chamber was also used as the actuator (Tsai and Lin 2001). A diffuser–nozzle micropump was realized with very simple silicon–glass stack in this case.

2.09.2.2.4.(iii) Electromagnetic actuators

Micropumps using electromagnetic actuators were also reported. One is used as a NdFeB magnet and a miniaturized coil actuator. The membrane-type check valves are used (Böhm *et al.* 1999a). A maximum pump rate of 2 ml min^{-1} and a back pressure of 125 hPa were obtained. A micropump consists of a similar electromagnetic actuator, and two ball-type check valves were also developed (Yamahata *et al.* 2005a). Housing of the ball valve is fabricated by powder blasting. A maximum pump rate around 5 ml min^{-1} and a maximum back pressure about 280 hPa were demonstrated.

2.09.2.2.4.(iv) Other types of actuators

A stacked silicon micropump consists of an electrostatic actuator, and two cantilever-type check valves were fabricated (Zengerle *et al.* 1992). Low power consumption and high-frequency operation are the features of this micropump. A maximum pump rate of 350 µl min^{-1} and a maximum back pressure of 310 hPa were obtained under a driving voltage of 200 V at 400 Hz. A micropump using micromachined TiNi shape memory alloy as the actuator was also reported (Makino *et al.* 2001). Si cantilever-type check valves and Si stuck structure were utilized in this case. A low-power and low-voltage-driven micropump was realized by continuous electrowetting (CEW) as an actuator (Yun *et al.* 2002). The surface tension–induced motion of a mercury drop is used for the actuator. This pump has two diaphragms located at the pump inlet and outlet where two Cu cantilever-type check valves are positioned. Input and output pressures inside the micropump cavity are controlled by the CEW actuator. A pump rate of 70 µl min^{-1} pump rate with a driving voltage of 2.3 V and a power consumption of 170 µW was demonstrated. A back pressure of about 800 Pa at an applied voltage of 2.3 V was also obtained.

2.09.2.3 Peristaltic Micropumps

One of the oldest micropump is peristaltic-type pump, which consists of piezoelectric disk actuator microvalves connected in series (Smits 1989). **Figure 16** shows the structure and the actuation principle of the thermopneumatically driven micropump (Grosjean and Tai 1999). An Au microheater is incorporated in the sealed cavity with 100% liquid fill. Considering the trade-off between power consumption and response time, a kind of Fluorinert™ is chosen as the liquid (Grosjean *et al.* 1999). Pumping is

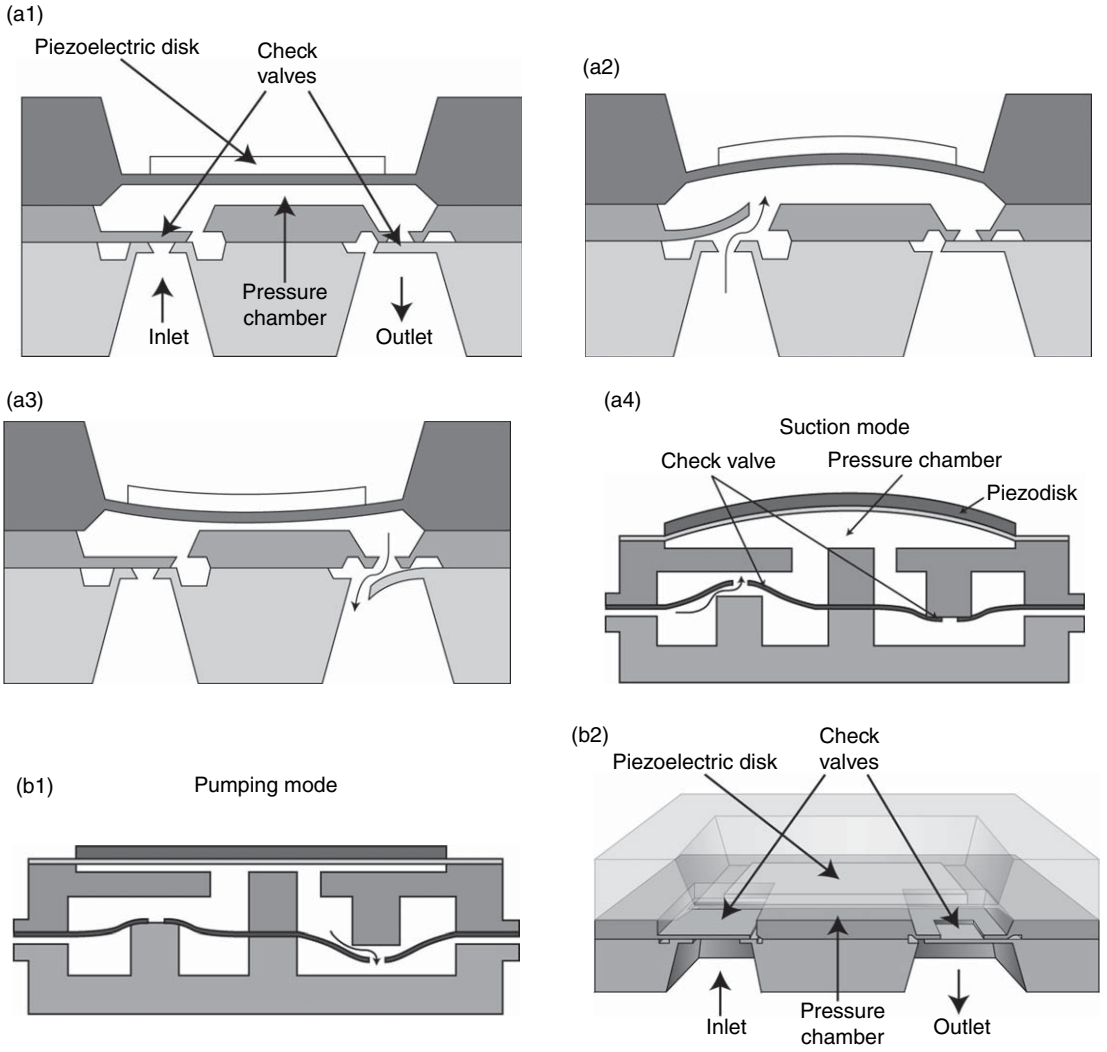

Figure 14 Typical diaphragm micropumps using a piezoelectric actuator. Figure 16 Peristaltic micropumps using thermopneumatic actuators. (Source: Grosjean C, Tai Y C 1999 A thermopneumatic peristaltic micropump. *10th Int. Conf. Solid-State Sensors and Actuators*, Sendai, Japan, Vol. 2, pp. 1776–9.)

performed by the phase-sifted sequential rectangular voltage. Since the pump has a symmetrical structure, bidirectional pumping is easily obtained. Self-priming operation with a flow rate of up to 6.3 µl min^{-1} was demonstrated with a power consumption of 291 mW. Three thermopneumatic actuator–type PDMS micropumps and three electrostatic actuator–type micropumps were developed (Jeong *et al.* 2005, Teymoori and Abbaspour-Sani 2005). These micropumps were designed for the disposable applications like drug delivery. A unique micropump using a magnetic field rotary pneumatic actuator was also proposed (Kim *et al.* 2006). For peristaltic actuation, magnetic fluids are generated in round-shaped channel by magnetic force. The magnetic force is applied by the stepping motor–controlled permanent magnet. Maximum pump rates of 2.8 µl min^{-1} at 4 rpm and 3.8 µl min^{-1} at 8 rpm were obtained.

2.09.2.4 Other Micropumps

A bidirectional micropump consisting of an active valve and an elastic buffer element driven by a piezoelectric actuator as shown in **Figure 17** was proposed (Zengerle *et al.* 1995a). Pumping directions are changed with the driving frequency. Gear pumps are one of the common pumping systems. Microgear pumps were fabricated by LIGA process and precision engineering (Döpper *et al.* 1997). In this case, an outside rotary motor is used to drive the gear. This type of micropump is useful to pump high-viscosity liquids.

2.09.3 Nonmechanical Micropumps

2.09.3.1 EHD Micropumps

In EHD pumping, fluid forces are generated by the interaction of electric fields and charges in the fluid. There are two types of the EHD micropumps: the high-voltage DC charge EHD injection micropump and the traveling wave–driven EHD micropump using induced charges in the bulk liquid.

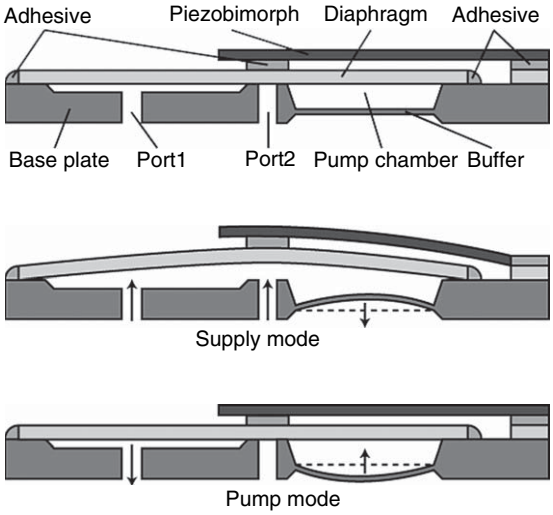

Figure 17 Bidirectional micropump using an active microvalve and an elastic buffer element. (Source: Zengerle R, Ulrich J, Kluge S, Richter M, Richter A 1995a Bidirectional silicon micropump. *Sens. Actuators* **A50**, 81–6.)

2.09.3.1.1 EHD injection micropumps

In EHD injection pumps, the motive force is the Coulomb force on ions injected from the electrode into the fluid by electrochemical reactions. EHD injection pumps required two facing electrodes (**Figure 18**) (Richter and Sandmaier 1990). High DC voltage was applied between the two electrodes. Due to the electrochemical reactions, the ions were injected from the emitter electrode into the liquid. The injected ions are subjected to an electric field and drag the liquid molecules around them. As a result, the bulk liquid motion is induced. Pumping is not restricted to DC fields. AC fields of relatively low frequencies are also available. Recently, 3D triangular bumps of solder were utilized as the electrode to maximize the electric field gradient (Darabi *et al.* 2002). The pumped fluids are restricted to the liquids of extremely low conductivity such as organic solvents.

2.09.3.1.2 Traveling wave micropumps

In traveling wave EHD pump, the free charges induced in the bulk liquid were utilized to drive the fluid. In general, application of the electric field in the presence of the gradient in permittivity or conductivity induces free charge in the volume of a material. The electrical conductivity of slightly conducting liquids depends on the temperature. Therefore, the gradient of the electrical conductivity can be achieved by developing the temperature gradient in the liquid. **Figure 19** illustrates an EHD pump using a temperature-induced conductivity gradient (Bart *et al.* 1990). The temperature and the conductivity gradient allow free charges to develop in the fluid volume. These charges are subjected to electric field and drag the liquid molecules around them. As a result, pumping force is induced. **Figure 20** shows the schematic diagram of the traveling wave EHD pump. The planer electrodes are formed on the bottom of the pump channel. The electric field waves are produced by applying the phase-shifted rectangular pulses on the electrodes. The temperature gradient is produced by the traveling wave itself and not by additional heating (Fuhr *et al.* 1992). In contrast to the EHD injection pump, relatively conductive liquids such as water solutions could be pumped.

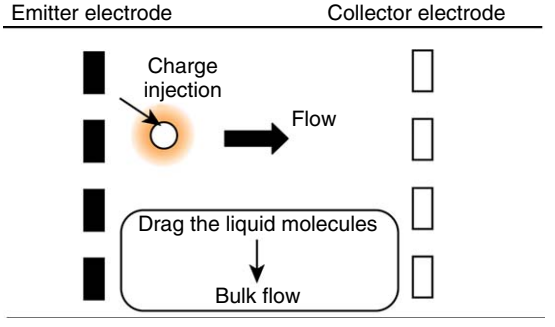

Figure 18 Schematic diagram of the electrohydrodynamic (EHD) injection pumps.

2.09.3.2 MHD Micropumps

The pumping mechanism for a MHD pump results from the Lorentz force. This force is produced when an electric current is applied across a channel filled with conducting solution in the presence of a perpendicular

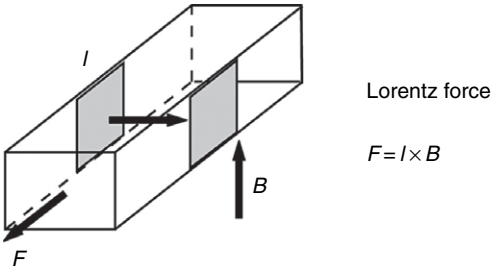

Figure 21 Vector diagram of a magnetohydrodynamic (MHD) pump. (Source: Lemoff A V, Lee A P 2000 An AC magnetohydrodynamic micropump. *Sens. Actuators B* **63**, 178–85.)

magnetic field. The Lorentz force is perpendicular to the current both in the channel and in the magnetic field. **Figure 21** shows the vector diagram of the MHD pump (Lemoff and Lee 2000). The flow along the length of the channel resulting from the Lorentz force has a profile similar to that of pressure-driven flow. Both the DC and the AC current can be utilized to produce the Lorentz force.

2.09.3.2.1 DC MHD micropumps

In a DC MHD micropump, a DC current is applied across the channel in the presence of a uniform magnetic field from a permanent magnet. Due to the electrolysis of the conductive solution, the bubble was generated and the pumping performance was degraded (Jang and Lee 2000). In order to avoid disruption of flow due to bubble formation, a frit-like structure was reported (Homsy *et al.* 2005). In this structure, the electrode and the pumping channel were separated; as a result, the high current density DC operation was achieved without gas bubble fluctuation.

2.09.3.2.2 AC MHD micropumps

In an AC MHD micropump, a sinusoidal electric current is applied across the microchannel in the presence of a perpendicular, synchronous AC magnetic field induced by an electromagnet (Lemoff and Lee 2000). Since the fields are synchronous, the Lorentz force point in the same direction throughout the cycle. The AC MHD micropump produces a continuous flow and is compatible with solutions containing biological samples. Using the high-frequency AC current, electrolysis of the conductive liquid can be avoided. As a result, the bubble formation and electrode degradation do not occur.

2.09.3.3 Ultrasonic Micropumps

Ultrasonic pumping is based on the phenomenon of acoustic streaming. When a flexural wave propagates in a thin membrane, a high-intensity acoustic field is generated in the fluid near the membrane. This acoustic field causes fluid flow in the direction of wave propagation (**Figure 22**) (Bradly *et al.* 1995). Since the acoustic field in the channel decays exponentially with the distance from the vibrating plate, the channel should be shallow to drive fluid flow efficiently. All kinds of liquids can be pumped. The flow rate can be controlled by changing the amplitude of the driving signal of the vibrating device. The flexural wave was generated by using a thin film of piezoelectric actuator (Miyazaki *et al.* 1991, Nguyen *et al.* 2000). **Figure 23** shows an acoustic streaming micropump using interdigitated transducers formed by a sputtered ZnO film and a sputtered aluminum electrode (Black *et al.* 1999, Moroney *et al.* 1991, Nguyen *et al.* 1999). The integration of the thermal flow sensor was also achieved (Nguyen *et al.* 2000).

2.09.3.4 Electrochemical Micropumps

In electrochemical micropumps, the gas bubble generated by the electrochemical reaction was utilized to drive the fluid flow. **Figure 24** shows the schematic diagram of an electrochemical micropump. The bidirectional pumping was achieved by using reversible chemical reactions. The precise regulation of the fluid flow can be realized by controlling the total amount of electric charge for the electrochemical reactions. The oxygen and hydrogen gas bubbles formed by the electrolysis reaction of water were used to drive the liquid (Böhm *et al.* 1999b). If the direction of the current is reversed, the previously produced gas can be reacted back to water and, as a

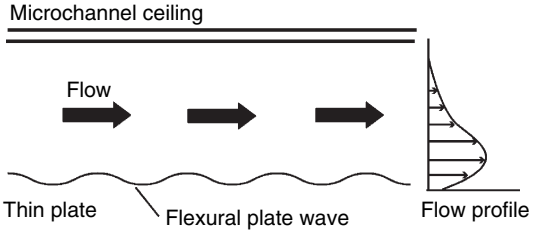

Figure 22 A flow channel with acoustic pumping. (Source: Bradly C E, Bustillo J M, White R M 1995 Flow measurements in a micromachined flow system with integrated acoustic pump. *Proceedings of the IEEE Ultrasonic Symposium*, pp. 505–10.)

result, the liquid can be drawn back. The redox reaction of an acidic electrolyte solution was used for pumping (Suzuki and Yoneyama 2003). The generation and shrinkage of the hydrogen bubble was utilized to realize the bidirectional pumping of the fluid. The chemical reaction was controlled using a potentiostat. Since the rates of growth and shrinkage were reproducible, accurate control of pumping was realized.

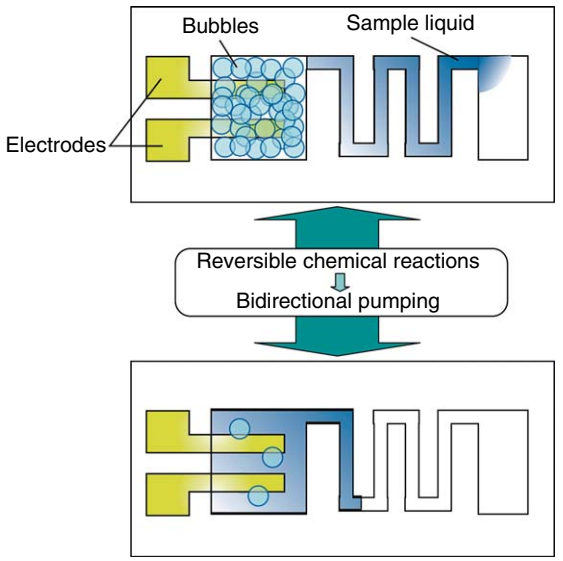

Figure 24 Schematic diagram of the electrochemical micropump. (Source: Böhm S, Olthuis W, Bergveld P 1999b An electrochemically actuated micropump for use in a push-pull microdialysis based *in-vivo* monitoring system. *10th Int. Conf. Solid-State Sensors and Actuators*, Sendai, Japan, Vol. 2, pp. 880–1.)

2.09.3.5 Other Nonmechanical Micropumps

2.09.3.5.1 Electroosmotic micropumps

Electroosmosis is one of the electrokinetic phenomena and is used as a precise liquid-handling technique. The electrical double layer at the interface between a channel wall and an electrolyte plays an important role to produce electroosmotic flow. When a voltage is applied between the two ends of the microchannel, the ions of the double layer are moved by the influence of the electric field. Due to the shear viscosity, the ions force the bulk liquid to move through the channel (**Figure 25**). The microchannel packed with the silica spheres (Takemori *et al.* 2005, Zeng *et al.* 2001) and closely spaced parallel plate microchannels (Chen and Santiago 2002) were utilized to achieve the high-pressure and high-flow-rate electroosmotic micropump.

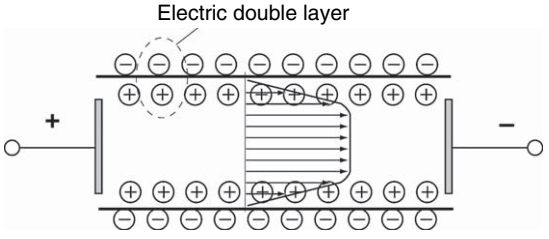

Figure 25 Pumping mechanism of electroosmotic flow. (Source: Zeng S, Chen C H, Mikkelsen J C, Santiago J G 2001 Fabrication and characterization of electroosmotic micropump. *Sens. Actuators B* **79**, 107–14.)

2.09.3.5.2 Chemical gas generating pumps

The chemically produced gases were used as the pressure source for liquid pumping. The generated gases drive the liquid sample from the reservoir to the outlet along the microchannel (**Figure 26**). The amount of chemical reactant affected working time and pumping volume. Because of its simple structure and easy fabrication, this type of micropump is suitable for the disposable lab-on-a chip and biomedical analysis systems. Nitrogen gas was generated by heat decomposition of azobis-isobutyronitrile (Hong *et al.* 2003). Oxygen gas was produced by the decomposition of hydrogen peroxide by catalyst (Choi *et al.* 2004).

2.09.4 Applications of the Micropumps

Recently, some micropumps designed to make their structure suitable for actual applications have been reported. Two types of micropumps using piezoelectric disk actuators for drug delivery applications were developed (Geipel *et al.* 2006, Maillefer *et al.* 1999). Stable and constant flow injection is required for this purpose. A plastic drug delivery system without using any electric power was developed (Su *et al.* 2002). An osmotic actuator consisting of a water semipermeable membrane, actuation membrane, and cavity was employed. A constant delivery rate of 0.2 $\mu l\,h^{-1}$ for 10 h is obtained. A diaphragm micropump with active microvalves driven by piezoelectric actuators was developed for an artificial sphincter system (Doll *et al.* 2005). A nozzle/diffuser micropump with an electromagnetic actuator was reported for cellomics applications (Yamahata *et al.* 2005b). The valveless structure is suitable for biological cell transport. High-pressure operation is required for actual use. For electronic applications, silicon electroosmotic micropump for integrated circuit thermal management was also reported (Laser *et al.* 2003).

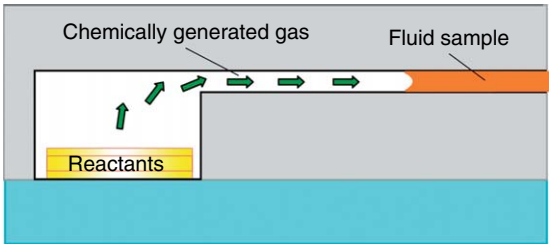

Figure 26 Schematic illustration of the chemically generated gas micropump. (Source: Hong C C, Murugesan S, Kim S, Beaucage G, Choi J W, Ahn C H 2003 A functional on-chip pressure generator using solid chemical propellant for disposable lab-on-a-chip. *IEEE 16th Int. Conf. Micro Electro Mechanical Systems*, Kyoto, Japan, pp. 16–19.)

2.09.5 Summary

Various types of micropumps have been developed over the past 20 years. Self-priming and bubble-tolerant micropumps are realized by optimizing the pump structure. Low-cost plastic micropumps are also developed considering biochemical and medical uses. Mass production of micropumps are already obtained by developing the large-scale batch fabrication technology. High-performance micropumps are realized by sophisticated silicon micromachining. Since the performances of the micropump are strongly dependent on the working principle, we have to choose the structure and the material of the micropump considering its application. To realize optimize design of the pump structure, CFD simulation is now getting a powerful tool. Integration and assembly with other fluidic elements are the most important issues to realize μTAS and LOC.

Biographies

Shuichi Shoji received his BS, MS, and Ph.D. degrees in Electronic Engineering from Tohoku University in 1979, 1981, and 1984, respectively. He was with the Tohoku University as a research associate and an associate professor from 1984 to 1992. In 1994 he moved to Waseda University as an associate professor and he is currently a professor in the Department of Electrical Engineering and Bioscience, and a Major in Nano-science and Nano-engineering, at Waseda University. His current interests are micro/nanodevices and systems for chemical/bio applications.

Hironobu Sato received his Ph.D. degree in Engineering from Waseda University, Tokyo, Japan, in 2005. From 2002 to 2005, he was a research associate at Waseda University. He is a postdoctoral fellow of the Japan Science and Technology Agency. He is interested in microfabrication and microfluidics.

Prof. Dr. Roland Zengerle is Head of the Laboratory for MEMS Applications at the Department of Microsystems Engineering (IMTEK) at the University of Freiburg, Germany. In addition he is a director at the Institute for Micro- and Information Technology of the Hahn-Schickard-Gesellschaft (HSG-IMIT). HSG-IMIT is a nonprofit organization supporting industries in the development of new products based on MEMS technologies.

The research of Dr Zengerle and his team of 50 engineers is focused on microfluidics and covers topics like miniaturized and autonomous dosage systems, implantable drug delivery systems, nanoliter and picoliter dispensing, lab-on-a-chip systems, thermal sensors, miniaturized fuel cells as well as micro- and nanofluidics simulation. Dr. Zengerle coauthored more than 200 technical publications and 25 patents. He is the European editor of the *Springer Journal of Microfluidics and Nanofluidics*. Dr. Zengerle serves on the International Steering Committee of the IEEE-MEMS Conference as well as on the Technical Program Committees of several other international conferences.

2.10.1 Introduction

Over the past decade, there has been a growing interest in developing microsystems or lab-on-a-chip (LOC) technologies for biodetection, biotechnology, chemical and biological reactors, or even medical, pharmaceutical, and environmental monitoring (Chow 2002, Dittrich and Manz 2006, Dittrich *et al.* 2006, Gardeniers and Van den Berg 2004, Huikko *et al.* 2003, Jain 2000, Jensen 1999, Langer 2000, Stone and

Kim 2001, Thilmany 2005, Verpoorte 2002). Lab on a chip is a minute chemical processing plant, where common laboratory procedures ranging from filtration and mixing to separation and detection are carried out in the palm of the hand. Resembling electronic circuit boards, these integrated devices contain a network of microconduits, which dilutes the sample, separates it into multiple channels for parallel analysis, mixes it with target-specific antibodies or reagents, propels it from one part of the device to the other, and detects the presence of chemical or biological targets. This whole set of precise and reproducible operations is done automatically in a single platform, which ultimately results in high data quality and reduces the need for trained personnel. This technology therefore has the potential of revolutionalizing various bioanalytical applications, the success of which is subjected to the possibility of handling tiny amounts of samples in a rapid and cheap manner, and analyzing them according to automatized and multiple parallel procedures that lead to minimal cross-contamination. To meet these very demanding criteria, a rapid mixing of the fluids to be manipulated must be achieved within the microsystems, as those used in biochemical analysis, drug delivery, point-of-care testing, crystallization, protein and RNA folding, and sequencing or synthesis of nucleic acids. Biological processes like cell activation, enzyme reactions, and protein folding often involve reactions that require mixing of various reagents and chemicals for initiation. In the case of large molecules, although the characteristic lengths associated with microdevices are small – typically on the order of 100 μm – diffusion alone does not allow sufficiently fast mixing. For example, at room temperature, the diffusion coefficient of myosin in water is about $10^{-11}\,m^2\,s^{-1}$, and the time constant for the diffusion along a length of 100 μm is thus intolerably large, i.e., about 10^3 s. Therefore, mixing several fluids in chambers or channels at the micrometer scale is not as easy as it might seem at first sight. Since the Reynolds numbers of flows in microdevices are usually very small (i.e., $Re \sim O(1)$), the flows are laminar and mixing enhancement cannot be reached by making use of turbulence-like flow patterns. **Figure 1** depicts the multifluid laminar flow scheme that is typically encountered in microfluidic channels (Stone and Kim 2001). Various streams colored with different dyes are brought together through Y-junctions. Parallel, side-by-side, laminar flow pattern is formed with diffusion that facilitates only very slow mixing process. In order to achieve reasonable speed and yield of chemical reactions and bioassays, micromixers must be necessarily integrated into the chips.

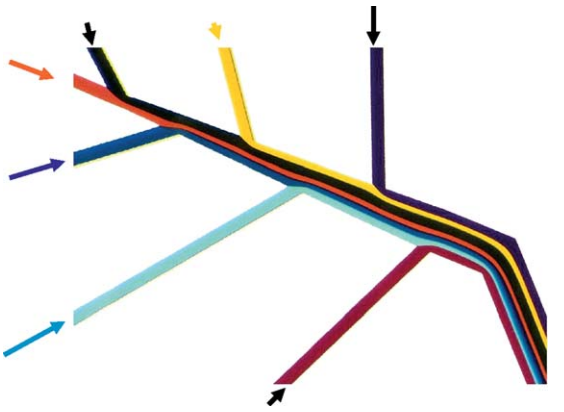

Figure 1 Various streams colored with different dyes are brought together through Y-junctions and flow downstream side by side with poor diffusion-controlled mixing. (Source: Stone H A, Kim S 2001 Microfluidics: Basic issues, applications, and challenges. *AICHE J.* **47**, 1250–4.)

In recent years, numerous micromixers based on various principles have been developed for various LOC applications. Generally speaking, mixing in microdevices is enhanced through chaotic advection that allows passive particles transported by a periodic velocity field to exhibit chaotic trajectories (Aref 1984, 1990, 2002, Ottino 1989). More specifically, the developed microscale mixing schemes can be divided into two categories, according to their so-called active or passive natures. A mixer is said to be active when its functioning relies on the use of a time-variant external energy source such as that provided by applied pressure, the electric field, and/or the magnetic field, to quote only a few of them. This external energy source excludes that which is employed for propelling the fluid itself, regardless of its state of mixing. Unlike active mixers, passive mixers use the same power source (which is in most of the cases time-independent) as that needed to propel the fluid, and typically take the benefit of irregular or asymmetric channel geometry to laminate the flowing fluids either in-plane or out-of-plane so as to promote chaotic advection. Each of these two types of micromixers has different capacity, mixing speed, and operating requirements. The lack of moving components makes passive mixers free of additional friction and wear effects even if their intricate channel topologies are often hard to microfabricate, and generally not switchable. Once a passive mixer is incorporated into a microdevice, it fulfills its function when fluids flow through it. In contrast, active mixers can be controlled externally, which makes them

suitable and attractive for reconfigurable microfluidic systems that can perform several different functions given different states of external controls. Various techniques used in microsystems for mixing enhancement are summarized below, starting first with the passive mixers before dealing with the active ones.

2.10.2 Passive Mixers

Due to the dominating laminar flow pattern in microfluidic systems, mixing in passive micromixers relies mainly on molecular diffusion and/or chaotic advection. Parallel lamination, split-and-recombine (SAR), injection, droplet, and chaotic mixers are among the most commonly used passive micromixers (Nguyen and Wu 2005).

2.10.2.1 Parallel Lamination Mixer

A parallel lamination mixer splits the inlet fluid streams into several substreams and subsequently joins those into one single stream. This process can be achieved by means of T-mixers, Y-mixers, and hydrodynamic focusing mixers, which essentially differ by their geometry.

2.10.2.1.1 T-mixer

The T-shaped micromixer was one of the first introduced micromixers for mixing in a microfluidic channel. Two fluid streams are directed into two different inlet arms of a T-channel, which then flow into a common long microchannel, as depicted in Figure 2. Although the flow in the mixing microchannel is in the laminar flow range, there may be developments of vortices depending on the magnitude of the Reynolds number in the mixing channel – denoted as $Re = ud/v$ where u is the average velocity in the mixing channel, d is the hydraulic diameter, and v is the kinematic viscosity of the fluid.

Figure 3 depicts the velocity profiles and concentration fields in the middle part of a T-mixer (in relation to the channel depth). The geometry of the micromixer is 200 μm (width of the mixing channel) by 100 μm (width of the inlet arms) by 100 μm (depth of the mixer). For low Re values, the velocity profile is parabolic, the two fluid streams flow side by side and there is only a small amount of mass transfer perpendicular to the main flow (Figure 3(a)). In this flow region, the mixing of the two fluid solutions relies only on molecular diffusion from one side of the channel to the other, which explains why long microchannels with small width are required. For higher Re values, a double vortex pair occurs, which can stir fluid and improve mixing. When Re exceeds a certain threshold value, an unsteady engulfment flow characterized by the development of a fine lamella takes place in the mixing channel (Figure 3(b)). In the engulfment flow region, the intertwinement of both input streams leads to an enlarged interfacial surface area resulting in a rapid mixing.

Figure 4 depicts the mixing performance of a T-mixer in which HCl solution is introduced into one of the two inlet arms, and NaOH solution with disodium fluorescein dye is injected into the other. The micromixer size is 600 μm (width of the mixing channel) by 300 μm (width of the inlet arms) by 270 μm (depth of the mixer). The observed fluorescence intensity is proportional to the product of the concentration of the HCl–NaOH reactive system. Obviously, when $Re = 150$, the product of the reactive system is very limited due to poor mixing. When $Re = 250$, rapid mixing occurs and the product is formed as the fluid streams flow downstream.

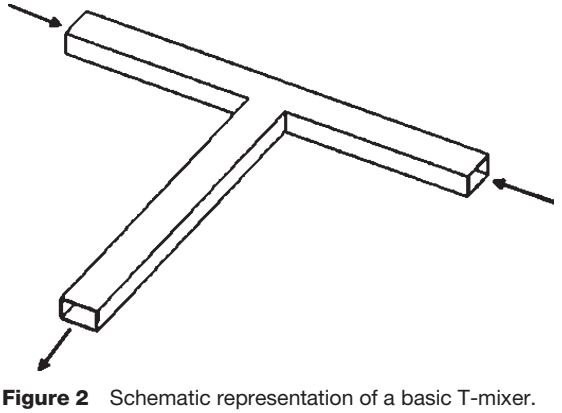

Figure 2 Schematic representation of a basic T-mixer.

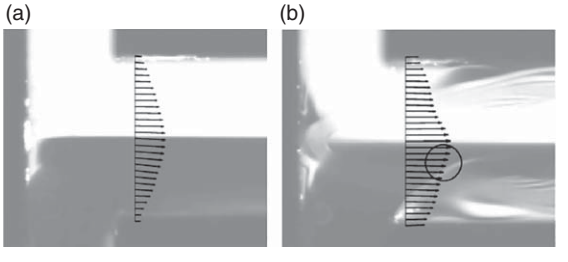

Figure 3 Velocity profiles and concentration fields in the middle part of a T-mixer at $Re = 120$ (a) and $Re = 186$ (b). (Source: Hoffmann M, Schluter M, Rabiger N 2006 Experimental investigation of liquid–liquid mixing in T-shaped micro-mixers using μ-LIF and μ-PIV. *Chem. Eng. Sci.* **61**, 2968–76.)

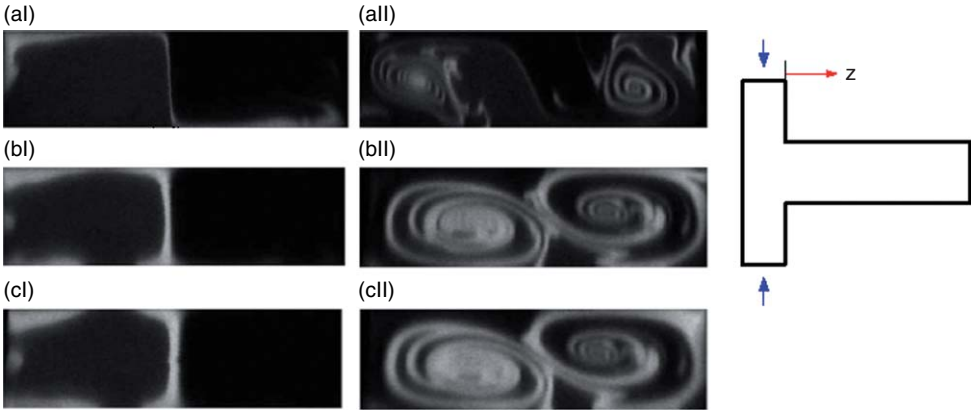

Figure 4 Cross-section areas of the microsystem containing HCl and NaOH with the dye disodium fluorescein at different *Re* (*left column*: *Re* = 150, *right column*: *Re* = 250) and various positions along the mixing channel. (a) *z* = 0.5 mm; (b) *z* = 5 mm; and (c) *z* = 10 mm. (Source: Hoffmann M, Schluter M, Rabiger N 2006 Experimental investigation of liquid–liquid mixing in T-shaped micro-mixers using μ-LIF and μ-PIV. *Chem. Eng. Sci.* **61**, 2968–76.)

Due to its simplicity, the basic T-mixer has been integrated in microsystems for various chemical and biological applications. For the sake of illustration, we mention its use for performing enzyme assays (Hadd *et al.* 1997), for measuring target analyte concentrations (Kamholz *et al.* 1999), for detecting ammonia in aqueous solution (Veenstra 1999), for studying rapid chemical reactions (Hinsmann *et al.* 2001), for crystallizing benzoic acid by mixing sodium benzoate and hydrochloric acid (Stahl *et al.* 2004), for nanoparticle precipitation (Schwarzer and Peukert 2004), and also its use in sol–gel reactors (Rivallin *et al.* 2005).

To reduce the mixing channel length of the basic T-shaped micromixer, several variations of the design/geometry have been proposed: square-wave, inclined, oblique, and wavelike microchannels (Jen *et al.* 2003) are some illustrations reported in **Figure 5**. The flow sways around these varying structures within the twisted microchannels, and secondary flows are induced, which significantly improve the mixing propensity of the system. Numerical calculations indicate that the inclined channel yields the most efficient mixing. Other variants, like those proposed by Jen *et al.* (2003), include substructures/subsections that may lead to optimum length of the mixing channel and consequently to significant enhancement of the mixing process.

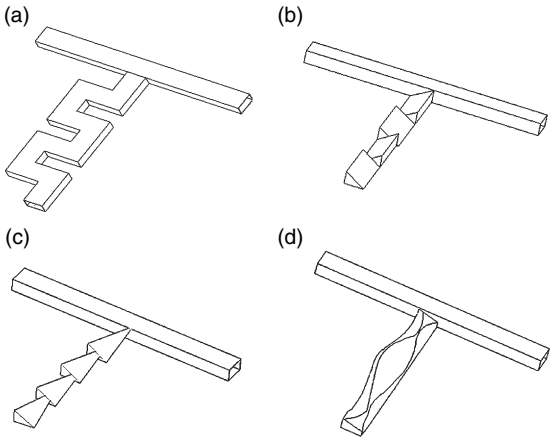

Figure 5 Schematics of (a) square-wave T-mixer; (b) inclined T-mixer; (c) oblique T-mixer; and (d) wave-like T-mixer.

2.10.2.1.2 Y-mixer

A Y-shaped micromixer is generally viewed as a subset of the T-shaped micromixer described in Section 2.10.2.1.1. The basic Y-mixer works on the same principles that govern the mixing quality of the basic T-mixer. **Figure 6** depicts the mixing performance of a typical Y-shaped micromixer. Two fluid streams, as marked by red and blue colors, are brought into contact at *Re* = 30 through the Y-junction. The two fluids begin to diffuse, which results in the formation of a mixed fluid layer. Diffusive mixing is the dominant mechanism in the straight mixing channel, and hence mixing remains very poor.

Figure 6 Mixing performance in a basic Y-mixer where two fluid streams (red and blue colors) meet at a Y-junction and enter a straight mixing microchannel at *Re* = 30. Scale bar, 0.2 mm.

As for the T-mixer, different geometries have been developed to improve the mixing performance of the basic Y-mixer. Figure 7 schematically depicts some of them. A method to reduce the mixing length is based on the introduction of a throttle immediately after the Y-junction, as represented in Figure 7(b) (Gobby *et al.* 2001). The mixing length decreases as the throttle size decreases, but at the expense of a higher pressure drop. Despite the reduction in the length of the mixing channel as generated by the throttle, the mixing mechanism therein still relies on molecular diffusion, which prevents fast and efficient mixing.

Another method sometimes followed for improving the mixing quality of a given Y-shaped micromixer is the replacement of the straight mixing microchannel by a square-wave microchannel, as sketched in Figure 7(c). The presence of the bends induces secondary flows, which can stir fluids, enhance mixing, and under certain conditions can even induce chaotic advection (Yi and Bau 2003). Unfortunately, for sufficiently low Reynolds numbers, the bend-induced secondary flows decay well before they have an opportunity to significantly stir the fluid, so that diffusive mixing remains the dominant process. Figure 8 depicts the mixing performance in a square-wave microchannel with a series of C-turns at $Re = 30$. Two fluid streams are introduced in the legs A and B of the Y part of the microsystem, and remain well separated after flowing through the bends.

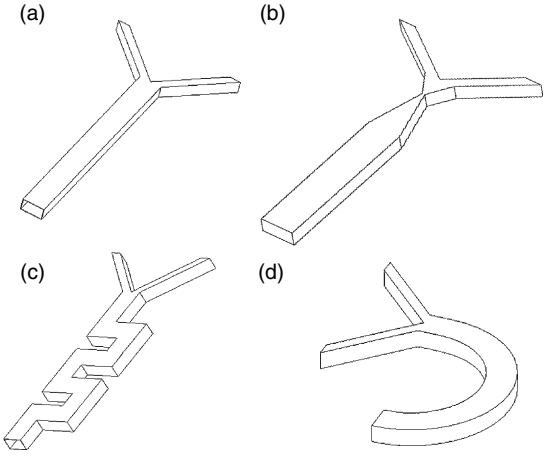

Figure 7 Schematics of (a) basic Y-mixer; (b) throttle Y-mixer; (c) square-wave Y-mixer; and (d) curved Y-mixer.

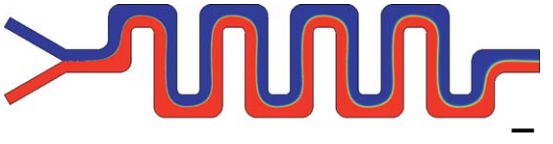

Figure 8 Mixing performance in a square-wave microchannel with a series of C-turns. Two fluid streams (red and blue colors) meet at a Y-junction and enter a square-wave microchannel at $Re = 30$. Scale bar, 0.2 mm.

At any flow rate, the flow through a curved microfluidic channel is obviously different from that through a straight channel. By simply introducing curvature in the mixing channel, vortices, also called Dean vortices, arise in the vertical plane of the curved channel as a result of an interplay between inertial, centrifugal, and viscous effects. Under appropriate and judiciously chosen conditions, these effects establish a radial pressure gradient whose magnitude, if sufficiently large, may lead to the generation of a transverse flow field. This transversal secondary flow associated with the Dean effects can be characterized in terms of a dimensionless number, the Dean number denoted as κ and defined as follows:

$$\kappa = \left(\frac{d}{R}\right)^{0.5} Re$$

where R is the flow path radius of curvature and d is the hydraulic diameter of the channel, i.e., $d = 4A/P$, where A is the cross-sectional area and P is the wetted perimeter. This dimensionless Dean number expresses the relative magnitudes of inertial and centrifugal forces to viscous forces. Figure 9 illustrates the Dean flow phenomena in curved microchannels. Two fluid streams are brought together through the Y-junction and enter a curved microchannel segment. At low κ ($\kappa \sim 1$), the secondary flow is not strong enough to perturb the axial laminar flow profile, and the two fluid streams remain well separated at the exit of the curved channel (Figure 9, *upper*). As κ increases ($\kappa \sim 10$), the induced transverse flow component acts to transport fluid from the inner wall of the channel radially toward the outer wall and the interfacial area between the two fluids significantly increases (Sudarsan and Ugaz 2006).

2.10.2.1.3 Hydrodynamic focusing mixer

Another way to reduce the mixing length in parallel lamination micromixers is by creating a thin jet containing the macromolecules of interest by hydrodynamic focusing (Hertzog *et al.* 2004, Knight *et al.* 1998, Park *et al.* 2006). Figure 10 depicts the three-inlet hydrodynamic focusing micromixer developed by Knight *et al.* (1998). The edges of the microchannels are marked with dashed lines, and the variables W_c and W_f represent the width of the channel and the width of the

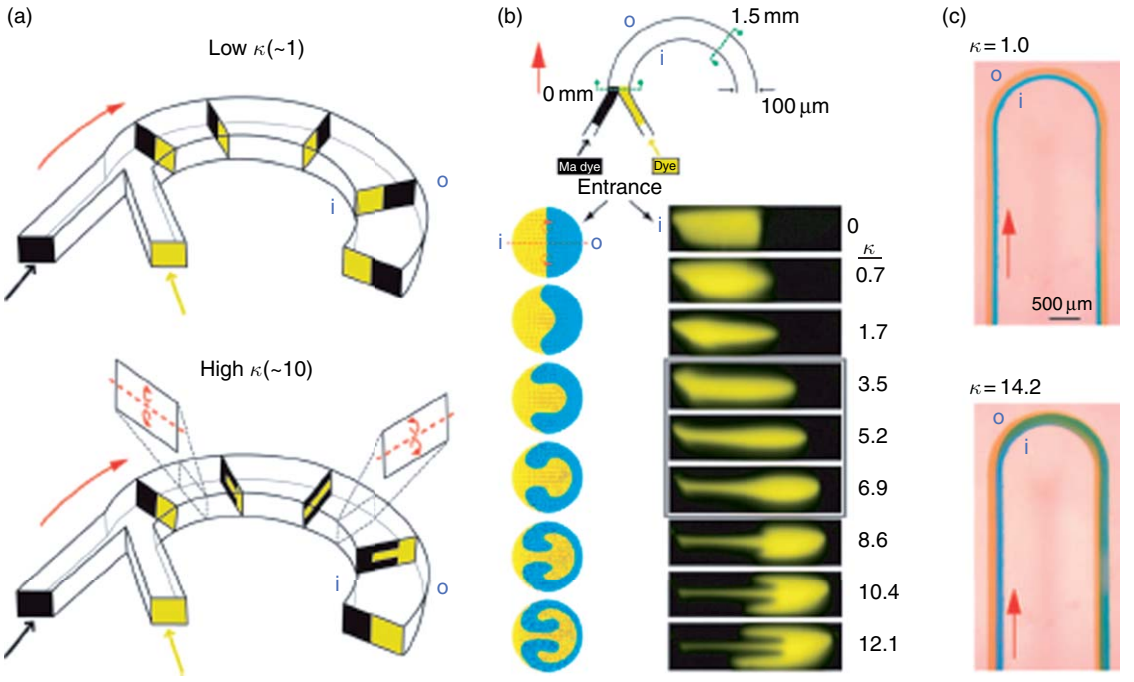

Figure 9 Dean flow phenomena in curved microchannels. (a) Idealized Dean flow-mediated rotation sequence (i and o denote the inner and outer channel walls); (b, *upper*) schematic of the curved microchannel geometry investigated (100 μm wide; 29 μm high; and 630 μm radius of curvature). The transverse flow field is examined at the entrance to the curved segment and at a location 1.5 mm downstream. Analytically computed velocity and concentration profiles are shown (*left lower*) beside confocal cross-sectional images of the transverse flow in the microchannel (*Right lower*) at flow rates in the range of $2.6 < Re < 45.1$ ($0.7 < \kappa < 12.1$). The boxed area represents conditions under which the transverse flow induces ≈90° rotation in the upper and lower halves of the channel. (c) Top-view images of aqueous streams labeled with blue and yellow dyes in a curved microchannel segment (200 μm wide; 29 μm high; and 630 μm radius of curvature). At $\kappa \sim 1.0$ (*upper*) the streams flow parallel to each other along the entire length, whereas at $\kappa \sim 14.2$ (*lower*) the blue stream is transported from the inner to the outer wall. (Source: Sudarsan A P, Ugaz V M 2006 Multivortex micromixing. *Proc. Natl. Acad. Sci. U S A* **103**, 7228–33.)

focused inlet stream, respectively. A solution containing given macromolecules is confined into a thin jet by a second solution without macromolecules flowing from two side channels perpendicular to the long axis of the mixing system. Low molecular weight reactants in the second solution rapidly diffuse into the thin jet with the macromolecules. The width of the focused stream does not depend on the magnitude of the applied pressure, but rather on the ratio, α, of the side pressure P_s to the inlet pressure P_i: $\alpha = P_s/P_i$. Focus occurs in a range of α that depends on the details of the channel geometry. Once the stream is focused, the width remains constant unless broadened by diffusion into the side flow or by increase in channel width. One particular problem associated with this type of mixer is the occurrence of premature mixing prior to the formation of the focused jet.

In order to reduce the premixing, a five-inlet hydrodynamic focusing mixer has recently been developed by Park *et al.* (2006) and is shown in **Figure 11**. Macromolecules in solution A are injected into the center of the channel, solution B flows into two side channels, and solution A without macromolecules flows in diagonal channels. The angle between the center and the diagonal channels is 45°. The sheath flow from the diagonal channels serves as a barrier between solutions flowing from the center and the two side channels during the focusing process. With minuscule amounts of sheath flow, the mixing uniformity, while maintaining rapid diffusive mixing, has improved by more than an order of magnitude.

2.10.2.2 Split-and-Recombine Mixer

Since the diffusion timescale is proportional to the square of the diffusion distance, splitting the streams to be mixed into multiple smaller streams and later rearranging them in alternating thin laminae will significantly decrease the mixing time (Bessoth *et al.* 1999, Erbacher *et al.* 1999, Jensen 1998, Sudarsan and

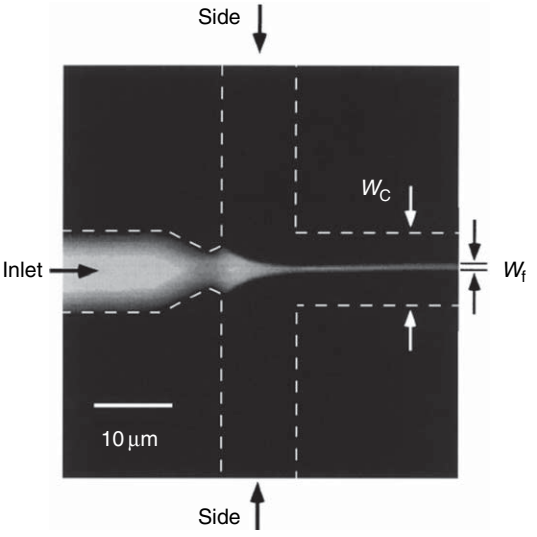

Figure 10 Three-inlet hydrodynamic focusing mixer. The edges of the microchannels are outlined with dashed lines. (Source: Knight J B, Vishwanath A, Brody J P, Austin R H 1998 Hydrodynamic focusing on a silicon chip: Mixing nanoliters in microseconds. *Phys. Rev. Lett.* **80**, 3863–6.)

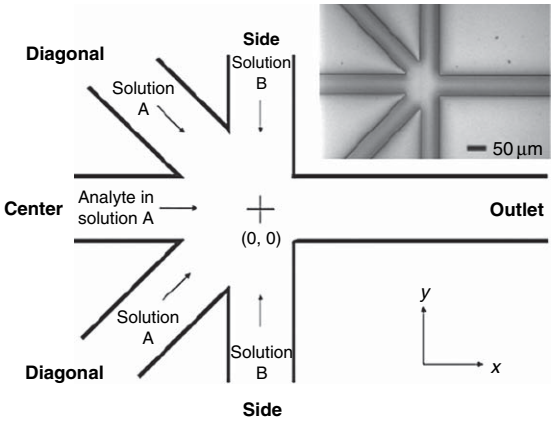

Figure 11 Five-inlet hydrodynamic focusing mixer. (Source: Park H Y, Qiu X, Rhoades E, Korlach J, Kwok L W, Zipfel W R, Webb W W, Pollack L 2006 Achieving uniform mixing in a microfluidic device: Hydrodynamic focusing prior to mixing. *Anal. Chem.* **78**, 4465–73.)

Ugaz 2006, Yamaguchi *et al.* 2004). Based on the channel configurations, SAR micromixers are called either 3D SAR or planar SAR (P-SAR) mixers. Let us examine the peculiarities of these.

2.10.2.2.1 3D SAR mixer

Figure 12(a) schematically depicts the SAR micromixer developed by Manz and coworkers (Bessoth *et al.* 1999, Erbacher *et al.* 1999). The microchip is made from a glass/silicon/glass sandwich. The silicon wafer is etched from both sides and contains a number of wafer-through holes whereas the Pyrex glass serves as a cover and bottom plate and further contains holes for inlet and outlet. On one side of the silicon wafer (layer 1), the inlet channel of liquid A is split into 16 microchannels with a width 1/16 of the total inlet channel width. This is achieved by repeated splitting of the channels in such a way that an array of symmetrical elements results. On the backside of the silicon wafer (layer 2), the channel for liquid B is split in the same way as that for the liquid A. In order to bring liquids A and B together, liquid B is introduced into layer 1 via a number of wafer-through nozzles. When liquid B comes out of a nozzle, it is allowed to develop into the full vertical height of the channel before it enters a channel with liquid A. Subsequently two neighboring channels are combined into one and this is repeated until all partial flows are united into one broad outlet channel. Figure 12(b) depicts the experimental result using fluorescein and rhodamine B at a total flow rate of 50 $\mu L\ min^{-1}$, and mixing in the millisecond regime has been successfully demonstrated.

Similar SAR micromixers using polymethylmethacrylate (PMMA) plates instead of silicon wafer were developed by Yamaguchi *et al.* (2004). Each of the two fluids to be mixed is divided into 16 transverse streams. Subsequently, two different adjacent flow streams are converged five times at a merge angle of 60°. The results demonstrated that about 90% mixing was achieved within 1 s after the streams had been merged.

The above designs are based on the splitting of the fluids to be mixed before they come into contact. A mandatory prerequisite to do so is the fabrication of successive small channels, which may lead to undesired plugging if particulate solutions are used, to higher pressure drops along the channel length, and to substantial dead volumes. To avoid the need for small channels, Munson and Yager (2004) designed a compact SAR mixer by splitting and then combining each fluid along a plane perpendicular to the splitting plane, which generates striations in the fluids to be mixed. By keeping the channel dimensions constant and increasing the number of striations, the characteristic dimension above which diffusion must occur is reduced. Figure 13 depicts the channel geometry of this SAR mixer. The mixer operates by splitting the fluid on each layer in the $y-z$ plane and merging it with the fluid from the other layer in the $x-z$ plane. A 1.8- and 3.0-fold enhancement in the rate of mixing as compared to that in a straight channel was obtained after the first and second mixing units, respectively.

The mixer operates by splitting the fluid on each layer in the $y-z$ plane and merging it with the fluid from the other layer in the $x-z$ plane. (Source: Munson M S, Yager P 2004 Simple quantitative optical method for monitoring the extent of mixing applied to a novel microfluidic mixer. *Anal. Chim. Acta* **507**, 63–71.)

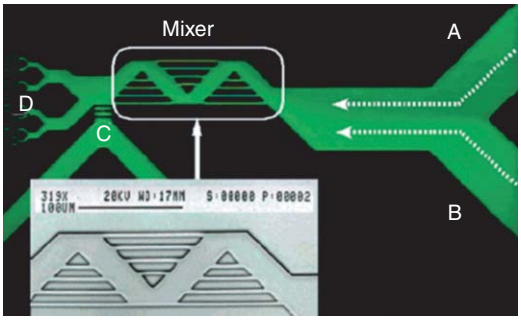

Figure 14 Photomicrograph of the planar split-and-recombine (P-SAR) mixer. The small image in the lower left corner is the scanning electron microscope (SEM) of the mixer. This mixer is about 100 μm × 200 μm wide and 10 μm deep. (Source: He B, Burke B J, Zhang X, Zhang R, Regnier F E 2001 A picoliter-volume mixer for microfluidic analytical systems. *Anal. Chem.* **73**, 1942–7.)

2.10.2.2.2 P-SAR mixer

In contrast to the 3D SAR mixers, all the axes of the channels in P-SAR mixers are located on the same plane, and the design is therefore simpler and does not require the construction of complex 3D geometries.

Figure 14 depicts the picoliter-volume P-SAR mixer developed by He *et al.* (2001). The major features of the design are the following:

(1) The mixing channels have two different channel sizes, one is 5 μm wide and the other is 27 μm wide.
(2) The smaller 5-μm-wide channels are parallel to the flow axis and vary in length; and
(3) The larger 27-μm-wide channels run back and forth through the parallel channel network at an angle of 45°.

The fluid motion is driven by electro-osmotic flow (EOF) instead of pressure-driven flow. It was observed that little mixing of the confluent solvent streams occurred in the upstream of the mixer where mixing would be achieved almost exclusively by diffusion. In contrast, after passage through the mixer, complete mixing was accomplished over a length of about 200 μm as determined by confocal microscopy and charge-coupled device (CCD) detection.

Another simple design has been proposed by Sudarsan and Ugaz (2006) and is depicted in **Figure 15**. Mixing is achieved by the secondary flow induced by Dean vortices as described in Section 2.10.1.1.2. In the P-SAR design, two fluid streams of different species are brought together through the Y-junction. The fluids enter the curved microchannel (marked i in the figure) and experience a transverse flow generated by the counterrotating vortices above and below the channel midplane that induce a

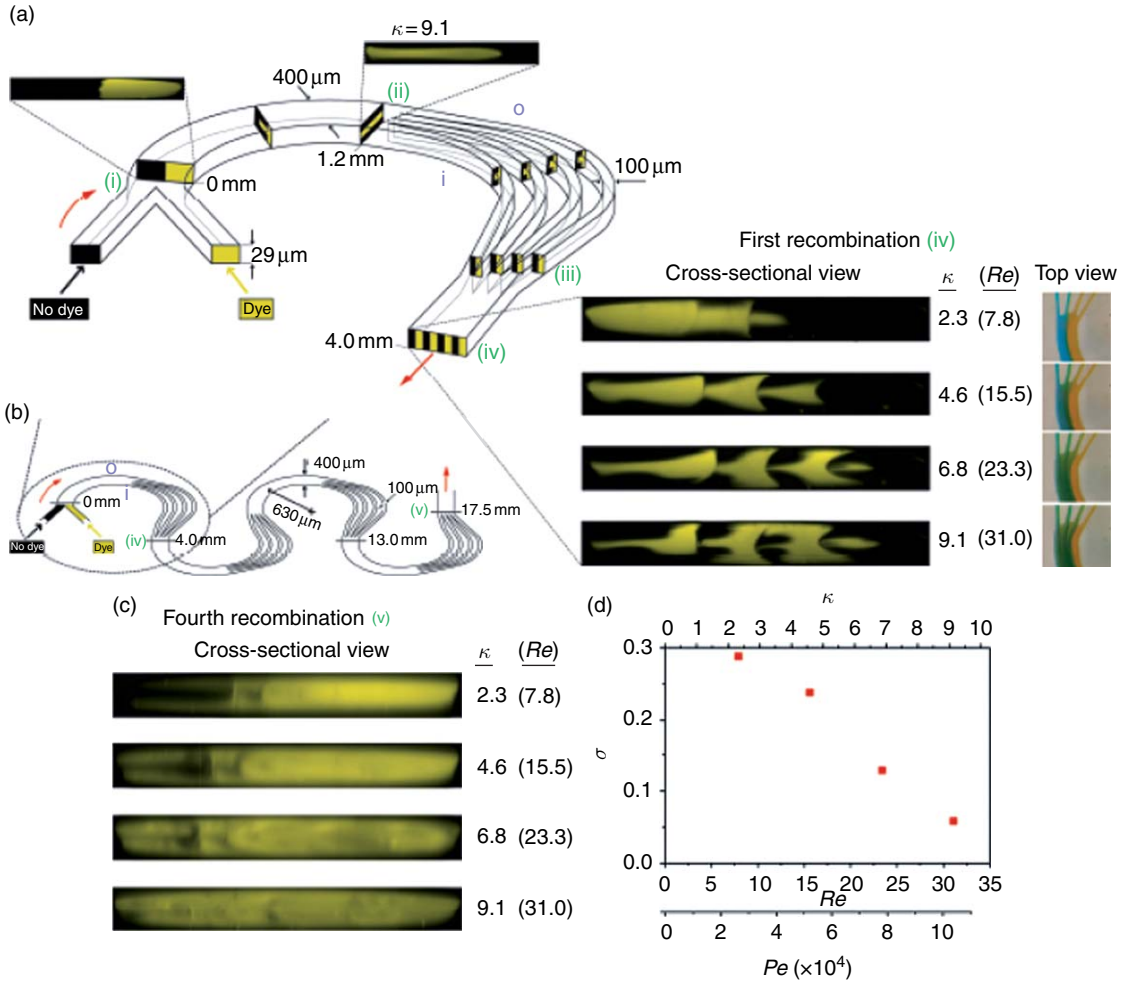

Figure 15 Planar split-and-recombine (P-SAR) micromixer incorporating four split streams. (a) Planar 2D microchannel geometry capable of generating alternating lamellae of individual fluid species in a split-and-recombine (SAR) arrangement (400 μm wide; 29 μm high; 630 μm radius of curvature; *Re* and κ are computed based on the 400-μm-wide segment; i and o denote the inner and outer channel walls, respectively). Flow schematics are shown inside the channel; corresponding confocal images are shown outside. (b) Schematic of a microchannel incorporating a series of successive P-SAR mixing elements. (c) Confocal cross-sectional images taken after the fourth recombination (position (v) in b). (d) Plot of σ (standard deviation of the intensity distribution over each image) evaluated from the confocal image sequence in C as a function of the Dean, Reynolds, and Péclet numbers (*Pe* was computed using $D = 3 \times 10^{-6}\,\mathrm{cm^2\,s^{-1}}$ for Rhodamine 6G). (Source: Sudarsan A P, Ugaz V M 2006 Multivortex micromixing. *Proc. Natl. Acad. Sci. U S A* **103**, 7228–33.)

corresponding pair of 90° rotations in the fluid (ii). At this point (1.2 mm downstream from the entrance i), the flow is split into four parallel streams that develop along curved trajectories inducing a second pair of 90° fluid rotations in each stream (between parts ii and iii of the mixer). Alternating lamellae of the two species are generated when the streams are rejoined 4 mm downstream from the entrance (iv). By employing a channel that implements a series of four successive P-SAR elements (**Figure 15(b)**), a level of 90% mixing is achieved at 17.5 mm downstream position for a Dean number $\kappa = 9.1$ (**Figure 15(c)** and **15(d)**).

2.10.2.3 Injection Mixer

Figure 16 schematically depicts the injection micromixer developed by Miyake *et al.* (1993), which has 400 micronozzles and each of them is 15 μm × 15 μm large at the bottom of a wide shallow channel on a silicon substrate. The sample fluid is introduced into the mixing chamber and the reagent is injected through the micronozzles into the sample at high speed. Because the micronozzles convert the reagent into microplumes, the effective contact surfaces with the sample are significantly increased and, as a result,

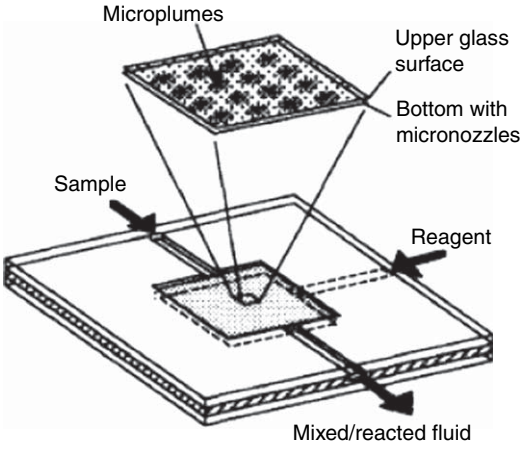

Figure 16 Schematic of an injection micromixer. (Source: Miyake R, Lammerinkz T S J, Elwenspoek M, Fluitman J H J 1993 Micro mixer with fast diffusion. *Proc. MEMS'93, 6th IEEE Int. Workshop Micro Electromechanical System*, San Diego, CA, USA, pp. 248–53.)

the mixing is greatly improved. The experimental results demonstrate that a homogeneous state of mixing is achieved within a few seconds.

The limitation of the above design is that the sample itself is not converted into microplumes. To solve for this limitation, Yang *et al.* (2004) proposed a new design shown in **Figure 17**. The mixer consists of two arrays of micronozzles that are located in parallel directions, and the nozzles are further parallel with respect to the substrate plane. The sample and the reagent are delivered to chambers A and B, respectively. They are then driven into the mixing chamber via the two arrays of micronozzles, which convert both the sample and the reagent into plumes of streams. The experimental results show that very fast mixing with a low pressure drop can be achieved.

2.10.2.4 Droplet Mixer

Another solution to reduce the mixing length is by mixing the liquids within a droplet moving through winding microchannels (Bringer *et al.* 2004, Günther *et al.* 2005, Liau *et al.* 2005, Song *et al.* 2003, Tice *et al.* 2003).

Figure 18 depicts the droplet micromixer developed by Song *et al.* (2003). In the micromixer, three separate aqueous streams converge into a single microchannel where they pinch off into droplets (called plugs) suspended in a perfluorinated oil containing a surfactant. As the plugs move through a serpentine microfluidic channel, the fluid inside the plug is folded, stretched, reoriented, and chaotic advection is induced. Under favorable conditions, submillisecond mixing in the plugs has been demonstrated. The critical advantage of this mixer is that the reactants are confined in each plug as the plugs steadily move down the channel, which prevents axial dispersion. Thus, the progress of the reactions occurring within the plugs is suitable for kinetic analysis, and the mixer can be used to perform millisecond kinetic measurements.

Despite its quality-controlled mixing, the above mixer is ineffective for mixing highly concentrated solutions (CS) of crowding agents such as bovine serum albumin and hemoglobin that are viscous and sticky, and thus extremely difficult to mix rapidly (Liau *et al.* 2005). To do so, the mixer was modified by introducing protrusions along the microfluidic channel walls as shown in **Figure 19**. The protrusions or bumps along the outer wall of the serpentine channel

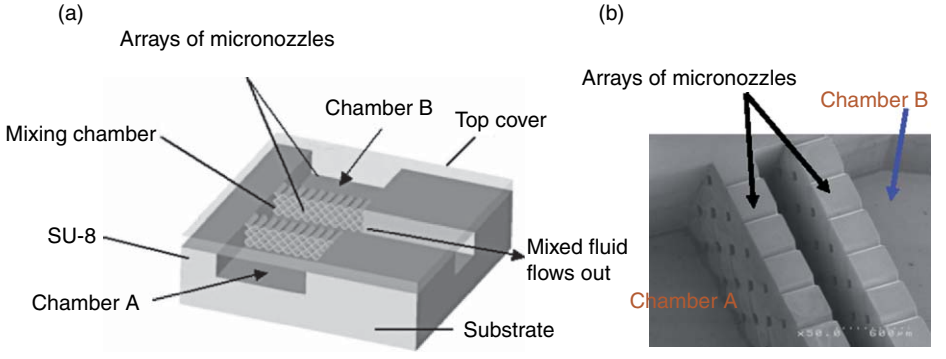

Figure 17 (a) Schematic design of the injection mixer with two arrays of micronozzles located in parallel directions. (b) Scanning electron microscope (SEM) image of the mixing chambers and nozzles. Three separate aqueous streams converge, then intersect with an oil stream, and pinch off into droplets (plugs) suspended in the oil carrier fluid. (Source: Song H, Bringer M R, Tice J D, Gerdts C J, Ismagilov R F 2003 Experimental test of scaling of mixing by chaotic advection in droplets moving through microfluidic channels. *Appl. Phys. Lett.* **83**, 4664–6.)

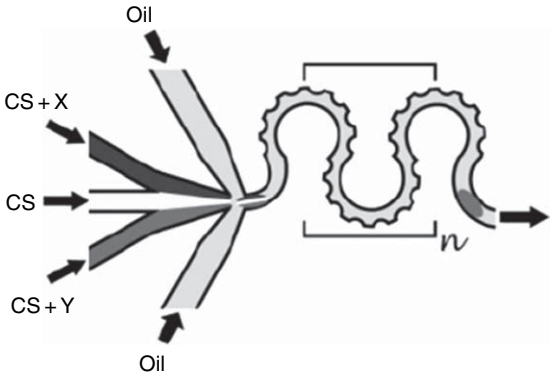

Figure 19 Schematic of a bumpy serpentine droplet mixer. (Source: Liau A, Karnik R, Majumdar A, Cate J H D 2005 Mixing crowded biological solutions in milliseconds. *Anal. Chem.* **77**, 7618–25.)

induce oscillatory flows within the plugs that fold and refold the flow very rapidly. This, in turn, induces rapid mixing of highly concentrated protein solutions, for example. Two streams of CS containing reactants X and Y separated by a third stream of concentrated solution intersect with two oil streams to form droplets suspended in oil (plugs). The plugs then move through n cycles of the bumpy serpentine microfluidic channel until the plug contents are fully mixed. The obtained experimental results show that chaotic mixing of CS can be achieved in the millisecond range. The developed mixer can be used for kinetic studies of biological reactions with millisecond time resolution under conditions of macromolecular crowding like those encountered for cells.

Besides the experimental work, theoretical investigations of chaotic mixing in a liquid droplet moving through a serpentine microfluidic channel have been performed (Muradoglu and Stone 2005). Their theoretical results indicate that the mixing quality depends on the droplet size, the capillary number, the viscosity ratio of the droplet phase to the ambient fluid. The best mixing is obtained when the droplet size is comparable with the channel width. The smaller the viscosity ratio, the better is the quality of the mixing. When the viscosity ratio is below a certain threshold value, the effects of the viscosity ratio on the mixing quality decrease rapidly. The Reynolds number has no significant impact on the mixing even if the quality of mixing somewhat increases with decreasing Reynolds numbers.

2.10.2.5 Chaotic Mixer

Besides diffusion, chaotic advection provides another important mechanism to enhance mass transfer in flows with low Reynolds numbers. The idea underlying chaotic advection is the observation that certain regular velocity fields can produce fluidic pathlines that uniformly fill the volume in an ergodic way. In such velocity fields, fluid elements that are originally close to one another, trace paths that diverge rapidly (exponentially fast in the ideal case), so that the material is dispersed throughout the volume very efficiently. It is important to note that chaotic advection cannot occur in steady 2D flows, but only in 2D time-dependent and 3D flows. Typically, passive chaotic mixers consist of complex 3D twisted conduits fabricated in various substrates such as silicon (Liu *et al.* 2000), polydimethylsiloxane (PDMS) (Stremler *et al.* 2000), ceramic tape (Yi and Bau 2003), or glass (Liu *et al.* 2000). There are several designs of chaotic passive mixers that cause transverse components of flow velocity to stretch, fold the material lines, and exponentially elongate the interface between two fluids.

In one configuration, all the conduits, such as the zigzag conduit and square-wave conduit, lay in the same plane, as represented in **Figure 20**. In these arrangements, the symmetry of the flow field is preserved, and chaotic advection occurs only at high Reynolds numbers (i.e., $Re > 80$). When the Reynolds number is below a certain threshold value, the mixing process remains governed by molecular diffusion (Mengeaud *et al.* 2002, Therriault *et al.* 2003).

The second arrangement consists of twisted pairs of bends with each pair forming a C-shape (**Figure 20(c)**) or a L-shape (**Figure 20(d)**). Previous results have shown that these mixers work well at moderate Reynolds numbers (Yi and Bau 2003). Unfortunately, in these mixers, mixing is not efficient at low Reynolds numbers because the bend-induced vortices decay well before they may significantly stir the fluid. **Figure 21** depicts the mixing result in a 3D C-shaped serpentine passive mixer at $Re = 0.2$. Nearly no mixing is observed close to the mixer outlet even after 15 bends, which indicates that no chaotic advection is induced. Combining the L-shaped serpentine mixer with the SAR technique described in Section 2.10.2.2, an out-of-plane L-shaped micromixer (**Figure 22**) has been developed and shown to work satisfactorily at low Reynolds numbers (Chen and Meiners 2004). In contrast to the basic L-shaped conduit, as illustrated in **Figure 20(d)**, the fluid streams are split out-of-plane, rotated in opposite directions, and recombined in the out-of-plane L-shaped mixer.

For generating chaotic advection at very low Reynolds numbers (i.e., $Re < 1$), Xia *et al.* (2005, 2006) proposed very complicated X-shaped crossing channels (**Figure 23**). The slanted channels are perpendicular to each other and exhibit an angle of 45° with the principal axis of the mixer. The channels are arranged in a periodic manner. In model a (**Figure 23(a)**), the two-layer channels first go across each other at a cross section A. Then at section B, the base-layer channel drives the fluid to the top layer through rotation and the top-layer channel turns the fluid by 90° in the same plane. Subsequently, the two channels meet symmetrically at section C and guide the fluid to the base layer. The structure at section D is similar to that at section B, and the only difference is that the two side channels are interconverted. Section C to D is the first half cycle. The second half cycle has structures similar to the first one except that the slanted channels turn in the opposite direction in an attempt to reduce the isolated fluid

volumes. The model b (**Figure 23(b)**) has similar but simpler structures in which the fluids are alternately driven from the base-layer channel to the top-layer channel from two sides of the mixer and rejoin the main flow at the knot positions. For both types of mixers, the channel depth in different layers is 150 μm, and the channel width is 300 μm. One can fabricate such micromixers by means of lithography-based microfabrication techniques. Using polymer materials, they can also be fabricated with the laser direct writing method and thermal bonding techniques. **Figures 24** and **25** depict the experimental mixing results of the mixer models a and b, respectively, at $Re = 0.01$, and the subfigures show the detailed fluid dispersion at different positions along the mixers. The results demonstrate that chaotic advection occurs at Re of $O(10^{-2})$, and rapid mixing can be achieved at extremely low Reynolds numbers with these mixers. Compared with model a, model b exhibits faster mixing.

Following a different approach, ribs or grooves on the channel walls can lead to the formation of transverse velocity components at low Reynolds numbers (Howell *et al.* 2005, Johnson *et al.* 2002, Stroock *et al.* 2002). **Figure 26** depicts a microconduit with grooves of certain depths positioned at the bottom of the channel. These are arranged in such a way that their direction forms a certain angle with respect to the main flow direction. For a pressure-driven flow, these grooves introduce anisotropic flow resistances into an

otherwise isotropic system. Fluids experience a lower resistance when flowing along the ridges and valleys constituting the grooves than when flowing perpendicular to them. In this way, a rotational element is introduced, resulting in corkscrew-like fluidic streamlines. **Figure 26(a)** schematically depicts two trajectories of passive particles. The frames in **Figure 26(c)** are confocal micrographs of the vertical cross section of a channel depicted in **Figure 26(b)**. The leading edge of the fluorescent fluid clearly shows the rotation and distortion of a stream of solution that was injected along one side of the channel. Under appropriate arrangement of different types of grooves (mainly differing with respect to their orientation), the induced transverse flow can produce chaotic flows. This design is also called staggered herringbone mixer (SHM). **Figure 27** depicts the performance of the SHM mixer. **Figure 27** (*left frame*) represents the channel with staggered herringbone structure. **Figure 27** (*right frame*) depicts the distribution of fluorescent molecules in the cross sections at distances of 0.2, 0.4, 0.6, 0.8, 1.0, and 3 cm down the channel at

$Re \sim 10^{-2}$. The results demonstrate that SHM works well in the range $0 < Re < 100$. The SHM mixing is more efficient than that achieved with similar microfluidic channels devoid of internal structures like ribs and grooves. For example, the basic T-mixer requires mixing lengths of about 1 and 10 m at Péclet numbers (Pe) $= 10^4$ and 10^5, and the SHM mixer performs the same task within 1 and 1.5 cm, respectively. The mixing efficiency of the SHM mixer can be further greatly improved with ribs or grooves placed at both the top and the bottom of the channel (Howell *et al.* 2005).

Taking advantage of the induced Dean vortices in alternately curved microfluidic channels, a much simpler channel design without any internal structure has been proposed (Jiang *et al.* 2004, Schonfeld and Hardt 2004, Sudarsan and Ugaz 2006). **Figure 28** schematically depicts a four-element meander mixer, which consists of a channel with rectangular cross

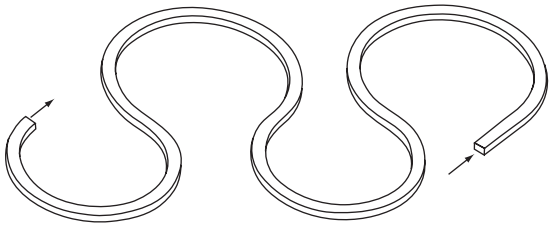

Figure 28 Schematic of four-element meander mixer.

section comprising four circular arcs and two straight inlet and outlet sections. Because of the periodic arrangement of the geometry, a periodic velocity field develops. The important design parameter is the dimensionless Dean number, κ. It has been demonstrated that when the Dean number exceeds a certain threshold value, four vortices develop, inducing a large interfacial area. **Figure 29** depicts the evolution of the species concentration (encoded in gray) at the inlet, the outlet, and at two intermediate positions within a circular arc segment for $\kappa = 150$ (*left column*) and $\kappa = 450$ (*right column*). At the inlet cross section, the species are located only in the right side of the conduit. As they flow downstream, at the cross section corresponding to $\varphi = \pi/2$, a pair of counterrotating vortices develops leading to the advection of the species into the left side of the channel, but a given fraction remains on the right side. At the cross section $\varphi = \pi$, most of the species are advected into the left side of the channel, and four vortices develop for $\kappa = 450$. At the outlet cross section $\varphi = 3\pi/2$, a steady velocity profile with four vortices is well developed for $\kappa = 450$. The interface between the two fluids is significantly elongated after the fluids flow through one circular arc segment. When the Dean number exceeds a particular threshold value, the interfacial stretching factor, denoted as λ and defined as the interface length at a certain position divided by the initial interface length, exponentially increases with the number of mixing elements. **Figure 30** depicts the experimental results of a scaled-up version of the meander mixer having 20 mixing elements with a length of 322 mm and a curved channel of a cross section of 1 mm × 1 mm. The mixing visualization was realized by employing a very fast ionic dye reaction, more precisely an aqueous solution of $Fe(NO_3)_3$ and NaSCN forming the intensely reddish Fe(III)-rhodanide according to a 1:1 stoichiometric reaction. The position 1 in **Figure 30** shows the mixing in the first and second mixing elements. The position 2 is located at 118 mm downstream and corresponds to the Nos. 7 and 8

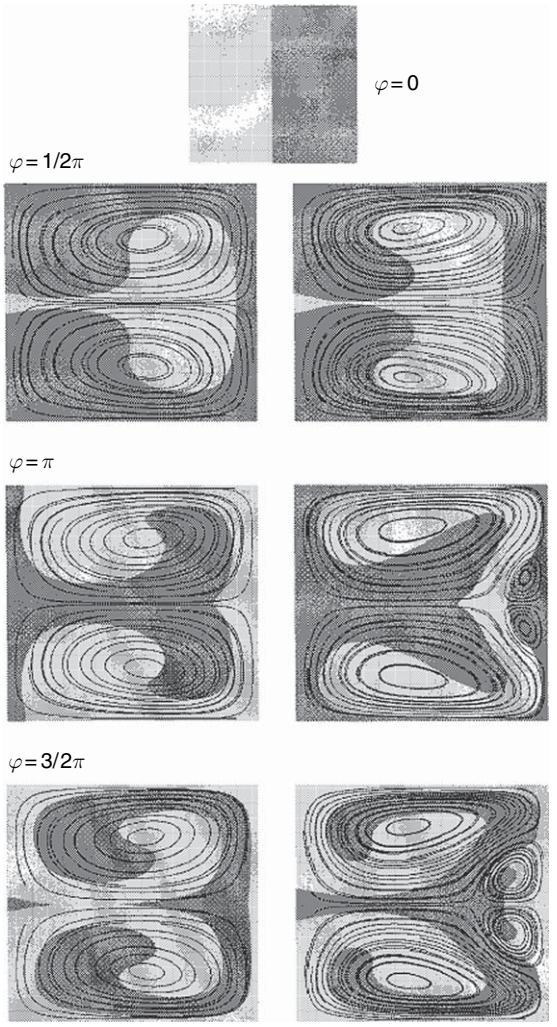

Figure 29 Evolution of species concentration within a circular arc segment at the inlet ($\varphi = 0$), two intermediate positions ($\varphi = \pi/2$ and $\varphi = \pi$), and outlet ($\varphi = 3\pi/2$) cross sections for Dean numbers $\kappa = 150$ (*left column*) and $\kappa = 450$ (*right column*). (Source: Schonfeld F, Hardt S 2004 Simulation of helical flows in microchannels. *AICHE J.* **50**, 771–8.)

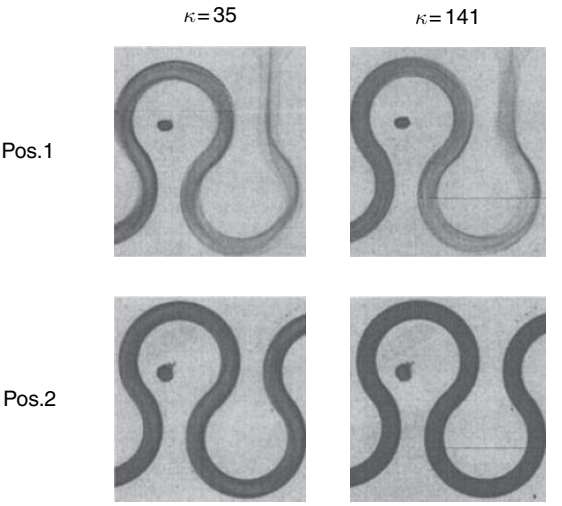

Figure 30 Experimental mixing results in the meander mixer for Dean numbers $\kappa = 35$ and141 at two different positions. (Source: Jiang F, Drese K S, Hardt S, Kupper M, Schonfeld F 2004 Helical flows and chaotic mixing in curved micro channels. *AICHE J.* **50**, 2297–305.)

mixing elements, where the two fluids are well mixed. Although the meander mixer has no internal structure within its alternately curved microfluidic channels, it requires a large space and only works under strict conditions of high Dean numbers or high Reynolds numbers.

Instead of introducing the internal ribs and grooves structure as done for the SHM mixer or introducing curved channels as in the meander mixer, another possibility consists in the patterning of materials characterized by different surface chemistry or equivalently different values of zeta potentials or surface charge densities so that recirculating transverse velocity components may arise in electroosmotically driven flows (Biddiss *et al.* 2004, Lee *et al.* 2005, Ng *et al.* 2004, Stroock *et al.* 2000). Before explaining the generation of these recirculation flows in some more detail, let us recall a few fundamental elements in surface chemistry science. Most of the solid surfaces are likely to carry electrostatic charges due to broken bonds and surface charge traps. For example, silicon-based materials are usually negatively charged, and Al_2O_3-based materials are positively charged. When a liquid containing a small amount of ions is brought into contact with such a solid boundary, counterions in the liquid will be strongly attracted to the charged solid surface forming an immobile compact layer at the solid–liquid interface. This layer is called the Stern layer. Outside the Stern layer, counterions and co-ions are accumulated following a Boltzmann statistics in a thin liquid layer, which is called the diffuse part of the electrical double layer (EDL). The thickness of the EDL is typically on the order of a few nanometers depending on the electrolyte concentration. Away from the EDL, the electrolyte is neutral and local ionic concentrations equal bulk values. This ionic charge separation within the EDL next to the solid wall (as compared to the electroneutral bulk electrolyte solution) causes either a positive or a negative potential difference across the EDL, denoted as zeta potential, sometimes also called electrokinetic potential. The magnitude of the zeta

potential depends, among other things, on the characteristics of the solid (surface chemistry) and the liquid (dielectric permittivity, viscosity, etc.). In the presence of an external electric field, the counterions in the EDL are attracted toward the oppositely charged electrode and drag the liquid along. In other words, the electric field, through its action on the counterions, creates a body force that, in turn, induces fluid motion, which is called EOF. When the thickness of the EDL is much smaller than the dimensions of the conduit, the EOF can be described by specifying a slip velocity at the wall, so the body force is nearly coincident with the bounding surface. EOFs have several important advantages over pressure-driven flows. They do not require any moving components like pumps and valves, and the fluid speeds in EOFs are independent of the transverse tube or channel dimension over a wide range of conditions, making this technique extensible to extremely small physical scales.

For steady, 1D and fully developed flow in a microfluidic channel, the EOF velocity, noted u, is simply given by the Smoluchowski equation written as below:

$$u = -\frac{\varepsilon_o \varepsilon_r \zeta}{\mu} E \qquad [1]$$

where ζ is the zeta potential; $\varepsilon_o \varepsilon_r$ and μ are the dielectric permittivity and the dynamic viscosity of the medium, respectively and E denotes the magnitude of the applied electric field. Relationship [1] is valid for sufficiently thin double layers, and is further strictly applicable for low values of the zeta potential where the Debye–Hückel approximation is correct. From expression [1], it is readily understood that the magnitude and the direction of the electroosmotic velocity can be controlled by the magnitude and the polarity of the zeta potential. Therefore, by selectively patterning negatively, neutrally, or positively charged material patches on the channel walls, a wide range of flow patterns in microfluidic channels can be created. For example, **Figure 31** schematically depicts the EOF field in the vicinity of the channel wall containing both negatively and positively charged materials. Since the negatively charged surfaces attract positive ions that drag the bulk fluid moving toward the cathode and the positively charged surfaces attract negative ions dragging the liquid toward the anode, the interaction between the two flows results in a local circulating flow, which can be used to accelerate and enhance mixing.

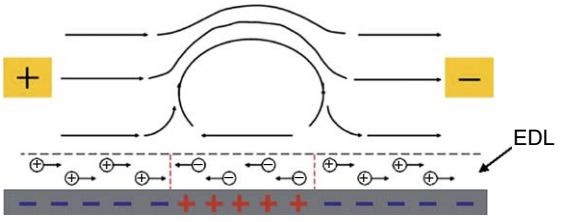

Figure 31 Illustration of the electroosmotic flow (EOF) field in the vicinity of a channel wall patterned with alternately negative and positive surface charges.

Using the rapid prototyping/soft lithography technique, the channel walls can be patterned with various surface charge configurations (Biddiss *et al.* 2004). **Figure 32** depicts some configuration examples as proposed by Biddiss *et al.* (2004). The gray zones of the channel walls have a positive surface charge, and the rest has a negative surface charge. Thus, the local electric double layer, or ionic concentration fields, and the local flow fields are different from patch to patch. **Figure 33** depicts the numerical and experimental mixing results in a microchannel with a uniform surface charge distribution (**Figure 33(a)**) and in a heterogeneous microchannel with six offset staggered patches (**Figure 33(b)**). Mixing experiments were conducted at applied electric fields ranging between 70 and 555 V cm^{-1}, which corresponds to Reynolds numbers of 0.08 and 0.7 and Péclet numbers of 190 and 1500, respectively. The numerical predictions agree very well with the experimental results. In a microfluidic channel with homogeneous distribution of the surface charge on the channel walls, the mixing depends solely on molecular diffusion process and requires 22-mm channel length to achieve 95% mixing at an electric field of 280 V cm^{-1}. For the staggered configuration, the formation of unsymmetrical concentration gradients indicates the presence of local

flow circulations, which advect a portion of the mixed downstream fluid back to the unmixed upstream region, and it only requires a channel length of 2.6 mm to meet 95% mixing. In contrast to previous passive chaotic mixers, this passive electroosmotic mixer can easily create a complex flow field in a straight microchannel without the necessity for complex channel geometry and internal structure.

2.10.3 Active Mixers

To facilitate rapid mixing, some active mixers have been developed and can be typically classified according to their stirring mechanisms, namely pressure perturbation mixers, thermosiphon-based mixers, magnetic mixers, dielectrophoretic mixers, peristaltic mixers, acoustic mixers, magnetohydrodynamic (MHD) mixers, and electroosmotic mixers. In the following, the basic functioning and the performance of each of these mixers are reviewed.

2.10.3.1 Pressure Perturbation Mixer

By using a standard MEMS technology, a micromixer with one main channel and one pair of side channels, as shown in **Figure 34(a)** (Lee 2002, Lee *et al.* 2000, 2001), can be fabricated. Two fluids of different natures are injected from the inlet with the same flow rate. The pair of side channels is connected to a pair of high- and low-pressure sources via a computer-controlled high-speed solenoid valve to achieve a kind of source–sink mechanism. Time-periodic pressure perturbations are applied perpendicular to the main stream. The time-averaged mass flow rate from the side channels is kept to zero. At small perturbation amplitudes, the material line undergoes weak oscillations as it passes through the intersection region. As the perturbation amplitude increases, the oscillation amplitude also increases. Chaotic advection appears for sufficiently large perturbation amplitudes. **Figure 34(a)** depicts the evolution of an interface between two fluids as obtained by numerical simulations (Lee *et al.* 2001). In the upstream region, the two fluids are well separated. Once the pressure perturbation is applied, lobe-like distortions of the interface are induced, which facilitates rapid mixing. **Figure 34(b)** depicts the experimental result and the lobe-like distortions of the interface, as observed in practice. **Figure 34(c)** depicts the chaotic mixing by the micromixer developed by Lee *et al.* (2001) for particular values of perturbation amplitude and frequency. The mixing performance can be significantly improved with

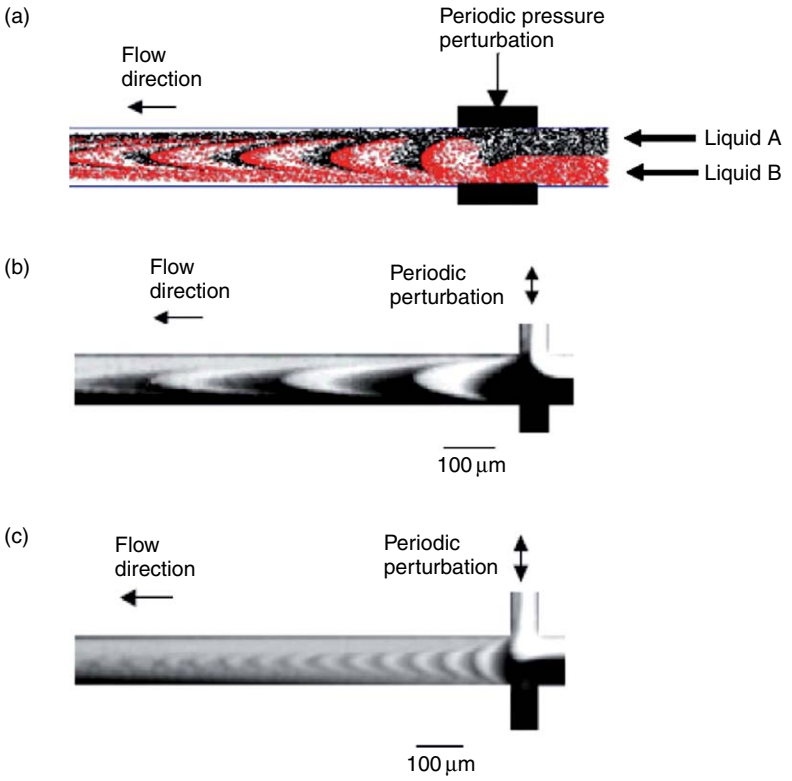

Figure 34 (a) Lobe-like distortions of the interface as induced by periodic pressure perturbations applied from side channels (simulation results); (b) experimental snapshot showing a highly convoluted interface; and (c) chaotic mixing as a result of pressure perturbation in a micromixer. (Source: Lee Y K, Deval J, Tabeling P, Ho C M 2001 Chaotic mixing in electrokinetically and pressure driven micro flows. *IEEE 14th Int. Conf. Micro Electro Mechanical System (MEMS 2001)*, Interlaken, Switzerland, pp. 483–6.)

pressure perturbations applied to multiple side channels (Niu and Lee 2003).

Recently, Niu *et al.* (2006) reported the design and fabrication of a novel microfluidic mixer chip, whose mixing mechanism is based on pressure perturbations applied to side channels orthogonal to the mixing channel. Different from the mixer evoked before and developed by Niu and Lee (2003) where the flow in the mixing channel is perturbed by means of mechanical pulsations, the pulsating pressure perturbation is now generated by controlling a smart material, an electrorheological (ER) fluid. **Figure 35(a)** schematically depicts the mixer chip, which consists of four PDMS layers fabricated using the soft lithography techniques. The fluid mixing channels (38 μm in depth and 200 μm in width) together with the main channel and six pairs of orthogonal side channels are located on layer I. Each of the six pairs of orthogonal side channels is separated by 200 μm from the neighboring pair. Layer II is a thin membrane layer with two pairs of electrodes. An ER fluid channel 200 μm in depth and 400 μm in width is located on layer III. The ER fluid channel consists of two branches connected to two ER fluid reservoirs through inlet and outlet tubes. Layer IV is a cover layer with two pairs of electrodes. The electrodes on layers II and IV are located along each branch of the ER fluid channels. The flow of the ER fluid can be slowed or stopped if a sufficient DC electric field is applied to any pair of the electrodes as a result of the so-called electrorheological effect, namely the coalescing of the nanoparticles into chains along the direction of the electric field that is orthogonal to the flow direction. The DC electric field signals on these two pairs of electrodes are in the form of two square-wave pulses with opposing phases, leading to a time-dependent pressure condition in the ER fluid channel between the two pairs of electrodes. Such temporal pressure variation is then transferred to the control reservoirs at the end of each side channel in layer I through the deformation of a 40-μm-thick PDMS diaphragm located in layer II. The induced pressure variation acting on the control reservoirs through the diaphragm deformation can be adjusted via the applied electric field strength and frequency. **Figure 35(b)**

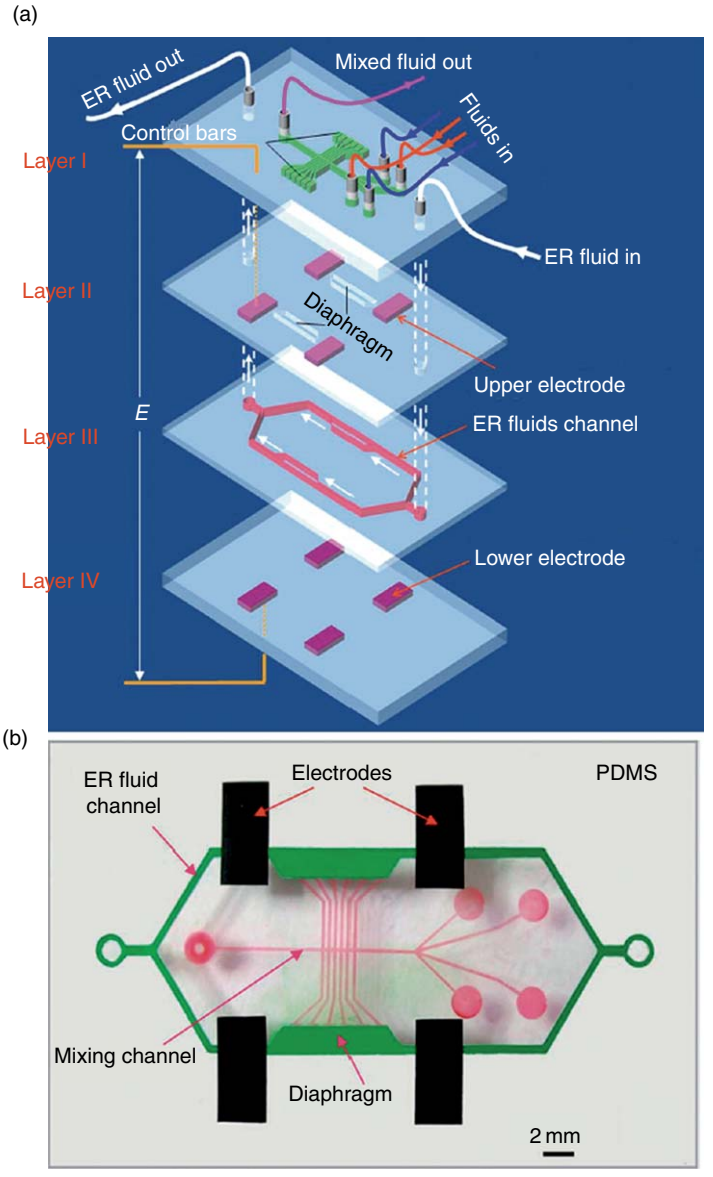

Figure 35 (a) Schematic representation of the mixer design and construction. Layer I is the mixing channel layer, layer II the thin membrane layer, layer III the electrorheological (ER) fluid channel layer, and layer IV the cover layer. Parallel electrodes are located on layers II and IV. (b) A photograph of the micromixer chip. (Source: Niu X, Liu L, Wen W, Sheng P 2006 Active microfluidic mixer chip. *Appl. Phys. Lett.* **88**, 153508.)

shows the image of the micromixer chip. Figure 36 depicts the experimental results of the mixer. In the absence of pressure perturbations in the side channels (Figure 36(a)), two fluid streams are injected into the mixing channel with a velocity of $200\,\mu m\,s^{-1}$, and a clear interface between the two fluid streams is observed, which indicates a poor mixing. In the presence of an electric field applied to the electrodes (Figure 36(b)), the main flow is perturbed by the induced pressure perturbations acting on the fluids in the side channels. The interface line is then stretched and folded intensively, and there is no discernible ink blob existing after a distance of 1.8 mm in the downstream region of the main channel.

2.10.3.2 Thermosiphon-Based Mixer

Usually buoyancy effects in microfluidic devices are very small because of the small length scales and small temperature variations. However, certain

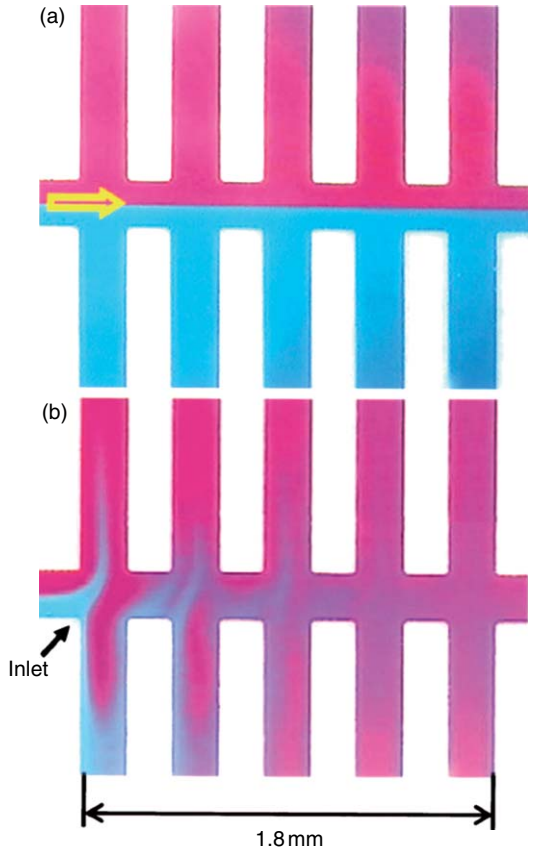

Figure 36 Experimental results of the pressure perturbation micromixer. Optical images of the mixing channel in the (a) absence and (b) presence of pressure perturbations applied to the side channels. (Source: Niu X, Liu L, Wen W, Sheng P 2006 Active microfluidic mixer chip. *Appl. Phys. Lett.* **88**, 153508.)

processes such as polymerase chain reaction (PCR) for DNA amplification require large temperature variations that may be sufficient to induce significant flow velocities even in micrometer-sized conduits. For example, for DNA amplification, Chen *et al.* (2004) and Krishnan *et al.* (2004) successfully developed a thermosiphon-based PCR reactor in which the heating source used for PCR reactions also drives the flow in a closed loop without the need of any mechanical pumps. **Figure 37** depicts the natural convection in a closed cylindrical cavity mounted vertically with the bottom surface set at a constant temperature of 97°C and the top surface is maintained at 61°C. The liquid close to the bottom surface will be less dense than the fluid close to the top surface, thus generating a buoyancy force, which, in turn, induces circulating flows. Natural convection occurs when the dimensionless Rayleigh number

$$Ra = \frac{g\alpha(T_2 - T_1)h^3}{v\kappa}$$

which represents the ratio of buoyant forces driving the instability to diffusive restoring forces acting in opposite direction, exceeds a certain threshold value. Here, g is the gravitational acceleration, α, v, and κ are the thermal expansion coefficient, the kinematic viscosity, and the thermal diffusivity of the fluid, respectively, h is a characteristic length scale, which is the height of the cavity in this case, T_1 and T_2 are the temperatures of the top and bottom surfaces of the cavity, respectively. The experimental and numerical results shown in **Figure 37** indicate that very complicated flow motions can be induced upon variations of the Rayleigh number, the aspect ratio h/d, or both.

When the temperatures T_1 and T_2 are time-dependent, a time-dependent natural convection results and can be used to produce chaotic advection (de la Cruz and Ramos 2006). **Figure 38** schematically depicts an enclosure with the temperatures of the left half of the upper wall periodically reduced and those of the right half of the bottom wall cyclically increased. The temperature changes are outphased. The two vertical walls are thermally insulated. The dimensionless temperatures of the right half of the upper wall and the left half of the bottom wall are maintained at $T = 0$. The temperatures shown in **Figure 38** are dimensionless, and are defined by $T = (\Theta - \Theta_m/\Delta\Theta)$. Here Θ is the dimensional temperature. Θ_H and Θ_C are the maximum and minimum wall temperatures, respectively, and $\Theta_m = (\Theta_H + \Theta_C)/2$ and $\Delta\Theta = \Theta_H - \Theta_C$. The first period of $T_1(t)$ and $T_2(t)$ are defined by the following expressions:

$$T_1(t) = \begin{cases} 0, & \text{for } 0 \le t < \pi \\ -0.5\sin^2(4t - 3\pi), & \text{for } \pi \le t \le \dfrac{9\pi}{8} \\ -0.5, & \text{for } \dfrac{9\pi}{8} \le t \le \dfrac{15\pi}{8} \\ -0.5\sin^2(4t - 6\pi) & \text{for } \dfrac{15\pi}{8} \le t < 2\pi \end{cases} \quad [2]$$

$$T_2(t) = \begin{cases} 0.5\sin^2(4t), & \text{for } 0 \le t \le \dfrac{\pi}{8} \\ 0.5, & \text{for } \dfrac{\pi}{8} \le t \le \dfrac{7\pi}{8} \\ 0.5\sin^2(4t - 3\pi), & \text{for } \dfrac{7\pi}{8} \le t \le \pi \\ 0, & \text{for } \pi \le t < 2\pi \end{cases} \quad [3]$$

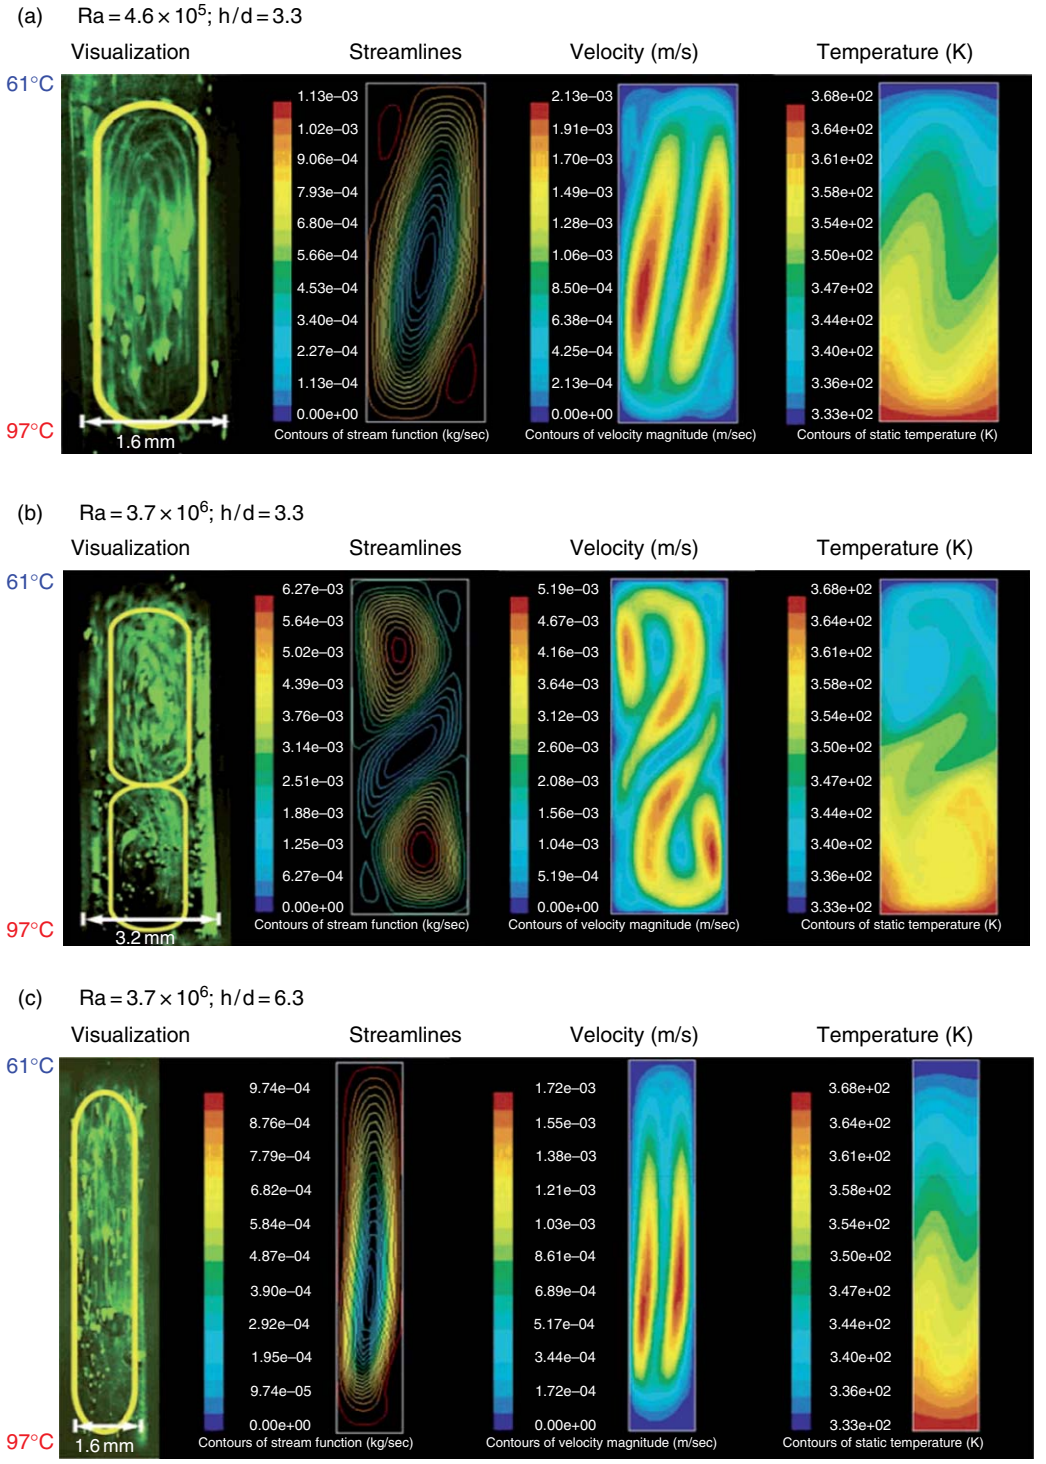

Figure 37 Experimental and numerical results of natural convection in high aspect ratio cavities heated from below and cooled from above. (Source: Krishnan N, Agrawal N, Burns M A, Ugaz V M 2004 Reactions and fluidics in miniaturized natural convection systems. *Anal. Chem.* **76**, 6254–65.)

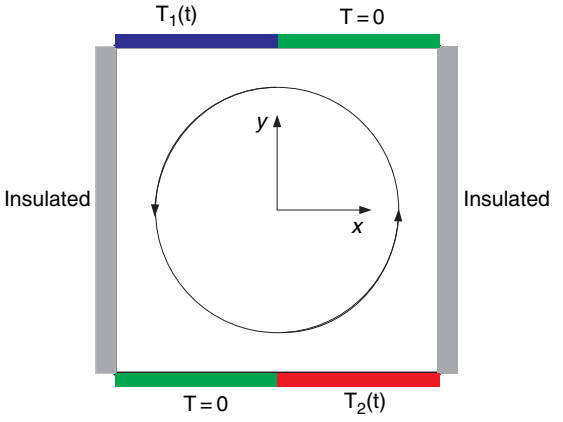

Figure 38 Schematic of a cavity filled with liquid to be mixed and thermal boundary conditions imposed on the walls of the cavity.

In eqns [2] and [3], t is the dimensionless time and the timescale is L^2/α. The temperatures T_1 and T_2 are alternated with a period of 2π. The oscillatory wall temperatures imposed on the left half of the top wall and the right half of the bottom wall yield the formation of alternating ascending and descending thermal plumes in the regions close to the vertical walls. The major feature of the induced transient natural convection is that the center of the vortex defined by the point of zero velocity varies with time. The mixing efficiency of the flow is evaluated by tracing the trajectories of 5×10^4 passive particles initially positioned according to a horizontal line at $y = 0$ where y is defined in **Figure 38**. **Figure 39** depicts the stretching and folding of the passive particles after 1/4, 1/2, 3/4, 1, 5, and 50 periods. The local stretching occurs mostly near the vertical walls where the largest stresses are generated by the convective plumes. The folding takes place near the horizontal walls where the fluid turns. After 5 periods, the material blob is spread across most of the area of the cavity. Witness that this analysis only considered the effect of the induced natural convection on the advection of passive tracers and neglected the molecular diffusion process that is highly dependent on the temperature. The actual mixing performance may be different from the theoretical predictions as obtained by de la Cruz and Ramos (2006).

When the temperature variations in minute systems are not sufficiently large to induce significant natural convection, one can mount the device on a rotating system such as a laboratory on a computer disk (CD) (Chen *et al.* 2004). In this case, the

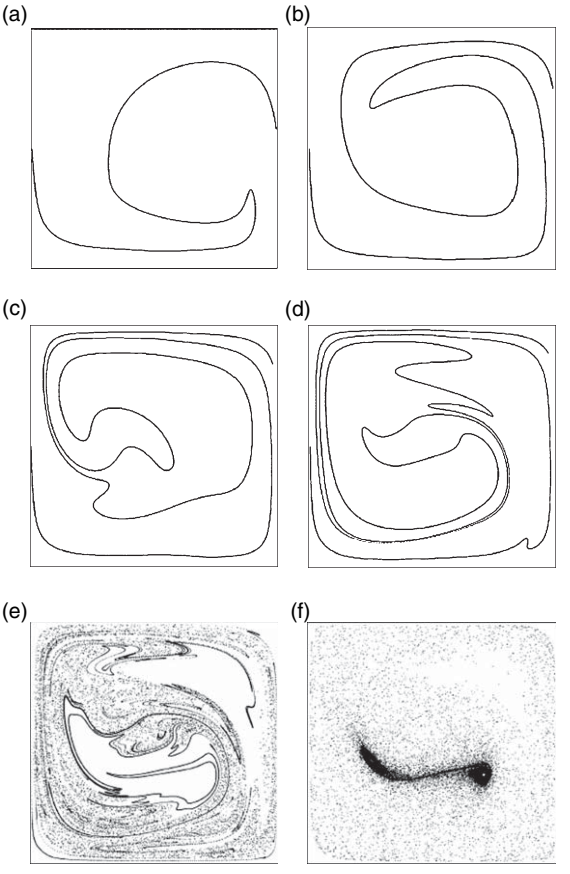

Figure 39 Deformation of a material blob with 5×10^4 passive particles after (a) 1/4; (b) 1/2; (c) 3/4; (d) 1; (e) 5; and (f) 50 cycles. (Source: De la Cruz L M, Ramos E 2006 Mixing with time dependent natural convection. *Int. Commun. Heat Mass Transfer* **33**, 191–8.)

centripetal acceleration, $w^2 r$, will replace the gravitational acceleration (g) in the expression of the Rayleigh number. In the above, w is the angular rotation speed and r is the distance between the center of rotation and a point in the microfluidic channel. Since very high accelerations ($>>9.8\ \mathrm{m\,s^{-2}}$) can be obtained in the rotating system, one can significantly reduce the size of the device and the temperature variations required to induce appreciable natural convection.

2.10.3.3 Magnetic Mixer

A magnetic force-based chaotic micromixer was developed for mixing biofluids with magnetic beads (Suzuki 2003, Suzuki *et al.* 2004). **Figure 40** schematically depicts the concept of the magnetic bead-based microseparation system of biomolecules. Two

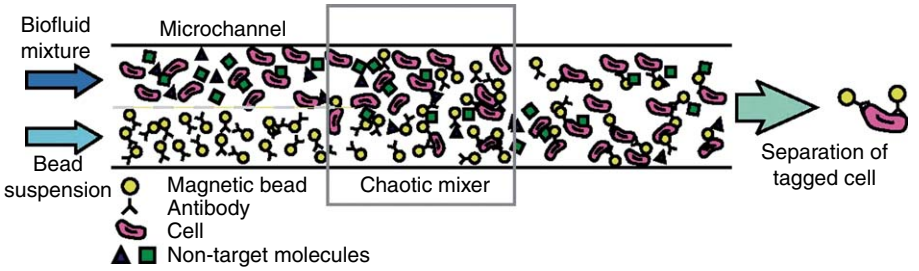

Figure 40 Schematic of magnetic beads-based microcell sorting system. (Source: Suzuki H, Ho C M, Kasagi N 2004 A chaotic mixer for magnetic bead-based micro cell sorter. *J. Microelectromech. Syst.* **13**, 779–90.)

fluid streams, a suspension of biomolecules and a suspension of magnetic beads, meet each other in the microchannel and are mixed in the mixing region. In this region, magnetic beads move around in a complicated way to enhance the biological binding of the magnetic beads to target biomolecules by a local and time-varying magnetic field as generated by microelectrical conductors embedded in the substrate beneath the conduit. Eventually, the tagged biomolecules are collected by using either a permanent magnet or an electromagnet at the downstream.

The developed magnetic micromixer previously described consists of microconductors embedded in the substrate and a serpentine-shaped microchannel formed on the surface (**Figure 41(a)**). The embedded high aspect ratio conductors allow a relatively large current to generate a magnetic field to move magnetic beads. A pair of current-carrying conductors works as a basic unit of a magnetic field source. By shifting the working conductors, it becomes possible to push and pull magnetic beads between high- and low-velocity regions. During the first phase, the

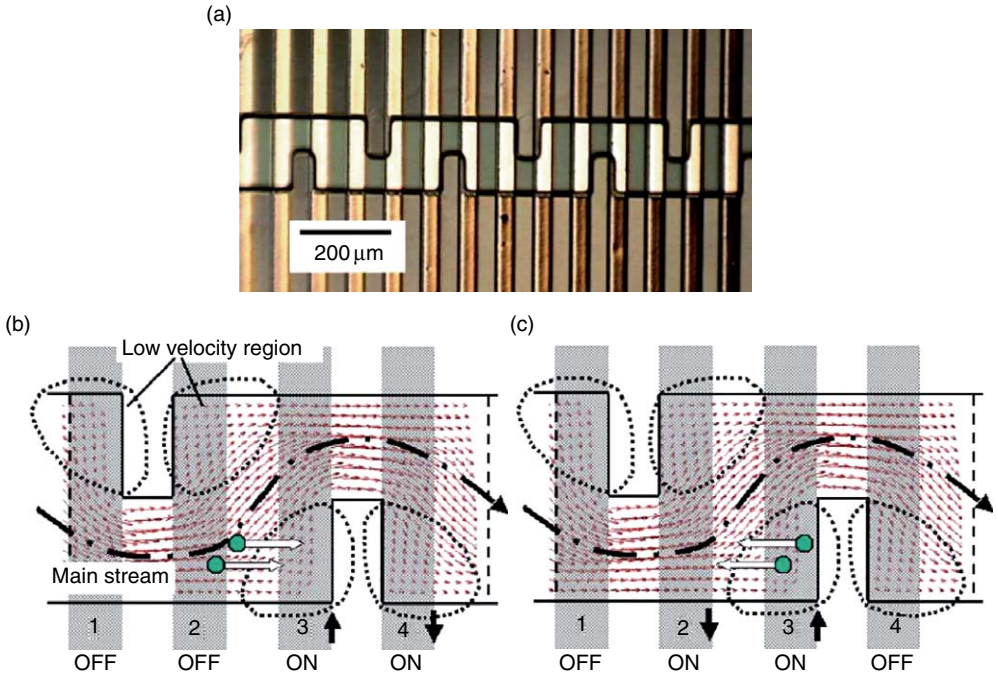

Figure 41 (a) An example of a magnetic mixing device. (b) Flow field and motion of magnetic beads (represented by two dots in the figure) when conductors 3 and 4 are turned on. (c) Flow field and motion of magnetic beads (represented by two dots in the figure) when conductors 2 and 3 are turned on. (Source: Suzuki H 2003 Development of chaotic micro-mixer using magnetic beads. Ph.D. thesis, The University of Tokyo.)

conductors 1 and 2 are turned off, the conductors 3 and 4 are turned on, and some magnetic beads (two dots in **Figure 41(b)** and **41(c)**) are attracted toward the inner edges and pulled into the low-velocity region at the corner of the channel (marked with dotted circles). In the second phase, conductors 2 and 3 are turned on, and the magnetic beads are pulled back to the mainstream. Therefore, by switching a pair of working conductors in a certain manner, it is possible to create stretching and folding by pushing and pulling magnetic beads between high- and low-velocity regions.

Figure 42 depicts a snapshot of the flow when all the conductors are turned off. Deionized water is flowing in the upper side, and a water suspension of 1-μm magnetic beads is flowing in the lower side. The volume ratio of beads is 1.6%, and the flow rate is 200 nl min^{-1}. The clear interface between the two fluid streams demonstrates that there is no mixing effect even though the channel is serpentine-shaped (the Reynolds number is about 10^{-2}). **Figure 43** depicts the sequential images of magnetic beads when the phase shift signal is applied to the conductors (the time period of one phase is 1 s). The time interval between each sequential image is 1 s. The magnetic beads are attracted sequentially by pairs of electrodes, and eventually, magnetic beads spread uniformly in the spanwise direction at the downstream. A similar magnetic mixer has been developed by Biswal and Gast (2004) in which rotations of paramagnetic linked chains of colloidal particles in a rotating magnetic field induce secondary flows to mix fluids.

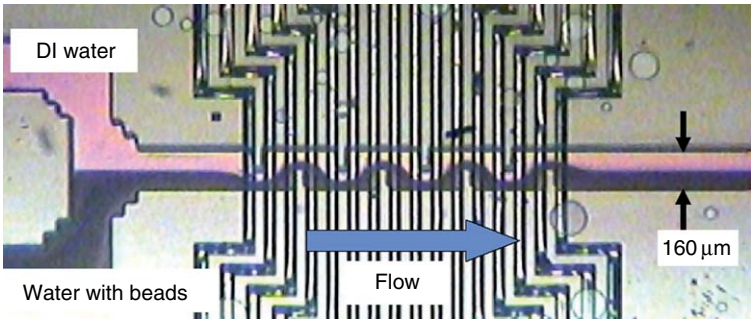

Figure 42 Experimental result of the magnetic mixer when no magnetic force is applied. (Source: Suzuki H, Ho C M, Kasagi N 2004 A chaotic mixer for magnetic bead-based micro cell sorter. *J. Microelectromech. Syst.* **13**, 779–90.)

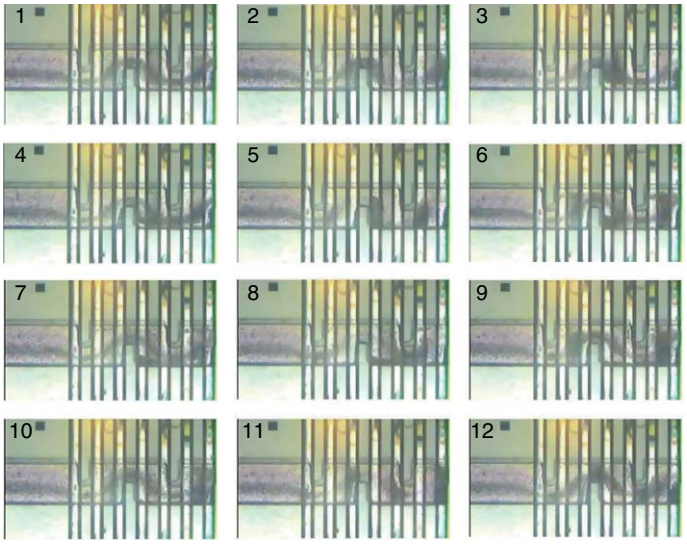

Figure 43 Experimental results of the magnetic mixer when the phase shift signal is applied to the conductors. (Source: Suzuki H 2003 Development of chaotic micro-mixer using magnetic beads. Ph.D. thesis, The University of Tokyo.)

The major disadvantages of the previous magnetic mixers are the high electric currents (i.e., 0.5 – 1 A) needed to generate a strong magnetic field, a high power consumption (about 1 W), and thus a significant Joule heating. Recently, Grumann *et al.* (2005) proposed another novel magnetic mixer in which a temporal magnetic force is generated by the spinning motion through a static magnetic field. **Figure 44** schematically depicts the magnetic mixer, which has an on-disk mixing chamber connected to two symmetric inlet reservoirs and an air vent via microchannels. Hydrophobic valves are embedded in the inlet channels to avoid uncontrolled inflow. The round mixing chamber with a volume of 25 µl connects to an outlet port. To prevent the beads from entering the outlet channel, its depth is smaller than the diameter of the beads. Therefore, the channel acts as a geometrical barrier and retains the beads inside the mixing chamber. A set of conventional permanent magnets resting in the lab frame is specifically aligned in order to periodically divert the magnetic beads. During operation of the mixer, the on-disk mixing chamber is first preloaded with a well-defined number of magnetic beads. Then, two liquids are filled into the inlet reservoirs and the disk is set into a spinning motion with a PC-controlled frequency curve. Instead of applying a time-varying magnetic field, from the viewpoint of the magnetic beads, a temporal magnetic force is generated by the spinning motion through a static magnetic field. Consequently, the beads are periodically deflected inbound and outbound, which induces chaotic advection to the liquid phase due to Stokes drag. **Figure 45** depicts the experimental results, and an ultimate mixing time of <1 s can be achieved with the combination of magnetic and centrifugal forces.

2.10.3.4 Dielectrophoretic Mixer

Dielectrophoresis (DEP) is defined as the lateral motion imparted on uncharged, polarizable particles as a result of polarization induced by nonuniform electric fields (Jones 1995). The DEP force results from the interaction between the nonuniform electric field and the induced dipole moment. Depending on the dielectric properties of the particle and the medium, the particle motion is directed either toward (positive DEP) or away from (negative DEP) regions of high electric field intensity. DEP can be achieved in both DC and AC electric fields, and it is particularly well suited for microfluidic applications and nanoassembly. One can readily control the direction of the electric field by judicious patterning of the electrodes on the substrate, and high-intensity electric fields can be obtained with relatively low potential differences, given the small gaps between the actuating electrodes.

The idea of perturbing the main flow with DEP force to enhance mixing was originally proposed by Deval *et al.* (2002) and Lee *et al.* (2001). **Figure 46** depicts the top view of the DEP micromixer developed by Deval *et al.* (2002). The mixer consists of two side walls located on opposite sides of the main channel 50 µm wide, and each of them is connected to four distinct electrodes at the bottom. Witness that the electrodes are isolated from the liquid by an

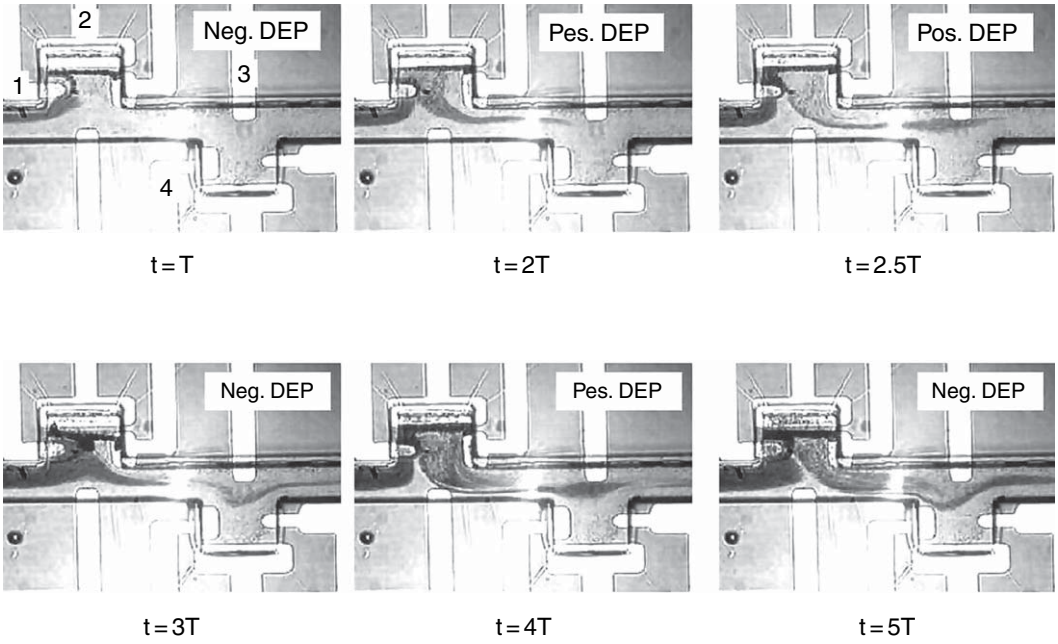

Figure 47 Experimental results of the dielectrophoresis (DEP) mixer. An AC voltage of ± 10 V is applied between electrodes 1 and 2 and between 3 and 4. AC frequency switches between 700 kHz (positive DEP) and 15 MHz (negative DEP) at a rate of $T = 0.5$ s. (Source: Deval J, Tabeling P, Ho C-M 2002 A dielectro-phoretic chaotic mixer. *Proc. 15th IEEE Int. Conf. Micro Electro Mechanical Systems 2002*, Las Vegas, NV, USA, pp. 36–9.)

insulating layer. Figure 47 depicts the successive snapshots of polystyrene particle positions over a total period of 2.5 s when ± 10 V AC is applied between electrodes 1 and 2 and between 3 and 4. The main flow is from left to right. When the particles enter the first cavity, positive DEP pulls them into the low-velocity region, attracted by electrode 1. As the frequency switches, they are repelled from the electrode 1 edges, and particles in the main stream of the flow are dragged downstream by the fluid. As the frequency switches back to the positive DEP, incoming particles are attracted upward, while a folding is created in the cavity as the particles far from the electrode experience a force too small to overcome fluid drag. The combination of the two opposite motions generates folding and stretching and greatly accelerates the homogenization of the particle distribution.

2.10.3.5 Peristaltic Mixer

The peristaltic mixer consists of a fluid-filled cavity bound from below and above by flexible membranes. By printing electrical conductors on these membranes and by passing electric currents through these conductors in the presence of a magnetic field, one can cause the membranes to vibrate with relatively large amplitudes in a prescribed way. Because the conductors can be shaped using microfabrication technology, one may induce fairly complicated motions. For example, by appropriate phasing of the current, one can induce traveling waves in the membranes, which, in turn, will cause peristaltic pumping in the fluid. The vibrating membrane can also be actuated by other means. The end walls serve to restrict the flow and thus force a cellular flow pattern. The induced cellular motion can be used to enhance mixing in a closed cavity (Carlsson *et al.* 2005, Selverov and Stone 2001, Yi *et al.* 2002a, b).

Figure 48 depicts the evolution of a material blob at times $t = 0, 600\,T$, and $1200\,T$ where T is the period of the wave in a peristaltic mixer with wave number $k = 3.8$, wave amplitude $\varepsilon = 0.01$, and Reynolds number, $Re = 25$ (Yi *et al.* 2002a). Initially, a vertical material blob is positioned in the range $1.5 < x < 2$. One can think of two materials, one dark and one light, being stirred. As time goes by, the interface between the two materials stretches and deforms. The thickness of the dark blob reduces dramatically thereby increasing the impact of molecular diffusion. Right on the membranes, the material does not move

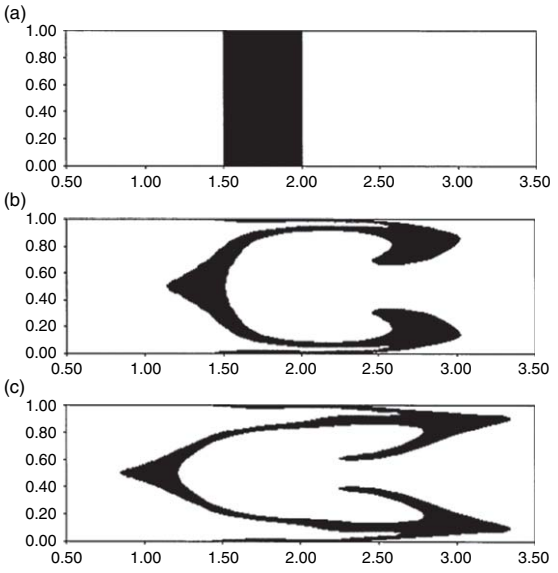

Figure 48 Evolution of a material blob at times (a) $t = 0$; (b) 600T; and (c) 1200T where T is the wave period. (Source: Yi M, Bau H H, Hu H H 2002 Peristaltically induced motion in a closed cavity with two vibrating walls. *Phys. Fluids* **14**, 184–97.)

because of the nonslip condition that holds there. The material in the vicinity of the membranes moves in the direction of the wave while (to conserve mass) the material in the center moves in the opposite direction. The stretching rate is nearly linear with time, which is much better than the rate of diffusion alone that scales with the square root of the time but less effective than the exponential stretching associated with chaotic advection. However, the stretching rate can be enhanced by oscillating both top and bottom walls at different frequencies and with different wave numbers.

2.10.3.6 Acoustic Mixer

When ultrasound is generated in a liquid, the latter would flow in the same direction as the ultrasound waves propagate (Wu and Du 1997). This phenomenon called acoustic streaming is well known for its transport properties: the fluid flows without any external mechanical contact. By appropriate use of the acoustic streaming in an adequate pattern, liquids in a closed chamber can be mixed with high efficiency (Suri *et al.* 2002a, b). **Figure 49** schematically depicts the ultrasonic mixer, which consists of a mixing chamber (closed bottle in **Figure 49**) containing the solution to be mixed and positioned vertically into an acoustic field in a water bath. A generator connected to an amplifier induces ultrasound waves using high-energy piezoceramic transducers. Two transducers are placed in the water bath outside the mixing chamber. One part of

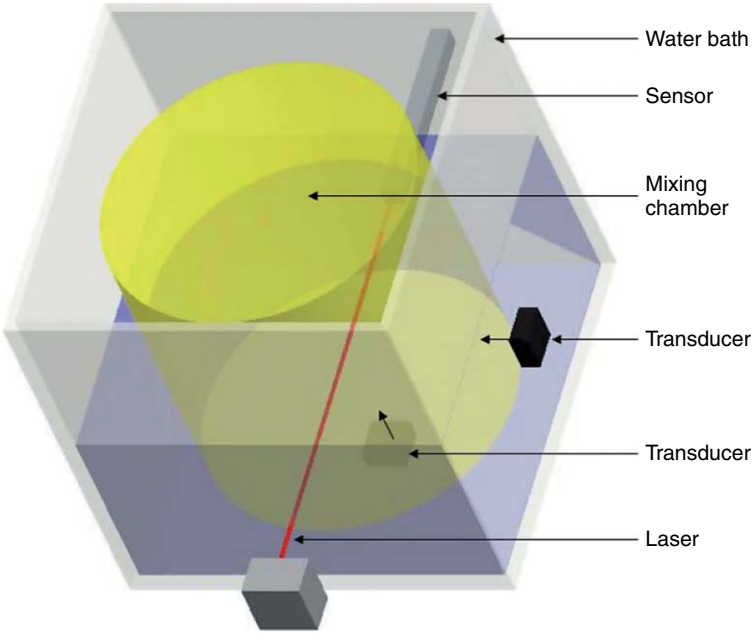

Figure 49 Schematic description of the ultrasonic mixer.

the emitted sound penetrates in the mixing chamber while another part is reflected and dispersed in the bath. The sound waves inside the chamber generate bubbles, the positions of which are changed, and the resulting streaming rotates the solution. To visualize the mixing, a laser beam traverses the glass cylinder and hits a photodiode connected to an oscilloscope. If transducer A is placed on one side of the chamber, for example, in the *x*-direction, the end walls of the mixing chamber serve to restrict the flow and thus a cellular flow pattern is induced. Similarly, when a second transducer B is aligned along a direction perpendicular to that of the transducer A, another cellular flow pattern is generated. By timewise alternations of two or more transducers positioned according to different directions, the resulting periodic acoustic streaming generates effectively chaotic mixing patterns. The main advantage of the mixer is that it allows the spinning of the solution inside a closed chamber without any mechanical contact. However, the temperature rise caused by acoustic energy may limit its applications for biological and chemical analysis.

In contrast, Katou *et al.* (2005a, b) developed a new ultrasonic mixer for mixing samples and reagents in an open-top vessel in which the mixture to be mixed has a free surface. **Figure 50** illustrates the concept of the proposed mixing method, which uses free surface waves in the vessel generated by ultrasound irradiation from outside the vessel. Both the vessel containing the liquid to be mixed and the sound source generating the ultrasound are placed in a water bath. The ultrasound irradiated from the sound source propagates in water, transmits through the vessel wall, and reaches the free surface of the liquid in the vessel. The free surface is tilted by the radiation pressure of ultrasound, which is generated at the boundary between the liquid and the air, and as a result, circulation flow arises and can be used to improve mixing. **Figure 51** depicts the experimental mixing results with 170 µl water and 3 µl dye when the sound source is periodically turned on and off. The mixture becomes homogeneous within about 0.5 s. The mixing performance can be significantly improved by using two ultrasound sources, one of them radiates through the bottom and the other through the sidewall of the vessel. Chaotic advection occurs by periodically actuating the two ultrasound sources (Katou *et al.* 2005b). In this new ultrasonic mixer, there is no significant temperature rise in the solution.

Alternatively, Liu *et al.* (2002, 2003) developed a novel ultrasonic mixer by exciting air bubbles in a liquid medium with a sound field, which is generated by a piezoelectric (lead zirconate titanate, PZT) disk attached to the mixing chamber. The mixer consists of a mixing chamber with a number of air pockets on the inner wall of the polycarbonate mixing chamber for trapping air bubbles, as shown in **Figure 52**. A PZT disk is glued onto the external surface of the chamber. When the PZT is actuated by a sinusoidal voltage, acoustic streaming is induced around the air bubbles. As a result, a churning motion is induced near the individual bubbles in the liquid. **Figure 53** shows the experimental mixing results in a 12 mm $\times$ 15 mm $\times$ 0.125 mm mixing chamber when the PZT is actuated at a frequency of 5 kHz with a

peak-to-peak amplitude V_{pp} of 10 V. A complete mixing is achieved across the whole chamber within 105 s, while the mixing based on diffusion alone takes about 6 h for the same chamber. The experimental results also demonstrate that a square sound wave provides faster mixing than does a sinusoidal sound wave, and a higher voltage amplitude results in faster mixing. Due to low frequency (~5 kHz) and low voltage (~10 V), the power consumption of the mixer is low (~2 mW) and the transducer therefore

adds almost no heat to the liquid. Such a mixer has been used in various biomolecular analyses such as immunomagnetic cell capture, bacterial viability assay, and DNA hybridization.

In the previous ultrasonic mixers, no through flow is present, and the only fluid motion in the chamber is due to the agitation induced by the acoustic streaming. However, in certain circumstances, it may be desirable to stir the fluids while it is pumped through the conduit. Such net fluid motion can be driven by an external pressure, i.e., the fluid is pumped continuously with a syringe pump. Yaralioglu *et al.* (2004) utilized acoustic streaming to disturb the pressure-driven main flow in a basic Y-mixer. **Figure 54** schematically depicts the ultrasonic mixer in a Y-shaped microfluidic channel using integrated PZT transducers. Two fluid streams are brought together through the Y-junction and continuously flow through the mixing channel. Ultrasound is introduced into the mixing channel by the embedded PZT transducers made of a thin film of zinc oxide. The thin film of ZnO is sandwiched between two electrodes, and it is deposited on the bottom surface of a quartz substrate. The PDMS channel is aligned along the transducers on the top surface of the substrate. The device is glued on a piece of printed circuit board, which has soldered high-frequency connectors. The electrical connection is achieved by means of a piece of 2-mil gold wire between the connectors and the transducer electrodes using silver ink. The transducers are evenly distributed along the mixing channel on the other side of the quartz wafer. One can fabricate transducers with various electrode patterns as shown in **Figure 54(b)**. **Figure 55** depicts the experimental mixing results obtained by pumping phenolphthalein and NaOH solutions into the mixing channel from the two inlet channels at the same

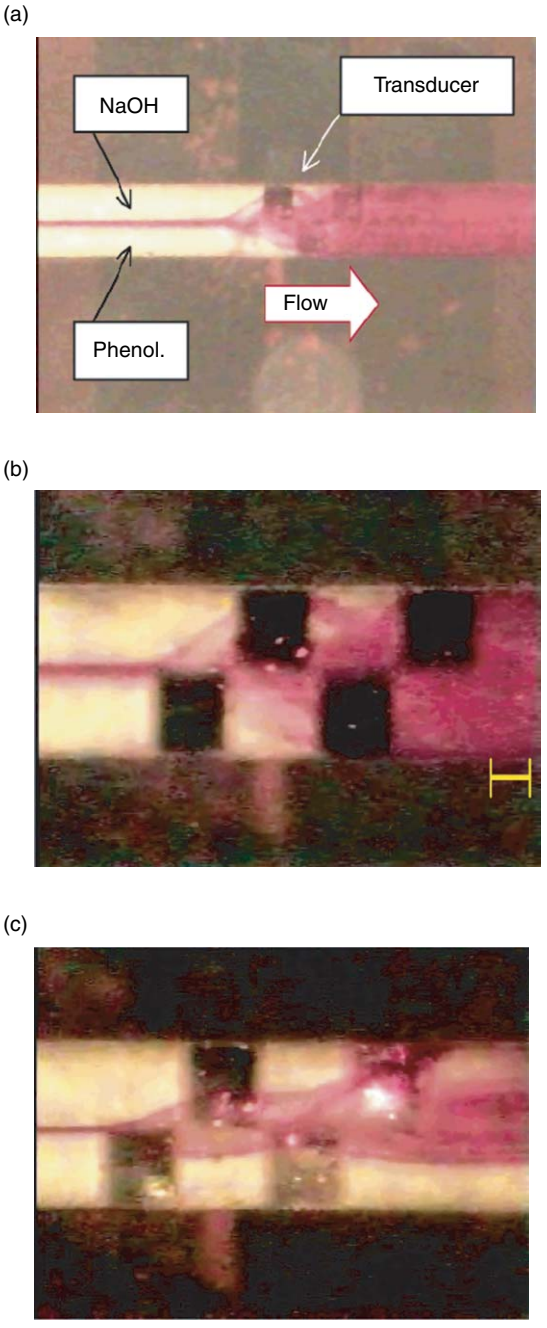

Figure 55 Experimental mixing results of the ultrasonic mixer in which two fluid streams are continuously pumped through the mixer and the main flow is disturbed by a secondary flow induced by the acoustic streaming of the liquid above the transducers. (a) The flow rate in the mixing channel is $10\,\mu l\,min^{-1}$; (b) in the vicinity of the transducers at flow rate $10\,\mu l\,min^{-1}$; and (c) in the vicinity of the transducers at flow rate $60\,\mu l\,min^{-1}$. (Source: Yaralioglu G G, Wygant I O, Marentis T C, Khuri-Yakub B T 2004 Ultrasonic mixing in microfluidic channels using integrated transducers. *Anal. Chem.* **76**, 3694–8.)

flow rates. The colorless solutions generate a pink color when mixed. By observing the intensity of the color, one can estimate the mixed amounts of the two solutions. When the total flow rate in the mixing channel is $10\,\mu l\,min^{-1}$ (the associated Reynolds number is 0.86), the two solutions remain well separated in the mixing channel before passing the transducer, and the diffused chemicals generate only a pink line at the interface of the two fluids. The yellow color of the solution well before the transducer is due to the gold electrode covering the bottom surface of the substrate where the transducers are fabricated. **Figure 55(b)** depicts the zoomed image of **Figure 55(a)** in the vicinity of the transducer, which is driven by a sinusoidal voltage of $V_{pp} = 1.2\,V$ at 450 MHz, and the pink color almost covers the entire channel, which indicates that complete mixing of the chemicals is achieved just following the transducer. **Figure 55(c)** depicts the mixing result when the total flow rate in the mixing channel is $60\,\mu l\,min^{-1}$. As the flow rate increases, color uniformity across the channel degrades. Therefore, for a higher flow rate, one has to increase the power level applied to the transducers to get a uniform mixing across the channel. The main mixing mechanism is the transverse secondary flow generated by the acoustic streaming of the liquid above the transducers. The stream pushes the fluid toward the top of the channel and a circulating flow perpendicular to the main flow is induced.

2.10.3.7 Magnetohydrodynamic Mixer

The application of electromagnetic forces to the pump, confine, and control fluids and is by no means new. MHD is, however, mostly considered in the context of highly conducting fluids such as liquid metals and ionized gases (Davidson 2001, Woodson and Melcher 1969).

Consider a conduit with two electrodes deposited along its opposing walls. The conduit is filled with a mixture of a weakly conductive solution. When a potential difference is applied across the two opposing electrodes, a current density $\mathcal{J}$ transmits through the solution. The entire device is subjected to a magnetic field of intensity B (**Figure 56**). The interaction between the electric current density $\mathbf{J}$ and the magnetic field $\mathbf{B}$ generates a Lorentz force $\mathbf{J} \times \mathbf{B}$, which is directed along the axis of the conduit (in the z-direction that is perpendicular to the cross section) and drives the fluid motion. Witness that the Lorentz force plays a similar role to that of a

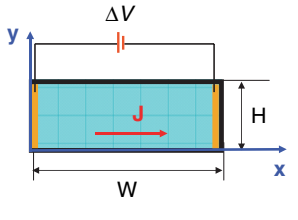

Figure 56 A cross section of a conduit filled with an electrolyte solution and exposed to a magnetic field of intensity *B*. Two electrodes are deposited along the opposing walls and are subjected to a potential difference ΔV, and a current density **J** transmits through the solution. The interaction between the current density **J** and the magnetic field **B** generates a Lorentz force $\mathbf{J} \times \mathbf{B}$ that induces fluid motion.

pressure gradient, and the induced flow motion is similar to a pressure-driven flow.

Since the direction of the current and thus the direction of the force can be controlled by appropriate design of the electrodes, a number of researchers have recently constructed MHD micropumps on silicon and ceramic substrates and demonstrated that these pumps are able to move liquids around in small conduits (Bau 2001, Jang and Lee 2000, Lemoff and Lee 2000, 2003, Zhong *et al.* 2002). Bau *et al.* (2001, 2002, 2003) also showed the feasibility of using MHD forces to control fluid flow in microfluidic networks. By judicious application of various potential differences to different electrode pairs, one can direct the liquid to flow along any desired path without the need of valves and pumps. **Figure 57** depicts a simple example of an MHD microfluidic network fabricated with low-temperature cofired ceramic tapes (Bau *et al.* 2003). The MHD network contains two reservoirs, one stores reagent A and the other reagent B. The solutions are pumped out of the two reservoirs, and flow through the conduit 1 which doubles as a stirrer. Once the reagents are stirred, they are pumped into the torus (conduits 2–3). The electrodes are then reprogrammed to circulate the fluid around the torus (2–3) for a desired number of times. Various regions of the torus can be maintained at different temperatures, allowing thermal cycling and potentially PCR. Once the DNA amplification is completed, the electrodes are reprogrammed and the fluid is pumped back either to conduit 1 or to conduit 4 for further processing. By changing the polarity of the electrodes, one can readily modulate the direction of the flow. Subsequently, the fluid is split into two separate paths (conduits 5 and 6) for parallel analysis. Finally, the waste is recombined at the conduit 7.

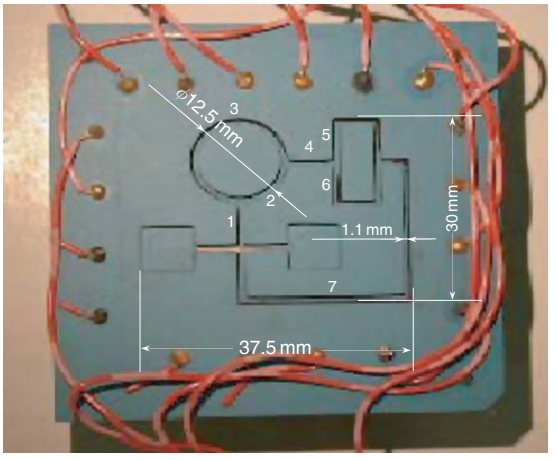

Figure 57 A prototype of a magnetohydrodynamic (MHD) microfluidic network. (Source: Bau H H, Zhu J, Qian S, Xiang Y 2003 A magneto-hydrodynamically controlled fluidic network. *Sens. Actuators B* **88**, 205–16.)

2.10.3.7.1 Annular MHD stirrer

Other applications of microfluidic MHD components and devices are MHD-based stirrers. Gleeson (2005) and Gleeson *et al.* (2004) proposed an annular MHD stirrer. Two electrodes are positioned along the inner and the outer walls of a toroidal conduit to form opposing electrodes, and the device is positioned in an external magnetic field. The direction of the flow is reversed periodically by switching the polarity of the two opposing electrodes. Such a stirrer takes advantage of Taylor dispersion (Taylor 1953) to increase the surface area between the two interacting fluids. **Figure 58** depicts the operation of an idealized MHD annular micromixer, which stretches the fluid interface at each revolution of the fluid around the annulus. This leads to a linear growth of the total interface length with time, which is much better than the rate of diffusion alone that is proportional to the square root of time but less effective than the exponential stretching associated with the MHD chaotic stirrers as developed by Bau and coworkers (Qian and Bau 2005a, b, Qian *et al.* 2002, Xiang and Bau 2003, Yi *et al.* 2002b).

2.10.3.7.2 MHD chaotic stirrer I: MHD stirrer in a chamber

Alternatively, one can pattern electrodes of various shapes, which in turn induce electric fields in different directions. The interaction of such electric fields with the magnetic field induces secondary flows that may

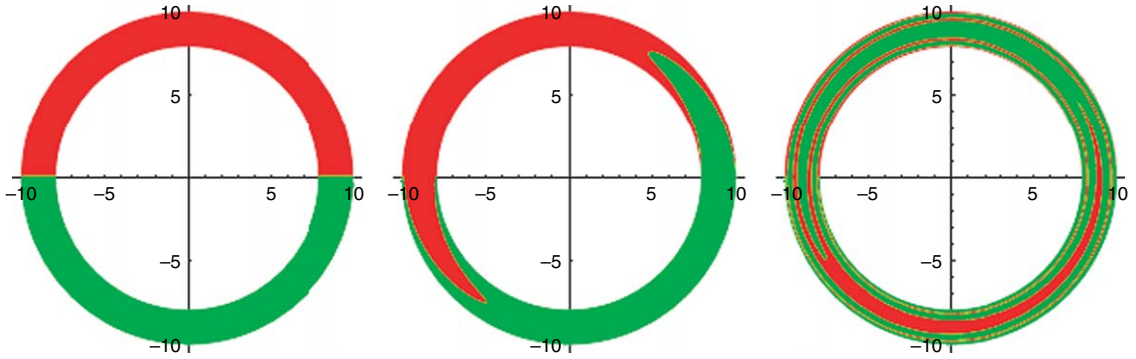

Figure 58 Operation of an idealized magnetohydrodynamic (MHD) annular mixer at three various times. (Source: Gleeson J P, Roche O M, West J, Gelb A 2004 Modelling annular micromixers. *SIAM J. Appl. Math.* **64**, 1294–310.)

benefit stirring and mixing. Although these secondary flows significantly enhance the mixing process, they are well ordered and the mixing remains rather poor. The performance can however be significantly improved. Indeed, by periodically or aperiodically alternating two or more different flow patterns, one can induce (Lagrangian) chaotic advection. Aref (1984) described the general ideas associated with chaotic mixing, and similar ideas were implemented in the context of microfluidic systems and MHD stirrers (Qian and Bau 2002, 2005a, b, Qian *et al.* 2002, Xiang and Bau 2003, Yi *et al.* 2002b).

Yi, Qian, and Bau (hereafter referred to as YQB) described a MHD stirrer consisting of a closed cylindrical cavity with an electrode (denoted C) deposited around its periphery and two additional electrodes A and B placed eccentrically inside the cavity (Yi *et al.* 2002b). **Figure 59** schematically depicts the MHD stirrer in a closed cavity. A magnetic field parallel to the cavity axis is externally applied. When a potential difference is applied across the electrode pair A–C, a circulatory flow pattern results with its center of rotation near the electrode A. **Figure 60(a)** depicts the computed streamlines and **Figure 60(b)** depicts the experimental passive tracer's trajectories when the electrode pair A–C is engaged. When a potential difference is applied across the electrode pair B–C, a similar flow pattern results with its center of rotation next to the electrode B.

When the electric potential differences are applied alternately across the electrode pairs A–C and B–C with a period T, the two different flow patterns are periodically switched on and switched off. At small periods T, the flow is regular and periodic in most of the cavity. At relatively large periods, the passive tracer experiences global chaotic advection. **Figure 61** depicts the Poincaré sections (*left column*) and flow visualizations (*right column*) at various periods. As the period T increases, the complexity of the flow increases.

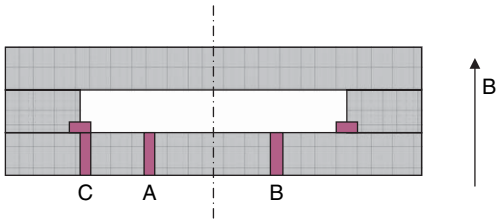

Figure 59 A schematic representation of a magnetohydrodynamic (MHD) stirrer in a cylindrical cavity. The plum segments denote the electrodes. Electrodes A and B are eccentrically located at the bottom of the cavity. Electrode C is shaped like a disk and surrounds the cavity. The cavity is filled with a weakly conductive solution and is positioned in a permanent magnet with magnetic field **B** parallel to the axis of the mixing chamber. (Source: Yi M, Qian S, Bau H H 2002 A magnetohydrodynamic chaotic stirrer. *J. Fluid Mech.* **468**, 153–77.)

2.10.3.7.3 MHD chaotic stirrer II: MHD stirrer in an MHD-controlled network

Later, Qian *et al.* (2002) developed a variant of YQB's stirrer that is better suited for integration into the MHD network shown in **Figure 57**. Only slight modifications are needed in the network's branches so that they can serve the double function of a pump and a stirrer. The basic building block (branch) of such a network is depicted in **Figure 62**. The branch consists of a conduit with two electrodes (denoted as C^+ and C^-) deposited along its two opposing walls. The conduit is filled with an electrolyte solution. Many conduits of the type depicted in **Figure 62** can be connected to form a network, and one example is shown in **Figure 57**. The entire device is subjected to a uniform magnetic field in the z-direction. When a potential difference is applied across the electrodes C^+ and C^-, the resulting current interacts with the magnetic field to form body

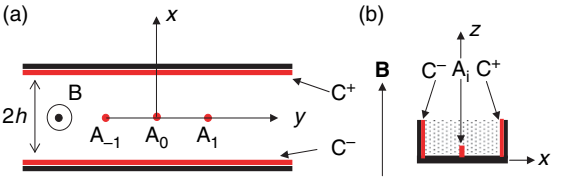

Figure 62 A liquid-filled conduit is confined between two parallel plates ($x=\pm h$). A uniform magnetic field, **B**, is parallel to the z-coordinate. Electrodes C^+ and C^- are deposited along the confining plates ($x=\pm h$) and point electrodes A_{-1}, A_0, and A_1 are positioned along $x=0$ with a separation distance denoted c. When the device operates as a stirrer, the electrodes C^+ and C^- are wired to form a single electrode C. (a) Top view and (b) side view. (Source: Qian S, Zhu J, Bau H H 2002 A stirrer for magnetohydrodynamically controlled minute fluidic networks. *Phys. Fluids* **14**, 3584–92.)

(Lorentz) forces that propel the fluid. By judicious application of different potential differences to different electrode pairs, one can direct the liquid to flow along any desired path. In other words, MHD allows us to control fluid flow in the microfluidic network in very much the same way as one controls electric current flow in an electronic circuit.

Additional point electrodes (denoted as A_i in **Figure 62**) are deposited along the centerline of the conduit's bottom. When the network branch operates as a stirrer, both electrodes C^+ and C^- are connected to the same terminal of a power supply so that they form a single electrode C. When a potential difference is applied across any of the central electrodes A_i and the electrode C, circulatory motion ensues with the liquid rotating around the engaged point electrode A_i.

When two or more electrode pairs are alternatively actuated, complex, chaotic flows are induced. **Figure 63(a)–63(c)** depicts the stroboscopic images of a passive tracer (I) and flow observations (II) when two agitators A_{-1}–C and A_1–C induce corotating motions and the alternation periods are $T=4$, 8, and 20, respectively. Each stroboscopic image is a superposition of snapshots that depict the location of the tracer particle at the end of each period, and it is referred to as Poincaré sections, which are often used as a diagnostic tool to determine the effectiveness of the stirring process. When the points that emerge lie on a smooth curve, the motion is deemed to be nearly regular (poor stirring). A scattered pattern corresponds to chaotic motion. When the period (T) is relatively small (**Figure 63(aI)**, only narrow regions of irregularity are observed. The chaotic region is a result of the homoclinic tangle next to

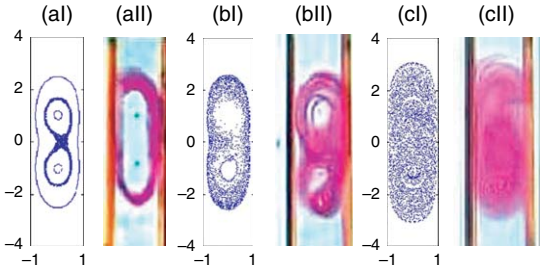

Figure 63 (I) Stroboscopic images and (II) flow visualization photos when two (corotating) electrode pairs are engaged. (a) $T = 4$; (b) $T = 8$; (c) $T = 20$. (Source: Qian S, Zhu J, Bau H H 2002 A stirrer for magnetohydrodynamically controlled minute fluidic networks. *Phys. Fluids* **14**, 3584–92.)

the hyperbolic point. Both the theoretical and the experimental data illustrate that at relatively small periods, the flow has a structure similar to the superposed flow topology observed in the limiting case $T \to 0$. As T increases (**Figure 63(b)**), the size of the chaotic region and the spread of the dye increase. When $T = 20$ (**Figure 63(c)**), the chaotic region has nearly occupied the entire region $-3 < y < 3$. Careful examination, however, reveals the persistence of small regular regions.

Another way to examine the stirring process is to track the history of a material blob inserted into the liquid. **Figure 64** depicts the evolution of a square material blob of edge size 0.1, centered at (0, 0), as a function of time by integrating the trajectories of 10^4 points initially evenly distributed within the square. The figure depicts the blob's evolution at times $t = 2T$ (**Figure 64(a)**), $3T$ (**Figure 64(b)**), $4T$ (**Figure 64(c)**), $6T$ (**Figure 64(d)**), and $20T$ (**Figure 64(e)**), and compares the computational results with experimental observations. The computational results qualitatively agree with the experimental flow visualizations. After about 6 periods, the material blob has covered most of the conduit.

This arrangement is similar to Aref's (1984) blinking vortex. However, in contrast to Aref's highly idealized, inviscid system, the stirrer developed here can be readily constructed, which is yet another example of Stokes flow that exhibits chaotic advection.

2.10.3.7.4 MHD chaotic stirrer III: MHD stirrer without internal electrodes

All the MHD stirrers described above require some of the electrodes to be patterned inside the conduit or chamber and away from the walls of the conduit/

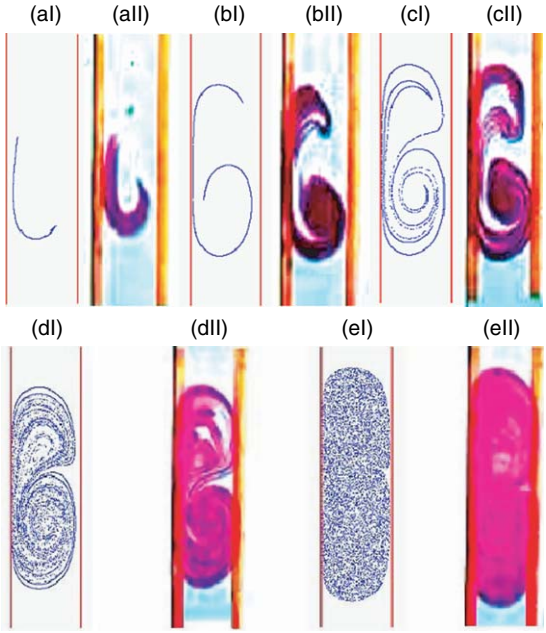

Figure 64 Deformation of a material blob alternatively excited by two electrode pairs. Counterrotating, $c = 1$ and $T = 20$. (I) and (II) represent the computational results and the visualization photos of the experiment, respectively. (a) $t = 2T$; (b) $t = 3T$; (c) $t = 4T$; (d) $t = 6T$; (e) $t = 20T$. (Source: Qian S, Zhu J, Bau H H 2002 A stirrer for magnetohydrodynamically controlled minute fluidic networks. *Phys. Fluids* **14**, 3584–92.)

chamber. In some cases, such internal electrodes may be intrusive. To alleviate this potential shortcoming, a new stirrer design that does not require any interior electrodes was developed (Qian and Bau 2005a). The same electrodes used for pumping are used for stirring. This arrangement requires fewer fabrication steps than were required in the previous designs, and it also minimizes the intrusion that arises when introducing internal electrodes. The newly designed MHD stirrer can operate as a stand-alone component or it can be incorporated into a MHD-controlled network.

The stirrer consists of a conduit equipped with individually controlled electrodes that are positioned along the opposing walls of the conduit, and there is a small dielectric gap between the adjacent electrodes. **Figure 65** depicts a photograph of the device. The conduit is filled with a weakly conductive electrolyte solution, and the device is placed in a static magnetic field of flux density **B**.

When the device serves as a pump, the electrodes along one side of the conduit's walls are wired to form a single electrode C^+, which is connected

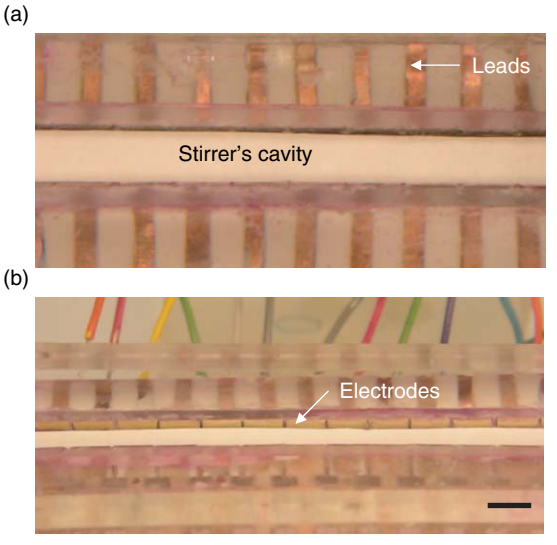

Figure 65 A photograph of the magnetohydrodynamic (MHD) stirrer without internal electrodes inside the microfluidic channel. (a) Top view showing the leads of the electrodes. (b) Oblique view showing the individual electrodes positioned along the wall of the stirrer's conduit. Scale bar, 2 mm.

to one terminal of the power supply. The electrodes along the other side of the conduit's walls are similarly wired to form a single electrode C^-. When a potential difference ΔV is applied between the two groups of electrodes C^+ and C^-, the current direction is nearly normal to the surface of the electrodes, the Lorentz force is directed along the conduit's axis, and the device operates as a pump.

When only two of the electrodes that are diagonally positioned along the opposing walls are activated (i.e., electrode pair $C_0^- - C_1^+$ as depicted in **Figure 66**), the direction of the current flow is oblique to the electrodes' surfaces and the resulting Lorentz force has a component transverse to the conduit's axis. As a result, one observes cellular flow to enhance mixing. When a potential difference is applied across another diagonal electrode pair such as $C_0^- - C_{-1}^+$, a nearly mirror image of the flow pattern forms. By periodically or aperiodically alternating the two flow patterns, one can obtain more complicated trajectories of the passive tracer particles and can achieve chaotic advection that elongates the length of the interface at an exponential rate. The stirring process is described more vividly in **Figure 66**. Red and green dye blobs were introduced into the conduit, and their evolution was tracked as a function of time. At $t = 0$, the red and the green dyes are well separated (**Figure 66**, $t = 0$). After one period, some of the red dye is surrounded by the green dye (**Figure 66**, $t = T$). As the time increases, through continuous stretching and folding, which are

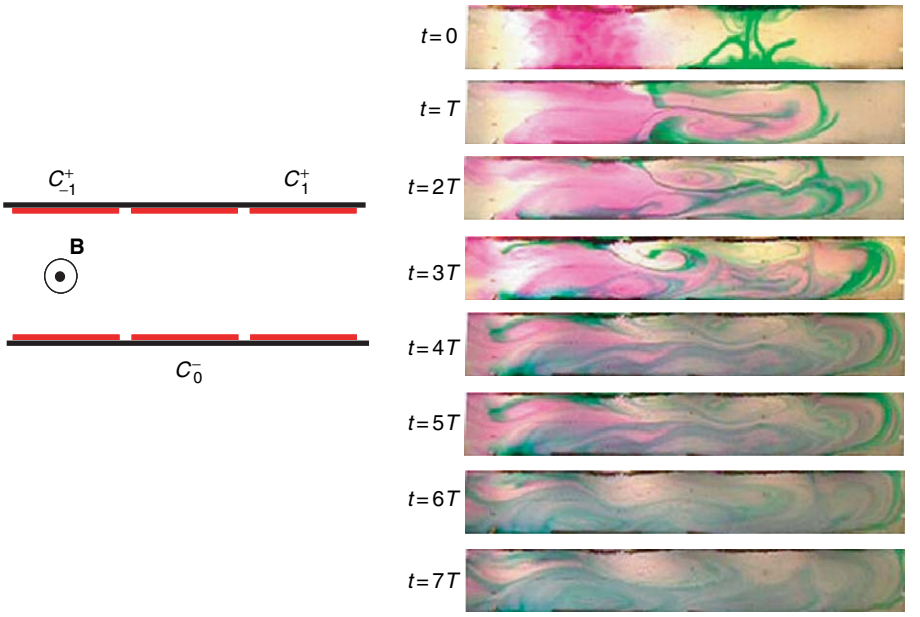

Figure 66 Images of the blending process when initially well-separated red and green dye blobs are introduced into the stirrer. The various images correspond to time $t = 0$, T, $2T$, $3T$, $4T$, $5T$, $6T$, and $7T$. Two diagonally positioned electrode pairs $C_0^- - C_1^+$ and $C_0^- - C_{-1}^+$ are alternatively active with a potential difference $\Delta V = 2.5$ V and a period $T = 4$ s. (Source: Qian S, Bau H H 2005 Magnetohydrodynamic stirrer for stationary and moving fluids. *Sens. Actuators B* **106**, 859–70.)

characteristics of chaotic advection, the two dyes blend in the mixing region. Here only three electrodes, C_0^-, C_{-1}^+, and C_1^+, are engaged, and one can increase the volume of the mixing region by increasing the number of engaged electrodes.

So far, we have described the operation of the stirrer when the only fluid motion in the conduit was due to the agitation induced by the MHD stirrer. In other words, no through flow was present. In certain circumstances, it may be desirable to stir the fluids while it is pumped through the conduit. Such net fluid motion can be driven either by an external pressure or by an MHD drive located some distance away from the stirring region. **Figure 67(a)** schematically depicts the new design in which both fluid propulsion and mixing are achieved by MHD. The device consists of a microfluidic channel with pumping electrodes C^+ and C^- located at both ends and deposited along the opposing walls of the channel. When a potential difference is applied across the electrodes C^+ and C^-, the fluid is pumped from one end of the device to the other. Between the pumping electrodes, there is a mixing region where several individually controlled mixing electrodes denoted as TO, TE, BO, and BE are positioned along the opposing walls with a small dielectric gap between the adjacent electrodes. In the mixing region, a transverse velocity component is created when a potential difference is applied across electrodes that are diagonally positioned. **Figure 67(b)** depicts the flow field and trajectories of passive particles in the mixing region when a potential difference is applied across electrode pair TO–BE. In the upstream of the mixing region, the velocity profile is parabolic. In the mixing region, the main flow is perturbed by the induced Lorentz forces and zigzag trajectories of passive particles result. As before, a potential difference is alternatively applied across electrode pairs TO–BE and TE–BO with a period T and a chaotic advection is induced in the mixing region. The fluids are mixed after they are pumped through the mixing region.

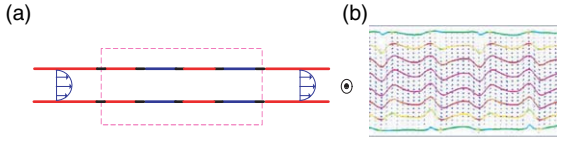

Figure 67 (a) Schematic representation of magnetohydrodynamic (MHD) pumping and mixing in a microfluidic channel. Pumping electrodes C^+ and C^- are located at both ends of the channel and are deposited along the opposing walls, and several individually controlled mixing electrodes denoted as TO, TE, BO, and BE are positioned along the opposing walls with a small dielectric gap between adjacent electrodes. The device is positioned in a magnetic field **B**. (b) Flow field and trajectories of passive particles in the mixing region when a potential difference is applied to the diagonally positioned electrode pair TO–BE.

2.10.3.8 Electroosmotic Mixer

Electroosmosis is very attractive for manipulating fluids in microdevices. It can be readily seen from eqn [1] that the zeta potential is an important factor that affects the EOFs. Zeta potential is related to, among other things, the surface chemistry or surface charge density of the channel, eventually the pH value of the solution, and the electrolyte concentration. A plug flow is generated if the surfaces are homogeneously charged, but heterogeneous charge surfaces are often unavoidable because of surface defects. In some situations, an inhomogeneous surface charge distribution is designed for generating desirable flow structures. For example, 3D recirculating EOFs are generated by patterning materials of different zeta potentials inside a channel, as discussed in Section 2.10.2.5.

To control the EOF, the zeta potential of a channel wall can be dynamically modulated as a result of changes in the potential applied to gate electrodes embedded beneath the solid–liquid interface (Lee *et al.* 1990, Lin *et al.* 2005, Schasfoort *et al.* 1999, Wu and Liu 2005). **Figure 68** schematically depicts the control of EOF in a channel with one embedded electrode called the gate electrode. Witness that the gate electrode does not contact the liquid. The zeta potential can be estimated from the following expression (Wu and Liu 2005):

$$\zeta = \sinh^{-1}\left(\frac{\kappa(\sigma_v - \sigma_s)}{4n_0 ze}\right)\exp(-\kappa d) \qquad [4]$$

In the above, $\kappa = (2n_0 z^2 e^2 / k_B T \varepsilon_0 \varepsilon_r)^{1/2}$ is the reciprocal screening Debye length, n_0 is the bulk ionic concentration, z is the valance of the symmetric ions, e is the elementary charge, k_B is the Boltzmann constant, T is the absolute temperature of the liquid solution, d is the distance from the outer Helmholtz plane to the shear plane, $\varepsilon_0\varepsilon_r$ is the dielectric permittivity of the solution, $\sigma_v = \varepsilon_0$

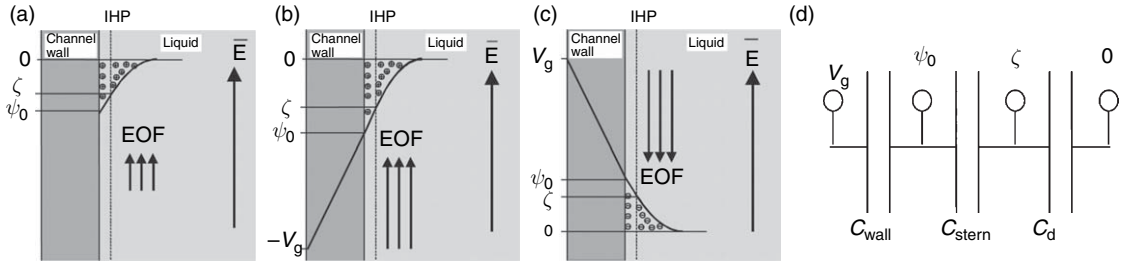

Figure 68 Schematic representation of controlling electroosmotic flow (EOF) through the modulation of the gate potential applied to the gate electrode embedded beneath the solid–liquid interface. (a) Illustration of the development of the zeta potential and EOF at the solid–liquid interface; (b) enhance EOF; (c) reverse EOF; (d) the three capacitors in series that are used to describe the effect of V_g on zeta potential, ζ. ψ_0 represents the surface potential of the insulator surface. (Source: Schasfoort R B M, Schlautmann S, Hendrikse J, Van den Berg A 1999 Field-effect flow control for microfabricated fluidic networks. *Science* **286**, 942–5.)

$\varepsilon_w(V/W)$ is the induced surface charge density due to the potential applied to the gate electrode, $\sigma_s = -(\gamma e/(1 + [H^+]/K_a))$ is the surface charge density at the solid–liquid interface, $\varepsilon_0\varepsilon_w$ is the dielectric permittivity of the channel wall, W is the thickness of the channel wall, V is the applied gate potential, γ is the sum of both the ionized and the protonated surface silanol group concentrations when the channel wall is made of SiO_2-based material, $[H^+]$ is bulk buffer hydrogen ionic concentration, and finally K_a is the acid dissociation constant of silanol groups.

From eqn [4], the modulation of the zeta potential through the control of the gate potential, V, strongly depends on the pH value and the concentration of the solution. The numerical simulations demonstrated that the lower the pH value and the lower the electrolyte concentration, the more sensitive the modulation of the zeta potential via the applied gate potential (Wu and Liu 2005). When there is no gate potential applied to the gate electrodes and the channel wall is negatively charged, the positive ions are attracted toward the charged surface, and the liquid moves in the same direction as that of the driving electric field (**Figure 68(a)**). One can increase the magnitude of the zeta potential, thereby enhancing the flow, by applying a negative gate potential to the embedded gate electrode (**Figure 68(b)**). One can also reverse the polarity of the zeta potential by applying a positive gate potential to the gate electrode, as shown in **Figure 68(c)**, which leads to a reversed flow.

One can pattern several individually controlled gate electrodes embedded beneath the solid–liquid interface, and complex flow field for enhancing the mixing can be generated by spatial and temporal modulation of the zeta potentials along the channel walls (Qian and Bau 2002, 2005b). **Figure 69** depicts two examples of flow patterns in a closed cavity with four electrodes (red segments) embedded along the top and bottom channel walls. The driving electrodes, i.e., the anode and the cathode, are located at the left and the right end, respectively, of the cavity. By controlling the gate potentials applied to the gate electrodes, the top and bottom channel walls are controlled to be negatively and positively charged, respectively. The liquid in the EDL next to the top channel wall moves in the same direction as that of the electric field, and the liquid in the EDL next to the bottom channel wall moves in the direction opposite to that of the applied electric field. The arrows in **Figure 69** depict the directions of the EOFs at the edge of the EDL. The left and right walls serve to restrict the flow and thus a clockwise

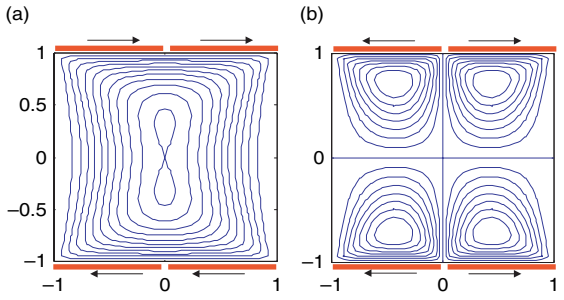

Figure 69 Streamline patterns for electroosmotic flows (EOFs) within a cavity with nonuniform zeta potentials at the top and bottom surfaces. The red lines represent the embedded gate electrodes, and the arrows denote the directions of the electroosmotic velocities at the edge of the electric double layer.

cellular flow pattern occurs (**Figure 69(a)**). By controlling the gate potentials applied to the gate electrodes located at the left half of the upper wall and the right half of the bottom wall, the polarities of the zeta potentials at the left half of the upper wall and the right half of the bottom wall are reversed and four counterrotating vortices occur within the cavity (**Figure 69(b)**).

We choose two basic flow patterns, say, A (**Figure 69(a)**) and B (**Figure 69(b)**), and maintain the flow field type A for a time interval $0 < t < T/2$, switch to the flow field type B for the time interval $T/2 < t < T$, and then switch back to the flow A. The process is repeated with a period T. The switching from one flow pattern to the other is accomplished by controlling the zeta potential distribution with the aid of the embedded electrodes. It is easy to imagine the trajectories of a passive (nondiffusing) tracer particle. In the time interval $0 < t < T/2$, the particle will follow the streamlines that correspond to the flow pattern A. In the time interval $T/2 < t < T$, the particle will follow the path dictated by the streamlines that correspond to the pattern B. As the flow field switches from A to B, the particle will trace a zigzag path that eventually will cause it to sample most of the cavity's area. **Figure 70** depicts the evolution of a material blob (i.e., dye) with 10^4 passive tracer particles when $T = 8$. These figures illustrate the stretching and folding process of the blob. Ultimately, the fluid particles spread to cover almost the entire area of the cavity. Numerical simulations conclude that chaotic mixing occurs by alternating two or more flow patterns in a cavity and in an open channel through the spatial and temporal control of

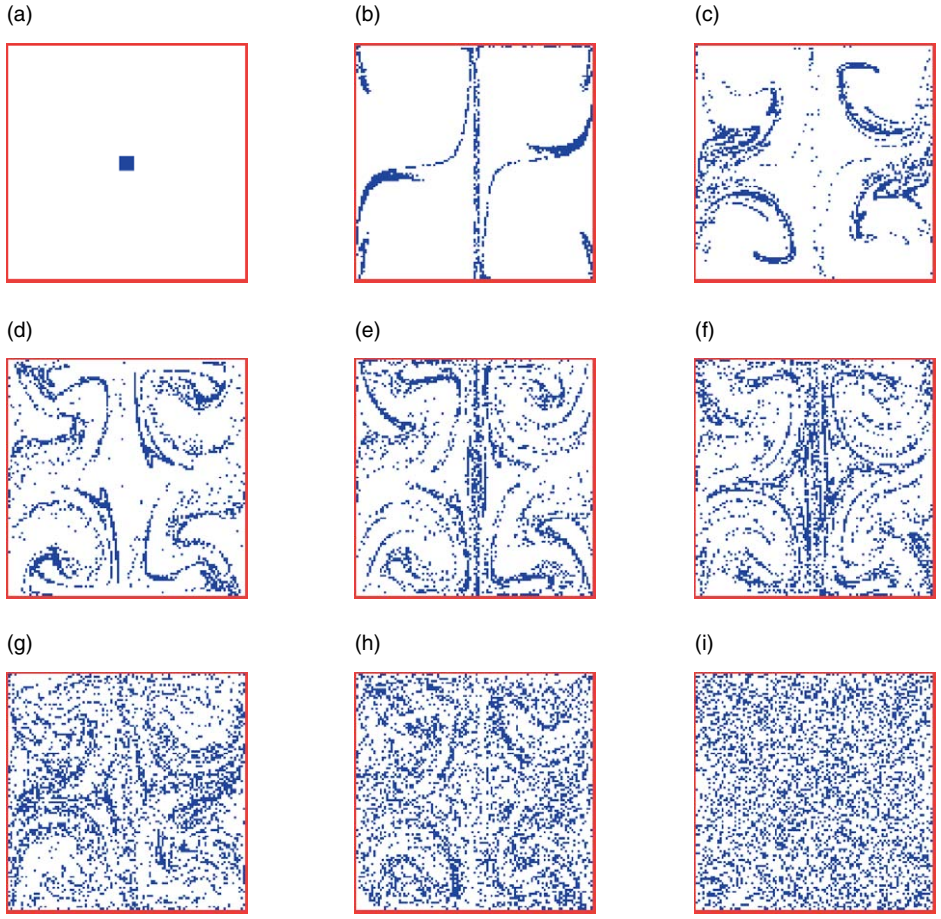

Figure 70 Deformation of a material blob of edge size 0.1 initially ($t = 0$) centered at (0, 0) at $T = 8$. (a) $t = 0$; (b) $t = 2T$; (c) $t = 4T$; (d) $t = 6T$; (e) $t = 7T$; (f) $t = 8T$; (g) $t = 10T$; (h) $t = 12T$; and (i) $t = 20T$. (Source: Qian S, Bau H H 2005 Theoretical investigation of electro-osmotic flows and chaotic stirring in rectangular cavities. *Appl. Math. Modell.* **29**, 726–53.)

the gate potentials (Qian and Bau 2002, 2005b). Later, the proposed electroosmotic mixer has been successfully tested in experiments (Lin *et al.* 2005, Wu and Liu 2005).

Figure 71 shows photograph of the electroosmotic mixer developed by Lin *et al.* (2005). Two fluid streams are brought together through the Y-junction and flow downstream in the straight microchannel equipped with inclined shielding electrodes (black segments). One can dynamically control the local zeta potential variations along the surface of silica-based microchannel through the control of the electric potential applied to the shielding electrodes. When a high voltage is applied to the shielding electrodes, negative charges will be induced on the channel surface by the capacitance effect. **Figure 72** depicts the images of fluorescence dye in the mixing region where the five-pair shielding electrodes are located. During the mixing, the shielding electrodes 1, 4, 5, 8, and 9 are activated with an applied potential of 900 V during the first half period, and the shielding electrodes 2, 3, 6, 7, and 10 are activated with an applied potential of 900 V during the second half period, and this procedure is repeated at a frequency of 0.5 Hz. Initially, the flow is laminar and stable with the two fluids clearly separated. When the control shielding voltage is alternately applied on the inclined shielding electrodes, significant mixing is observed due to the induced wave-shape flow pattern.

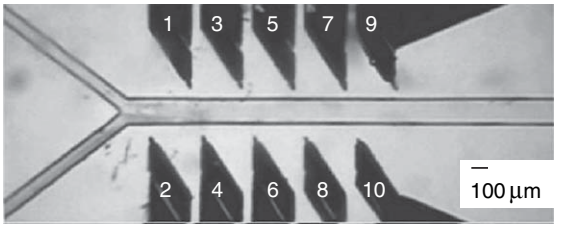

Figure 71 Photograph of the electroosmotic mixer with inclined shielding electrodes. Spatial and temporal variations of the zeta potential along the microchannel are controlled through the control of the potentials applied to the individually shielding electrodes. Figure 72 Images of fluorescence dye in the mixing region with five-pair inclined shielding electrodes. (a) Simulation results and (b) experimental results. (Source: Lin J L, Lee K H, Lee G B 2005 Active mixing inside microchannels utilizing dynamic variation of gradient zeta potentials. *Electrophoresis* **26**, 4605–15.)

A similar electroosmotic mixer was developed by Wu and Liu (2005) with Al electrodes embedded at the middle of the straight channel. By periodic control of the zeta potentials via the gate potentials applied to the embedded Al electrodes, excellent mixing efficiency of over 90% has been successfully achieved after the liquid flows through a 5-mm-long microchannel.

Since the electroosmotic velocity is proportional to the local zeta potential and the local electric field, instead of dynamically controlling the variations of the local zeta potentials, one can also manipulate the electric field with fixed zeta potentials along the channel walls. For example, one can enhance mixing using alternatively switching EOF by applying a switching DC driving electric field (Lin *et al.* 2004a,b). This mixer is basically a T-mixer that works with a switching DC field to induce EOFs for sample driving and flow instability generation. A ground electrode is located at the outlet of the T-mixer. In a convectional switching mode, the driving voltage is applied alternatively first to one inlet reservoir and then to the other. In other words, a driving voltage is applied to one inlet, denoted as inlet A, and the other inlet, denoted as inlet B, remains open during the first half period. During the second half period, the driving voltage is applied to the inlet B, and the inlet A is open. This procedure is repeated with a period T. The switching of the driving voltage from one sample reservoir to the other is achieved with a high-voltage relay. A floating voltage that is about 80% of the applied driving voltage is established at the inlet B when the driving voltage is applied to the inlet A, and the presence of the floating voltage prevents the fluid exiting from the inlet A from entering the inlet channel B. Therefore, the fluids from the two inlet channels flow alternatively into the mixing channel, which

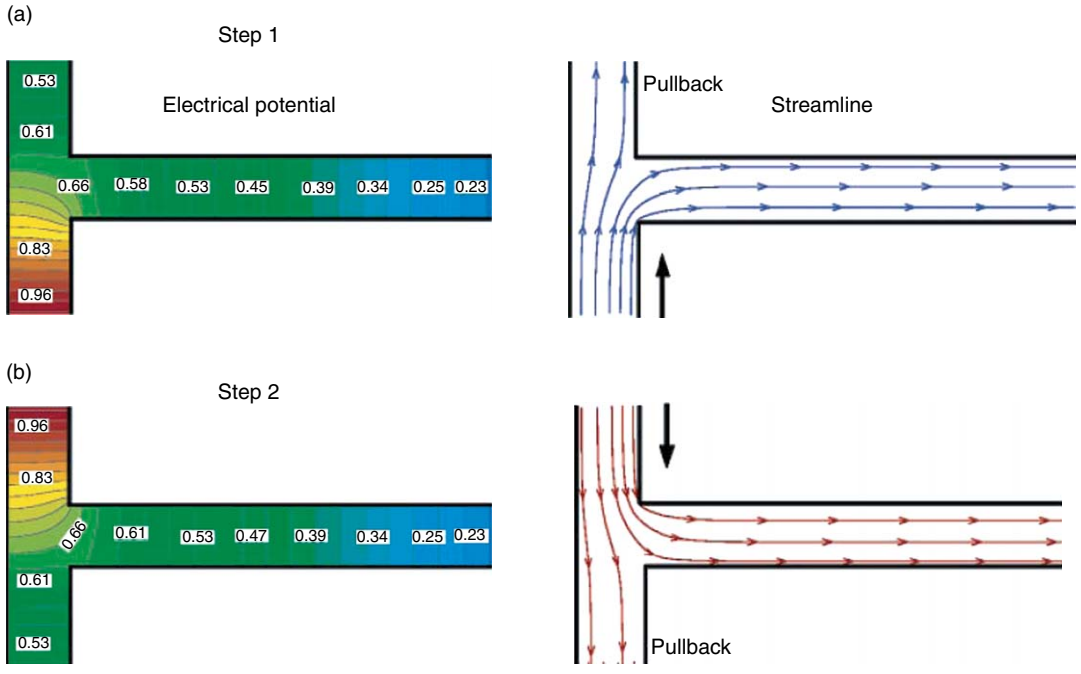

Figure 73 Electric potential distributions and streamlines in pinched switching model. (Source: Lin C H, Fu L M, Chien Y S 2004 Microfluidic T-form mixer utilizing switching electroosmotic flow. *Anal. Chem.* **76**, 5265–72.)

increases the flow instability and the contact area of the two fluid samples. However, the maximum mixing efficiency is below 60% at different switching frequencies. To improve the mixing efficiency, a pinched switching model is proposed in which a lower voltage is established at the open inlet channel by connecting a series of high-ohmic resistors between the reservoir and the ground end. Therefore, the fluid from the driven inlet flows not only into the mixing channel but also partially into the open inlet as shown in **Figure 73**. When the applied voltage switches to the other inlet, the fluid that previously flowed into the open inlet is expelled. As compared to the convectional switching model, continuous flow instability with larger amplitude is generated in the pinched switching model. The pinched switching model significantly improves the mixing performance and a 97% mixing performance has been experimentally achieved within a mixing channel 1 mm downstream from the T-junction when a 60 V cm^{-1} driving electric field is applied at a switching frequency of 2 Hz. **Figure 74** depicts the numerical and experimental results of the T-mixer with pinched switching EOF. The maximum mixing efficiency of 90% is obtained within 2 s for the driving electric field of 180 V cm^{-1} at a switching frequency of 8 Hz. Later, Fu *et al.* (2005)

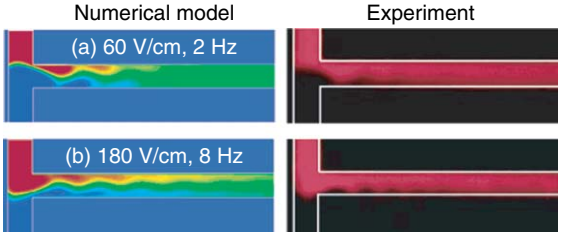

Figure 74 Numerical and experimental results of the T-mixer with alternately switching electroosmotic flow (EOF). (Source: Lin C H, Fu L M, Chien Y S 2004 Microfluidic T-form mixer utilizing switching electroosmotic flow. *Anal. Chem.* **76**, 5265–72.)

utilized the same strategy of switching driving voltage in a double T-mixer. Relative to the previous electroosmotic mixer in which the local zeta potentials are dynamically controlled, the fabrication and the operation of this mixer are simpler since it does not require the fabrication and delicate control of the embedded gate electrodes.

When a driving potential is applied to a pair of electrodes that are arranged in such a manner that they remain parallel to the channel, it can be expected that the EOF crosses the channel, and such flow can be used to perturb the main pressure-driven flow in the mixing channel (Sasaki *et al.* 2006, Sundaram and Tafti 2004). **Figure 75** schematically

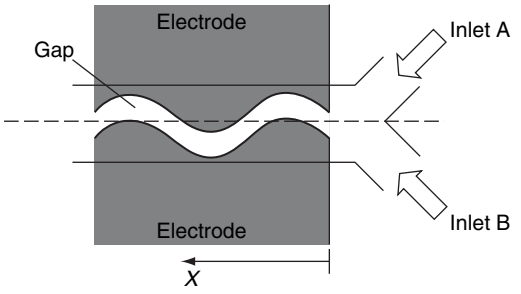

Figure 75 Schematic of a Y-shaped microfluidic channel with a pair of meandering electrodes located at the bottom of the channel to induce AC-EOF. (Source: Sasaki N, Kitamori T, Kim H B 2006 AC electroosmotic micromixer for chemical processing in a microchannel. *Lab Chip* **6**, 550–4.)

depicts a Y-shaped microfluidic channel with a pair of meandering electrodes patterned at the bottom of the channel. Two solutions are introduced into the Y-shaped channel with a two-port syringe pump, and they flow downstream in the straight microchannel of a 120 μm width and a 40 μm depth. The gap between the electrodes is 40 μm, and the periodicity of the meandering structure is 250 μm. When an AC voltage is applied to the meandering electrodes, an asymmetric circulating EOF perpendicular to the main flow is induced. The purpose of the meandering electrodes is to make periodical changes in both direction and velocity of the induced AC-EOF along the fluid stream. **Figure 76** depicts the typical experimental results when two solutions are introduced into the channel at a rate of 1 μl min^{-1}, and the total flow rate of the confluence is 2 μl min^{-1}, which corresponds to a mean velocity of 8.1 mm s^{-1} and $Re \approx 0.5$. In the images, the fluorescence intensity from part of the electrodes is enhanced due to reflection effects on the electrode surface. Before applying the AC voltage (**Figure 76(a)**), the clear interface between the two fluid streams indicates poor mixing within a length of several hundred micrometers from the junction. When a sinusoidal voltage ($V_{pp} = 20$ V at 1.0 kHz) is applied to the meandering electrodes, two fluid streams are distorted immediately and the fluorescence from the upper half side of the channel is observed at about $x > 250$ μm (**Figure 76(b)**). The experimental results from Sasaki *et al.* (2006) demonstrated that the mixing length increased almost linearly with the flow velocity of solution and the mixing time was independent of the flow velocity. For a flow velocity up to 12 mm s^{-1}, 90% mixing has been experimentally achieved within 0.2 s, while 4.4 s is required for diffusion mixing under the same condition. The mixing length also increases with the viscosity and/or the ionic strength of the solution due to the decrease in the magnitude of the AC-EOF.

When two fluid streams with different conductivities meet in a microchannel, electrokinetic instability (EKI) originating from polarization due to a conductivity gradient under high electric field conditions occurs (Chen *et al.* 2005, Lin *et al.* 2004a, b, Park *et al.* 2005, Shin *et al.* 2005). **Figure 77** depicts the EKI in a microchannel of 1 mm width, 100 μm depth, and 40 mm length as observed by Lin *et al.* (2004a, b). Two buffer solutions with different

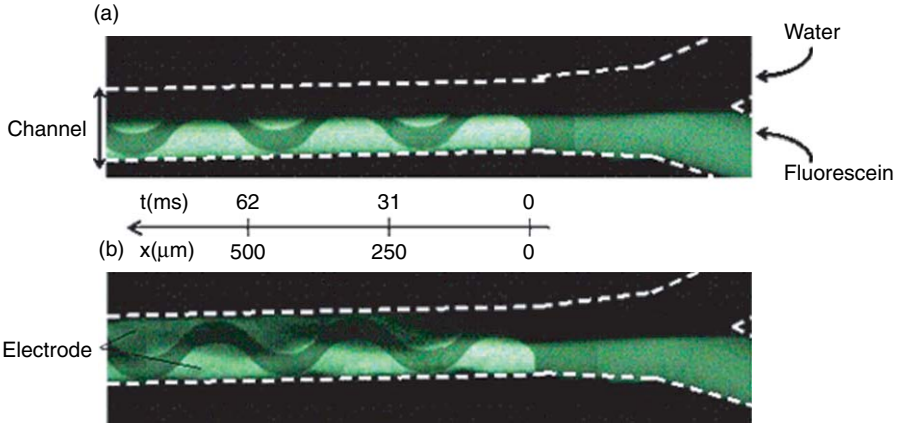

Figure 76 Experimental mixing results in (a) the absence and (b) the presence of an AC voltage ($V_{pp} = 20$ V at 1 kHz) applied to the meandering electrodes. (Source: Sasaki N, Kitamori T, Kim H B 2006 AC electroosmotic micromixer for chemical processing in a microchannel. *Lab Chip* **6**, 550–4.)

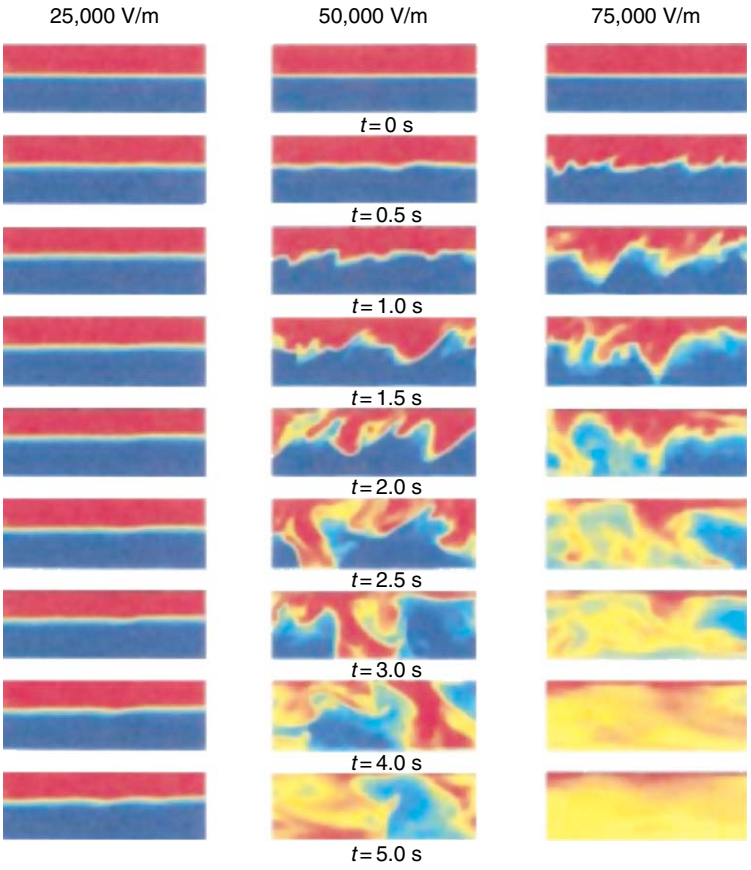

Figure 77 Instability of an electroosmotic flow (EOF) with solutions of different electrical conductivities under various electric fields as a function of the time after introduction in the microchannel. (Source: Lin H, Storey B D, Oddy M H, Chen C, Santiago J G 2004 Instability of electrokinetic microchannel flows with conductivity gradients. *Phys. Fluids* **16**, 1922–35.)

conductivities, one dyed buffer solution with a conductivity of 50 $\mu s\,cm^{-1}$and the other undyed buffer solution with a conductivity of 5 $\mu s\,cm^{-1}$, are introduced into the microchannel using a syringe pump. After the fluids are loaded into the channel, the syringe pump is deactivated and a potential difference is applied to the driving electrodes located at the inlet and outlet reservoirs that connect the channel. The driving electric field initiates an EOF in the channel. In this figure, the blue color pertains to the undyed, low-conductivity stream, and the red color represents the dyed stream with high conductivity. For a low electric field of 25 $kV\,m^{-1}$, the interface between the two streams is only slightly perturbed at 4.0 and 5.0 s. When the strength of the applied electric field exceeds a certain threshold value, an unstable fluid motion is generated, which provokes stretching and folding of the interface and thereby a rapid mixing of the two streams. At an electric field of 75 $kV\,m^{-1}$, the fluids are well mixed within 5 s. The conclusion of this is that EKI phenomenon can be successfully used to enhance mixing in microfluidic channels.

The EKI phenomenon has been adopted for micromixing by applying DC or AC electric fields in the lateral direction on liquid layers with different ionic concentrations. Strong downstream mixing was observed by the induced EKI for EOF (Oddy *et al.* 2001, Park *et al.* 2005). **Figure 78** schematically depicts a micromixer that incorporates the EKI as the stirring mechanism for rapid stirring of two fluid streams. The micromixer consists of two fluid channels of 300 μm width and 100 μm depth and a square mixing chamber (1 mm × 1 mm × 100 μm). The micromixer is fabricated using two wet-etched Borofloat glass substrates. The two fluid streams are

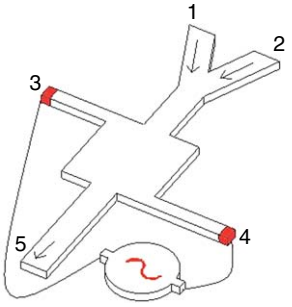

Figure 78 Schematic of an electrokinetic instability (EKI) mixer.

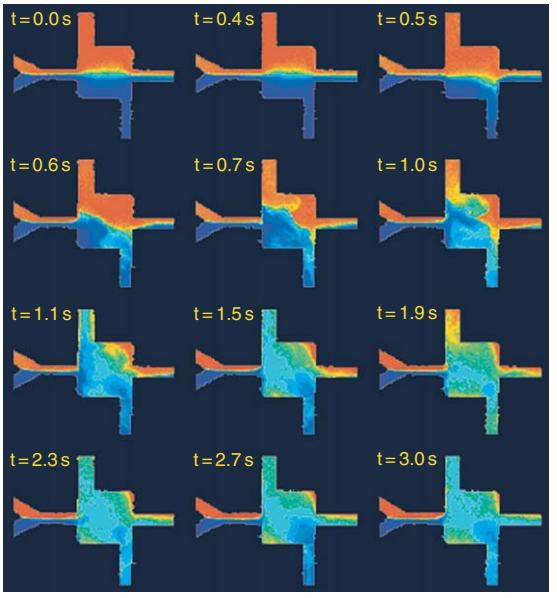

Figure 79 Experimental results of the electrokinetic instability (EKI) mixer. Fluids A and B are continuously advected from left to right, and the fluid interface is immediately disturbed upon application of the AC electric field. (Source: Oddy M H, Santiago J G, Mikkelsen J C 2001 Electrokinetic instability micromixing. *Anal. Chem.* **73**, 5822–32.)

introduced into the inlet ports 1 and 2 and are advected either electroosmotically or with pressure toward the square mixing chamber. Side channel ports 3 and 4, connected to either side of the mixing chamber, have two electrodes connected to them between which an AC electric field is applied. Molecular diffusion continues the mixing process while the stirred fluid is advected downstream from the mixing chamber toward port 5. Under certain oscillating frequencies and strengths of the applied AC electric field in the mixing chamber, EKI is induced, which in turn leads to stretching and folding of the fluids in the mixing chamber, and thus enhances mixing. In contrast to the previous electroosmotic mixer, depicted in **Figure 75**, where there is no conductivity gradient in the introduced fluids, the mixing mechanism in the EKI mixer is the EKI in the presence of conductivity gradients in the bulk fluids. **Figure 79** depicts the experimental results, and the fluid in the mixing chamber is qualitatively well mixed approximately 2.5 s after the application of the AC electric field. The disadvantage of this mixer design is that low-frequency AC voltages on the order of kilovolts are required for efficient mixing.

2.10.4 Conclusions

Laminar mixing in microfluidic devices is difficult to achieve due to the inherently low Reynolds numbers of the flows and the lack of turbulence. Various passive and active mixers have been developed to enhance laminar mixing in microfluidic LOC devices. In passive mixers, the mixing is obtained by the natural motion of the fluid as it flows through the mixing elements where mixing relies on molecular diffusion and/or chaotic advection. The microchannel geometries of passive mixers are often complicated and require intricate fabrication to create complex 3D geometries. The active mixers are principally driven by chaotic advection and are therefore usually more effective in mixing than their passive counterparts. However, the appropriate functioning of active mixers requires the use of accessories to supply adequate time-dependent external energy sources, which makes them difficult and expensive to be integrated into microfluidic systems. In contrast, passive mixers can be readily integrated in microfluidic systems because they do not need external power sources except for those engineered in the field of fluid delivery.

Although many different types of micromixers have been proposed, each type of mixer has its own advantages, drawbacks, and limitations. There is no single mixing device that is suitable for all applications and some micromixers are more appropriate for a certain application than others. The comparisons of the various mixers used in microsystems are documented in **Table 1**.

Table 1 Various micromixers for microsystems

	Description	*Advantages*	*Disadvantages*
Passive mixers			
Parallel lamination mixers	Split the inlet fluid streams into several substreams and subsequently combine these into one single stream	Simple structure; no moving parts	Slow mixing speed; requires long channel length
Split-and-recombine mixers	One stream is splitted into n laminae with width equal to $1/n$ of the original channel's width. Subsequently, two alternating thin laminae are recombined until all partial flows are united into one broad outlet channel	No moving parts; fast mixing	Large pressure drop; substantial dead volumes; delicate fabrication
Injection mixers	The fluids are injected through micronozzles and subsequently converted into microplumes	No moving parts; fast mixing	Large pressure drop; delicate fabrication
Droplet mixers	Mix the liquids within a droplet moving through winding microchannels	No moving parts; fast mixing	Poor kinetic performance of concentrated systems to be mixed
Chaotic mixers	Spatial-dependent transverse velocity components are created with complex 3D structures or channel walls patterned with various surface charges	No moving parts; chaotic advection	Complex 3D structure; delicate fabrication; relatively large Reynolds numbers are required; long channel length
Active mixers			
Pressure perturbation mixer	Time-variant pressure perturbations are applied transversely to the main stream	Chaotic advection; no moving parts	External pressure source and switching valves are required
Thermosiphon-based mixer	Natural convection is induced in the presence of large, time-dependent temperature variations	No moving parts	Requires large temperature variations and thus possibly alters the chemical/structural properties of thermosensitive systems to be mixed
Magnetic mixer	By time-wise and local control of the magnetic field, chaotic trajectories of the magnetic beads are generated, which results in mixing	No moving parts; chaotic advection	High power consumption; Joule heating
Dielectrophoretic mixer	Polymer particles are driven by time-wise DEP forces to generate chaotic trajectories	Chaotic advection; no moving parts	Requires high electric field; Joule heating
Peristaltic mixer	The fluid motion is induced by the traveling wave along the boundary wall	Chaotic advection	Moving mechanical parts (walls)
Acoustic mixer	Fluid flows in the same direction as the direction of propagation of the ultrasonic wave. The 3D flow patterns can be generated by time-wise activation of two or more transducers along different directions	Chaotic advection; no moving parts; nonintrusive	High power consumption; Joule heating
Magnetohydrodynamic mixer	Secondary flow is induced by the Lorentz force through the interaction between the electric and magnetic fields	No moving parts; low voltage; convenient circular flow; easy fabrication	The solution must be weakly conductive; electrode corrosion; bubble generation; body force
Electroosmotic mixer	Complex electroosmotic flows are induced by temporally varying the wall's zeta potentials or the applied electric field	No moving part	Requires high electric field

Biographies

Shizhi Qian received his first Ph.D. for his work on multiphase flow in gas–solid fluidized bed boilers from Huazhong University of Science and Technology, P.R. China, in 1998. Since 2000, he has been pursuing research in the area of lab-on-a-chip technology at the University of Pennsylvania (Upenn) and obtained his second Ph.D. on modeling complex interactions in microfluidic systems from Upenn in 2004. He is currently an assistant professor in the Department of Mechanical Engineering, University of Nevada, Las Vegas. His current research interests focus on lab-on-a-chip technology for biomedical, clinical, and environmental applications, electrokinetics and electrodics, and magnetohydrodynamics.

Jérôme F.L. Duval graduated as a Physico-Chemist engineer in 1999 from the National Graduate School of Chemistry and Physics of Bordeaux in France. From 1999 to 2003, he was with the Department of Physical Chemistry and Colloid Science of Wageningen University and Research Center, Wageningen, the Netherlands, as a Ph.D. student under the supervision of Profs. H.P. van Leeuwen and J. Lyklema. He obtained his Ph.D. thesis (Cum Laude) with a manuscript entitled Faradaic and Adsorption-Mediated Depolarization of Electric Double Layers in Colloids. After 2 years of a joined postdoctoral research program in Wageningen and in the Department of Analytical and Biophysical Environmental Chemistry, Geneva, Switzerland, he entered the Centre National de la Recherche Scientifique (CNRS) in France as a Chargé de Recherche (Assistant Professor). He is currently working in the Laboratory Environment and Mineralurgy in Nancy (France) and his current research topics cover the electrokinetics of complex interfaces (bio- and environmental particles), microfluidics, the electrokinetic phenomena of the second kind, particle interactions, and the coupling between electrode kinetics and electrokinetics.

2.11 Gas Sensors

Ulrich Bonne, Hopkins, MN, USA

Nomenclature

Variables

A	Heat transfer surface area (cm^2)
Bn	Bonne number, defined as $Bn = D_{O_2}/(M_{gas}/M_{CH_4})^{0.5}$
C	Peak or channel capacity of a GC system; or Coulomb, unit of electrical charge
c_p	Specific heat in J (mol K)$^{-1}$ or cal (mole K)$^{-1}$; 1 cal = 4.184 J
C_V	Volumetric composition correction factor (dimensionless)
d	Diameter (cm) or (in.)
D	Mass diffusivity ($cm^2\ s^{-1}$)
D_{O_2}	Molar demand for oxygen of a fuel to achieve stoichiometric combustion, e.g., $D_{O_2}(CH_4) = 2$
D_T	Thermal diffusivity ($cm^2\ s^{-1}$)
f	Frequency (Hz)
G	Sensor output; ΔG = output resulting from the difference between the downstream–upstream sensing element resistances of the sensor in the inset in Figure 1. Outputs in V or mV
h	Heat transfer per unit surface area and temperature difference (W $(m^2\ K)^{-1}$)
H	Height of a theoretical GC separation plate
k	Thermal conductivity (W (m K)$^{-1}$)
k'	Retention or capacity factor. $k' = K/\beta$
K	Equilibrium constant
L	Length (cm)
m	Mass flow (g s^{-1})
m_x	Mass flux (g $(cm^2\ s)^{-1}$)
M	Molecular weight (g mol^{-1})
Nu	Nusselt number, total heat transfer/conductive heat transfer. $Nu = Q/(k\Delta TA/d) = hd/k$
p	Pressure (dyne cm^{-2}); 1 bar = 10^6 dyne cm^{-2} = 10^5 Pa
Pr	Prandtl number, momentum diffusivity/thermal diffusivity, $Pr = v/D_t = \eta c_p/(kM)$
Re	Reynolds number, inertial force/viscous force, $Re = vd/v = m_x d/\eta = md/(A\eta)$
R	Universal gas constant, R = 1.9872 cal (mole K)$^{-1}$ = 8.3145 J (mol K)$^{-1}$
R^*	Resolution, $R^* = t_R/W_{1/2}$
t_R	Retention time (s)
t_o	Flow-trough time (s)

v	Velocity (cm s^{-1})
V	Volume (cm^3) or abbreviation for volts
$W_{1/2}$	Half-width and $W^*_{1/2}$ average half-width
α_1	First TCR, with $R = R_o(1 + \alpha_1\Delta T_o + \alpha_2\Delta T_o)$, $\alpha_1 \sim 3500$ ppm ($°C^{-1}$) for Pt
α_2	Second TCR
β	Volumetric ratio of mobile phase/stationary phase = gas/film in a GC column
γ	Ratio of specific heats, $\gamma = c_p/c_v$
Δ	Difference, as in Δp
η	(Dynamic) viscosity in Poise or g $(cm\ s)^{-1}$; 0.000178 P for N_2 at 20°C
ν	Kinematic viscosity, $\nu = \eta/\rho(\cdots$"
π	Constant, 3.1416
ρ	Density (g cm^{-3}) and specific gravity, ρ/ρ_{air}
τ	Response time, to achieve 63.2% of final signal value (s or ms)
Subscripts	
c	Capillary
m	Mass
M	Main flow channel, or mole-related
o	Reference
p	Pressure
v, V	Volume

2.11.1 Introduction and Fundamentals

Gas sensors are generally understood as providing a measurement of the concentration of some analyte of interest, such as CO, CO_2, NO_x, SO_2, without at this point dwelling on the plethora of underlying approaches such as optical absorption, electrical conductivity, electrochemical (EC) and catalytic bead (see Section 2.11.3). However, and as discussed in Section 2.11.2, many other gas sensors measure a physical property of the environment around them, such as simple temperature, pressure, flow, thermal conductivity, and specific heat, or more complex properties such as heating value, supercompressibility, and octane number for gaseous fuels. The latter may require capital-intensive (engines) or destructive testing, e.g., via combustion, or involve the measurement of a number of parameters to serve as inputs to a correlation with the complex property of interest.

When the sensor provides a multiplicity of outputs, as with optical or mass spectrometers (MSs), we refer to it as a gas analyzer. Gas chromatography (GC), differential thermal analysis (DTA), ion mobility, and nuclear magnetic resonance (NMR) are additional examples, some of which will be detailed in Section 2.11.4. Such analyzers, preferred by the author, should not be confused with sensor arrays, in which different sensing materials (typically polymers and metal oxides) are used on each element of the array, which then needs to conform to difficult-to-achieve stability requirements.

The performance of all of the above-mentioned sensors and analyzers may be characterized by their signal-to-noise (S/N) ratio, minimum detectable limit (MDL), selectivity, and response time. Increasingly, power consumption, size, and weight are becoming more important as interest and demand increases for handheld, battery-powered sensors, with or without wireless capability. These specifications may be viewed as simple performance parameters, because they are relatively simple to quantify.

Self-calibration, drift, S/N, and false alarm rate (FAR) (mainly for composition sensors or analyzers) require more sophisticated approaches, but are of increasing importance in all applications such as for medical, industrial, environmental, security, and first-responder use. Section 2.11.5 goes into the details of this subject.

Another classification of gas sensors and analyzers could be based on their sampling method: by diffusion, pumped transport, or via remote optical sampling to induce fluorescence, absorption, or scattering.

Researchers, designers, and planners continually face the need to make development or fabrication decisions before all the facts are available. Therefore, there is a perennial need to generate estimates about the performance and sensitivity of devices, structure, and also sensor systems. This is where mathematical modeling, be it simple or complex or *ad hoc* (to simulate a specific sensor) or multipurpose (such as ANSYS, FLUENT to simulate heat transfer or flow of a sensor within a given programmatic framework, which is adapted to individual geometries and conditions) can be of tremendous help. Rather than dedicating a section specifically to this subject, several examples will be discussed throughout this chapter.

The intent of this chapter is not to provide an exhaustive review of the world of gas sensors, nor a history of their development, but to highlight and share selected gas-sensing approaches that impressed the author in meeting modern expectations for performance, features, and cost.

The issue of cost merits additional comments. Contrary to initial negative reactions one might have about it, because of its potential commercialism, the author subscribes to the view that cost just adds a tough professional challenge (conservation, sustainable development, affordability) to all the others related to achieving generic and useful sensor performance attributes mentioned above. In fact, many elegant sensing approaches are withering on the shelf because few potential users could afford to implement them.

2.11.2 Physical Property Gas Sensors

2.11.2.1 Introduction

Among gas sensors to determine physical properties such as pressure, flow, specific heat, viscosity, and density, this section focuses on the fabrication and performance of microsensors primarily measure thermal effects. Some of the sensor outputs are direct thermal properties themselves, such as temperature, thermal conductivity, and specific heat, while others are indirect, inferred, or correlated such as flow, density, viscosity, heating value, oxygen demand, and octane and cetane numbers (Bonne 1992, 1996, Higashi *et al.* 1986). Let us start with the measurement of flow and pressure, which may be viewed as special cases in between the above-mentioned direct and indirect groups.

Traditional flow sensing with hot-wire anemometers had evolved to hot-film microanemometry in the 1980s (Higashi *et al.* 1986), for which the hot film was a 50- to 100-nm film of permalloy (FeNi) or platinum, passivated by and sandwiched between unsupported films of silicon nitride of ~1 μm in total thickness. This MB structure is created by etching out an underlying area to a depth of about 150 μm of the supporting silicon chip, which only measures 1.7 mm × 1.7 mm. **Figure 1** illustrates the makeup of this MB in cross section and in top views showing the heating and sensing elements (as well as other resistors to be detailed later on); the scanning electron microscope (SEM) photograph, shows the contact pads for gold-wire bonding. (The heating and sensing elements are also visible but are shown more clearly in the line drawing.) All resistive elements consist of the above-mentioned thin-metal film located either on the MB (R_h, R_u, R_d) or on the solid substrate (**Figures 2** and **3**). The substrate resistors are thereby held at or close to ambient temperature.

The basic measurement consists of accurately sensing changes in the absolute (for temperature) or relative (for flow) resistance of the elements. The heater (R_h, see central element in **Figure 1(a)–1(c)**) is controlled to maintain an approximately constant temperature differential of 70–200°C above ambient (~160°C for most commercial AWM-Series flow sensors (Catalog #15 1998)), as achieved by the circuit of **Figure 2(a)**. The zero temperature coefficient of

resistance (TCR) resistor R_c compensates for the temperature influence on the value of Pt coefficient of resistance (TCR), i.e., the nonzero value of α_2, so that the flow or thermal conductivity outputs are largely temperature-compensated. Such flow sensor chips offer a large dynamic flow range (~3000:1), a short response time (~1 ms), low power (0.1–10 mW), chip-to-chip interchangeability within 5%, wide temperature range (−60°C to 160°C), good stability (drift <50 ppm after dozens of −20°C to 120°C thermal cycles) (Bonne 1992, 1996), and low chip manufacturing cost, but have limitations imposed by packaging materials and electronics.

It is this basic MB structure (Higashi and Johnson 1987) (see **Figures 1** and **5**) that spawned a number of sensor ideas, research efforts and productized sensors: of physical gas properties (Bonne 1992, 1994, Bonne and Kubisiak 2001a), uncooled optical radiation

(especially IR) bolometers (Wilson *et al.* 1991), flow or wind direction (Bonne *et al.* 2003a, Djorup 1993, Huising *et al.* 1993), gas composition (several) (Bonne 1994b, Bonne *et al.* 2000a, Cole *et al.* 1986, Schierbaum *et al.* 1991, Zanini *et al.* 1995), tilt and acceleration (MEMSIC Inc., Zhao and Cai 2005), and vibratory sensors or actuation-based sensors (Bonne and Kubisiak 2001a). The following are the core features that enabled the fabrication of the above sensors:

(1) Measuring thermal conductivity, specific heat, and temperature and correlating these with pressure (see point (3)), gas density, viscosity, heating value, supercompressibility, and octane number (Bonne 1991–1993). Others leveraged the microthermal gradients to make tilt, level, acceleration (MEMSIC Inc., Zhao and Cai 2005), or rotation sensors.
(2) Depositing special coatings on the heatable MB (or microhotplate (Cavicchi *et al.* 2000), such as metal oxides (SnO_2, WO_3, Pt- or In-doped SnO_2, etc.) to sense NO_x, CO, and combustible gases nonspecifically (Boger *et al.* 2005, Cavicchi *et al.* 2000, Dable *et al.*, 2004, Kunt *et al.* 2000, Meier *et al.* 2004, Tiffany *et al.* 2000, Visser *et al.* 1994)), hydrated LiCl to sense dew point (Bonne *et al.* 1996), and yttria-stabilized zirconia (YSZ) to sense O_2 (Cole *et al.* 1986).
(3) Making the MB structures either so small that they become commensurate with the mean free path of ambient air molecules, so that the measurable heater power becomes pressure dependent (Bonne and Kubisiak 1994, James *et al.* 1988, Priti *et al.* 1993), or sensitive enough to respond to the small, pressure-induced changes in thermal conductivity (Bonne and Kubisiak 1994, Priti *et al.* 1993).
(4) Exploiting various effects obtained by exposing such thermal microflow sensors to oscillatory flow induced by off-the-shelf miniactuators such as microphone speakers (Bonne *et al.* 2001a, Bonne *et al.* 2001), or to electronic resonance effects associated with their circuits (Bonne and Kubisiak 2001b).

2.11.2.2 Sensing Gas Flow, Thermal Conductivity, *k*, Specific Heat, c_p, and Temperature

In describing the above except for point (2), to which we will come back to in Section 2.11.3, we will now focus on various gas sensor concepts based on MB and Microbrick™ structures (Padmanabhan *et al.* 2006), whereby the heater and sensing thin-film film resistors of the latter are supported on bulk solid insulators. Although consuming a little more power, MK flow sensitivity (S/N ratio) is higher and the response time is shorter.

But it was the shift in thermal flow sensor output signal, as shown in **Figure 3(a)** (and more dramatically also in **Figure 15**), that induced the effort to find ways to correct for it, and in the process led to further ideas on how to leverage the gained insights into additional uses of such sensors. **Figure 3** shows how the flow signal curves shift (without a change in shape; at low flows it is important to properly determine the offset, G_o) with gas composition, which provided an early clue about the existence and mathematical structure of flow-independent composition correction factors. Solving this problem was of fundamental interest to thermal anemometry and especially if we were to use thermal microanemometers for metering natural gas, the composition of which changes enough with time to cause uncorrected metering errors of up to 10%. This effort coincided in time (1985–2000) with a growing interest by the natural gas distribution industry to modernize traditional bellows-based gas meters with electronic and wireless ones (Bonne 1991, 1992, Bonne *et al.* 1990, Visser *et al.* 1994). Early researchers had tried to correlate physical gas properties to heating value, to avoid destructive and bulky calorimetry (e.g., correlations with dielectric constant and density, thermal conductivity, speed of sound, and viscosity (Altemark *et al.* 1979, Durst *et al.* 1999, Sommers *et al.* 1979)), but did not make use of specific heat or try to use the correlations to correct flow sensor outputs, because electronic gas meters were still in their infancy.

The composition correction factor was defined as C_V = (uncorrected flow/corrected flow), where for practical reasons, flow here means standard volume flow. C_V had to meet a number of expectations:

- Be pressure independent to avoid the need for pressure sensors. The pressure independence of thermal flow sensors, was experimentally validated and holds for constant gas composition (Bonne *et al.* 1995a), but does not hold when composition is varied.
- Revert to a value of unity for flow sensing with the reference or calibration gas.
- Show little or no temperature sensitivity, in view of the inherent temperature compensation built into available flow sensors (Catalog #15 1998).

- One correction constant had to be valid over the full dynamic flow range in view of the uncovered simple shift of the flow curves for different gases, when plotted on a log–log scale.

The form of the empirically correlated composition correction factor, C_V, meets the above expectations, with even only the first two terms in:

$$C_V = \left(\frac{k}{k_o}\right)^{-0.8827} \left(\frac{C_p}{C_{po}}\right)^{1.110} \left(\frac{\mathrm{Pr}}{\mathrm{Pr}_o}\right)^{-0.333} \quad [1]$$

The subscript o indicates the values for the reference gas. A theoretical foundation and derivation for eqn 1] was provided later (Bonne 1990–1992), which rationalized the need for the third but weak term involving the Prandtl number. The physical properties in all three terms are fundamentally independent of pressure, but not of temperature. By way of example, if one defines $C_V = 1$ for N_2, then $C_V = 2.12$ for ethane (C_2H_6), despite having close to the same molecular weight (MW) and thus density. **Figure 3(b)** shows the result of applying composition correction, which was valid for more than four orders of magnitude, for gases with vastly different properties as in the case of helium (He), methane (CH_4), nitrogen (N_2), and C_2H_6.

After uncovering and demonstrating thermal flow sensor composition correction based on the measurement of k and c_p, preferably at two different temperatures (Bonne 1990–1992, 1994a, 1996, Bonne *et al.* 1990), the question about accuracy came to the fore (Frampton *et al.* 1996) and how large a S/N could be achieved, which prompted the development of a standardized approach to visualize S/N and short-term drift and temperature correction, which is discussed in detail in Section 2.11.4. But it also prompted the question about correlation to other gas properties such as natural gas density (see **Figure 4**, demonstrating the feasibility for a good correlation of the simple type $\rho = \rho(k(T), c_p(T))$), viscosity, heating value (Bonne 1992, Bonne and Kubisiak 1996, Bonne *et al.* 1994), supercompressibility (Bonne 1993), octane number (Bonne 1993), and oxygen demand (Bonne 1996b), as well as the determination of equivalent liquid properties (Bonne 1996a). The above correlations consisted of multiterm polynomials and were in large part enabled by the high degree of orthogonality between k and c_p. Being able to predict oxygen demand of a fuel, made feedforward control of fuel/air ratio possible, so that no sensors would have to be exposed to the harsh exhaust gas environment. See also **Table 2** for such control.

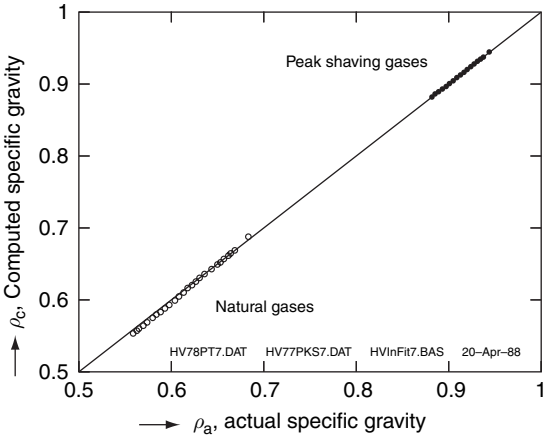

Figure 4 Microbridge chip-based k and c_p measurement and correlation with gas density, expressed in terms of specific gravity, of over 140 fuel gases (natural gases and peak shaving gases (with a 50% addition of propane and air). The standard deviation for this correlation was ±0.33%. (Source: Bonne U 1996a Sensing fuel properties with thermal microsensors. 2.11.2.3 Sensing Pressure with Thermal Microsensors

Extending the state-of-the art applications of micro-Pirani pressure sensors (James *et al.* 1988, Mastrangelo and Muller 1991, Priti *et al.* 1993, Bonne and Kubisiak 1994) Bonne and Kubisiak:

(1) Demonstrated an operating range of thermal conductivity-based pressure sensors (Pirani gauges) to above 200 bar.
(2) Corrected their output for the influence of changes in gas composition and temperature.
(3) Demonstrated repeatabilities and short-term S/N comparable to the state-of-the-art precision (±0/1%) industrial pressure sensors (Bonne and Kubisiak 1994), although their output sensitivity to drift in the used k and c_p measurements was higher.

The used sensor chips (see **Figure 1(c)**) were special in the sense of being endowed with a micro-Pirani pressure-sensing structure used earlier (James *et al.* 1988; see **Figure 7**), and not used in Honeywell's commercial MB sensor chips (Catalog #15 1998).

Figure 9 shows the measured output of the small Pirani microsensor of Figure 7 over a pressure range spanning more than six orders of magnitude, in N_2. The drop in pressure sensitivity to be less than a millibar is associated with the larger than 100-μm mean free path, being much larger than the dimensions of the thermal conductivity sensing structure. Larger structures are known to measure down to lower pressures. The still changing output above 1 bar is what caught our attention as being a novel feature, which we attribute to the nonideal gas changes in thermal conductivity, which may be used for making burst-proof pressure sensors in the future.

The online composition corrections of these thermal pressure sensors were made via thermal measurements with two MB sensors of different dimensions (see Figure 1(c), *upper left corner*, and its magnified view in Figure 7) so that the effect of absolute thermal conductivity changes are sensed and effectively eliminated. The required measurements include temperature, heater conditions (in gas or vaccum), and steady state and transient heat transfer conditions, and were performed with single 1.7 mm × 1.7 mm, Si chip sensors machined from single Si wafers, as depicted in Figure 1(c). Figure 8 shows the measurement data before and after applying the composition correction, as well as the used expression for the correction. The values of the involved constants were $Q_{vac} = 0.33$ mW, i.e., the measured residual heat loss in vacuum, $k_{air} = 68.255$ μcal (cm K s)$^{-1}$, $A_1 = 0.64998$, $A_2 = 1.291638 \times 10^{-6}$ psi cm, $A_3 = 0.65996$, and $A_4 = 2.741976 \times 10^{-7}$ psi cm. The remaining or unknown gas parameters are k_i = thermal conductivity of gas i in μcal (cm K s)$^{-1}$ and L_i = its mean free path in centimeter. By sensing Q we could determine the pressure, p (in psia). In the expression in Figure 8, k_i thus defines the heat loss at high pressure and L_i the transition region from the Q_{vac}. The second exponential term was needed to improve the quality of the curve fits, which was not deemed surprising in view of the odd geometry of the narrow MB structure.

To visualize the achieved S/N of the MB sensor graphically and compare it to pressure sensors available commercially, Figure 10 shows measured data of both the former and the latter (for which we chose an available Honeywell ST3000 piezoresistive pressure sensor), labeled P_{MB} and P_{ST3000}, respectively. Note that the log(y_i)-axis data were plotted after increasing their magnitude 20-fold, i.e., $y_i = C_i(P_i/P_1)^{20}$, so that a 1% noise level would correspond to the shown scale bar. The C_i are simply spacing constants to separate the individual parameter traces on the chart. As shown, the peak–peak noise levels differ by only a factor of about 2. Section 2.11.4 provides further discussion about such visualization plots, which we found very revealing and educational.

2.11.2.4 Actuation-Based and Self-Oscillating Sensors

The original motivation for exploring the behavior of small and constant amplitude AC-modulated flow was to create repeatable, oscillating, volumetric flow signals at the prevailing temperature and fluid pressure, so that these signals would reflect the characteristic of the fluid, without being influenced by the main flow, and enable one to use such signals to correct flow sensor output errors resulting from changes in gas composition.

The setup depicted in Figure 11 to generate AC-modulated or reciprocating flow at the second or normalizing sensor at first used a sawtooth drive generated by a Hewlett-Packard HP8116A signal generator. The flow sensor amplifier with filter was a Model 113 by Princeton Applied Research. A key requirement is that both flow sensors be made as equal as possible.

Exposing thermal flow microsensors to oscillatory or reciprocating flow with the above setup enabled us to demonstrate a number of exciting new sensing approaches and characterizations, as follows (Bonne and Kubisiak 2001a):

- Submillisecond flow sensor response time versus flow velocity and microsensor structure.
- Compact and affordable composition correction, C_V, for volumetric fluid flow sensors, without the need to sense k or c_p.
- Concentration of binary mixtures, based on measurement of C_V.
- Fluid properties based on actuator-induced flow or compression, such as viscosity or $\gamma = c_p/c_v$, respectively. The determination of $\gamma = c_p/c_v$ from the induced temperature changes due to adiabatic compression of the gas in a closed cavity, as is discussed in a later publication.

The used micromachined thermal flow sensor chips consisted of either:

(1) Off-the-shelf, front-etched MB sensor chips of ~1.7 mm × 1.7 mm, with bridges of ~0.2 mm × 0.25 mm as depicted in **Figure 1(a)**. (Figure 1(c) has additional features, such as the pressure sensor, not included in the photo of the commercial version). (Higashi and Johnson 1987, Higashi *et al.* 1986, Honami *et al.* 1999).

(2) Developmental micromembrane sensor chips, similar to MB sensors except for etching away the silicon under the sensing membrane from the backside of the chip, rather than through the openings at the front side. The gases and vapors to be sensed then had access only to the front side, which would therefore prevent the problem we had seen with occasional gasoline vapor condensates and with breakage of MBs resulting from excessively high mass flux, e.g., over 30 g $(s\ cm)^{-1}$. In addition, such membrane-based sensors would burst at differential pressures between 50 and 100 psid, and exhibit undesirable stress-effect errors caused by changes in differential fluid pressure. Such effects were ~60× larger than the small pressure dependence of the thermal conductivity of air, which is only 0.18% bar^{-1}. We therefore decided to proceed only with sensors discussed in (1) and (3).

(3) Developmental, very rugged, Microbrick sensor chips of equal size but without etched cavities (see top of **Figure 5** and **Figure 11(b)**), so that the thin-film resistors are supported by a polymer (e.g., carefully back-filled epoxy) or glass (Pyrex or quartz). The purpose of using such sensor chips was to make high-performance sensors also available for flow and property measurements in applications involving harsh environments such as condensing vapors or liquids, high mass flux process streams and those carrying dust particles. Condensates collected under the MB microspaces are extremely hard to remove even by raising the microheater temperature by an extra 80°C. Moderate mass flux conditions in either gases or liquids (>5 g $cm^{-2}\ s^{-1}$), especially when associated with entrained dust (sand or rust particles of up to 0.3 mm diameter), have broken such sensors, so that reliable operation in industrial applications with gas or water mass fluxes of up to 80 or 500 g $cm^{-2}\ s^{-1}$, respectively, would have been short-lived. The concern that such Microbrick sensors would trade ruggedness for sensitivity and speed was found to be unsubstantiated. **Table 1** lists further design and performance data of Microbrick sensors. They are clearly burst-proof and designed for operation in harsh environments, and they operate with gas or liquid mass fluxes up to 500 g $cm^{-2}\ s^{-1}$, with condensable vapors and suspended sand or dust (they survived MIL Spec ice storm and sandstorm tests).

Figure 6(b) shows a comparison of flow responses between a MB and an early Microbrick sensor, via measurements obtained before and after backfilling the etch pit of the same MB sensor with epoxy. In this way, small chip–chip differences were eliminated, and the observed shift was solely due to the change in heat transfer characteristics. For this comparison, the heater temperature rise above ambient was kept at ~30°C by suitable adjustment of the heater control circuit. **Figure 6** shows that the signal noise, as

Table 1 Microbrick™ fluid flow and property sensor performance data

Mechanical/packaging	
Sensor chip	FWB Microbrick-II, mask #0857A
Primary package	Chip on Au-plated TO18 header with glass cover seal; 0.168″ OD platform
Electronics	
Input heater power	$\sim 2^{\circ}C\,mW^{-1}$, also known as thermal efficiency
Environmental	
Approvals	Microbridge chip approved for operation in flammable gas mixtures[a], no UL, CSA, or PTB approvals are in place for Microbrick sensors
Temperature range	$-40^{\circ}C$ to $150^{\circ}C$ for chip and substrate
Heater temperature rise	$\sim 6^{\circ}C$ to $140^{\circ}C$, depending on application and fluid phase (liquid or gas)
Sample fluid pressure range	No limitation
Chip protection from	
Flow and particulates	None. Passed Mil-Std-810e Sand Blast Test
Performance	
Sensitivity	
Flow	0.8 V from 0 to 100 m s^{-1}, for $\Delta T_{htr} = 35^{\circ}C$
TC	*~1.5 V for change from methanol to water, ~1.230 V for air to n-butane*
Noise (short term)	$<\pm 1.6\,mV_{RMS}$
Flow range	0.2–200 m s^{-1} in air
Drift	≤400 ppm in 10 years or after >1 million thermal cycles from $-40^{\circ}C$ to $120^{\circ}C$
Chip response time (63%)	<1–0.2 ms in air; $\tau_{electronic}$<4.8 ms
Signal stability (total)	
Versus ambient temperature	With compensation: $\leq 0.03\,mV^{\circ}C^{-1}$ from $0^{\circ}C$ to $60^{\circ}C$ ambient temperature
Versus sample liquid pressure	*$-0.25\,mV\,bar^{-1}$ (0.017 mV psi^{-1}) in 100% methanol (natural TC versus pressure), for 8–56 bar (100–800 psig), 20°C*
	$-5.3\,mV\,bar^{-1}$, a decrease in line with natural TC increase of air with pressure
Versus input voltage	*≤5 mV V^{-1} in air, from 15 to 22 V*
Versus vibration	*≤5 mV for 1–100 g at 600–6000 RPM. ≤22 mV g^{-1} for ±1 g in methanol*
	≤1.3 mV g^{-1} for ±1 g in air

[a]Certificate No. BVS 94.C. 7001 U, for Honeywell Flow Sensor Type AWM 2***V, DMT-Gesellschaft für Forschung und Prüfung mbH, Bergbau-Versuchsstrecke, Dortmund, Germany, July 15, 1994. The approval is for operation in continuously (=Zone 0) explosive environments (even in H_2–air), while powered with <26.9 mW at 25°C or <22.2 mW at 65°C. The approval type EEx Ia I/II C means: (E)uropean (Ex)plosion protection (I)ntrinsic safety; a, category that allows two faults in the circuit; I, mining/II, industrial application; C, applicable for gases with quenching distances of <0.5 mm (CH_4–air being about 2 mm and ignition current of <0.45× smaller than that of CH_4.

indicated by the 1-sigma error bars, is ~5–20% lower for the Microbrick. In view of its faster response and thus its expected greater sensitivity to microturbulence, we are still searching for an explanation of this beneficial effect.

For actuators, we used commercially available, 10- to 12-mm OD, membrane-based, low-cost, solenoid earphone speakers, with resonances in the 2-kHz region (International Components Co.). The displacement of such membranes was measured under a microscope and provided a surprisingly linear response under DC conditions, with center displacements on the order of 0.01 mm V^{-1} (or ~0.001 mm V^{-1} for the lead zirconate titanate (PZT)-based versions), as reported earlier (see data in **Figures 7 and 8** of Bonne and Kubisiak 2001a).

Two sizes of compensated flow sensor packages were designed and fabricated, with maximum main flows of 1 and 200 L min^{-1}, featuring flow channel cross sections of 0.015 and 1.77 cm^2, respectively. They hold the two flow sensors and the actuator membrane, as indicated in the conceptual sketch of **Figure 11**. Actually, all four sensors were off-the-shelf AWM4300 flow sensor packages rated to operate at a maximum nominal flow of 1 L min^{-1} (Catalog #15 1998), except that in the nominal 200 L min^{-1} version, the main flow sensor was mounted in a bypass across the honeycomb flow straightener, all housed in a Delrin polymer package, as shown in **Figure 12**, in comparison with the much bulkier "k and c_p" version. For the final, built-in electronics for the determination of C_V, we switched the solenoid drive from a sawtooth to a sine wave (and monitored the root mean square (RMS) sensor output rather than the peak–peak output) because of the ~10× reduction in the noise level.

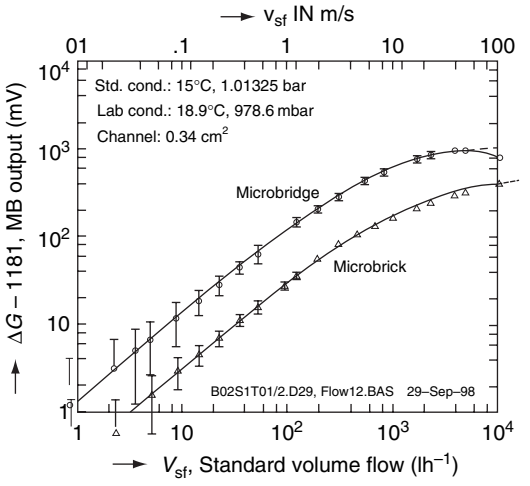

Figure 6 Comparison of microstructure flow sensor outputs before and after backfilling the MB with epoxy, to make an early version of a Microbrick. (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185.)

Speed of response: The useful operating frequency range of both sensors and actuators, with due consideration to resonance effects, was in the 40- to 100-Hz range and the one most free of disturbances for the used actuators (Bonne and Kubisiak 2001a). The flow sensors themselves showed the capability to operate beyond 500 Hz, especially the faster and more rugged Microbrick version, which showed response times down to ~0.2 ms.

Figures 13 and **14** show the results of measuring the speed of response of the above-mentioned MB and Microbrick sensors. The first experiment was designed to determine the response time of the sensor, in order to define a frequency range of operation. **Figure 13(a)** and **13(b)** shows two examples: with triangle wave inputs of 6 V_{p-p} to generate square wave AC flows of the indicated frequencies we obtained the signals shown, from which we then derived the response times, i.e., the times needed to achieve 63.2% of the final signal value.

Repeating such measurements at different frequencies resulted in the plotted response time and sensor output signal data in **Figure 14**, for both MB and Microbrick sensors. These sensors were mounted in standard AWM43000 packages (see **Figure 11(d)**), which feature flow channels of 0.5 mm × 3 mm in cross section at the sensor chip, which resulted in the linear gas velocities shown on the top *x*-axis. (The bottom *x*-axis shows the flow-generating actuator frequency, from which the top-axis velocity past the normalizing sensor was calculated, based on the known actuator displacement.) At 1 m s^{-1} on that scale in **Figure 14**, for example, the 63.2% response times are $\tau \sim 0.8$ and 0.3 ms, and at 3 m s^{-1} about 0.4 and 0.2 ms, for the MB and Microbrick chips, respectively. The decreases in response times with increasing velocities, are in line with increased convective heat transfer and stronger thermal coupling. We interpreted the reason for the shorter response times of the Microbrick versus the MB to the stronger thermal coupling between the heater and the upstream and downstream sensing elements (see the top two cross-sectional sketches in **Figure 5**). The strength of such coupling also influences the shape of the sensor output curves at very high flows. As **Figure 6** indicates, the MB signal peaks near 30 m s^{-1} (4000 l h^{-1} in the 0.34 cm^2 flow channel) and decreases after that due to the insufficient heat flux in the thin membrane to maintain the needed temperature of the sensing elements. Such limiting heat flux may not occur in the structure of

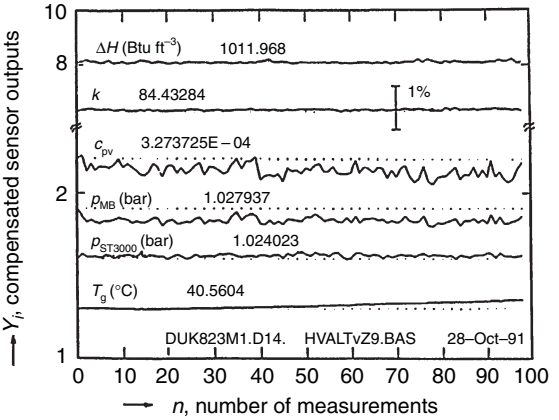

Figure 10 Short-term repeatability of thermal pressure MB sensor measurements, including its compensated output, P_{MB}, compared to an industrial-grade Si piezoresistive sensor, PST_{3000}, and to additional MB outputs, for CH_4; *y*-scale: 20×. (Source: Bonne U, Kubisiak D 1994 Overpressure-proof, thermal pressure sensor for gases. *Solid-State Sensor and Actuator Workshop*, Hilton Head Island, SC, USA, June 13–16, 1994, Tech. Digest, p. 76; © 1994 reproduced with permission from IEEE.)

the Microbrick sensor, which in this case was the identical MB chip, after it had been ruggedized by filling epoxy under the bridge, the output of which is also shown in **Figure 6** and seen to be shifted to higher flows by a factor of about 4×, after subtracting out the 1181 mV zero-flow offset. This offset is purposely set by the circuit, so that small negative flows can be observed as well. For additional performance parameters of the Microbrick sensor chip, see **Table 1**.

In summary, the above response time measurements have taught us that we can safely use normalizing actuator frequencies, f, of up to $f = 1/(2\pi\tau)$, which, with conservative values of $\tau = 0.8$ and 0.3 ms amount to 200 and 530 Hz for the MB and Microbrick, respectively, provided no other effects such as resonances limit such measurements.

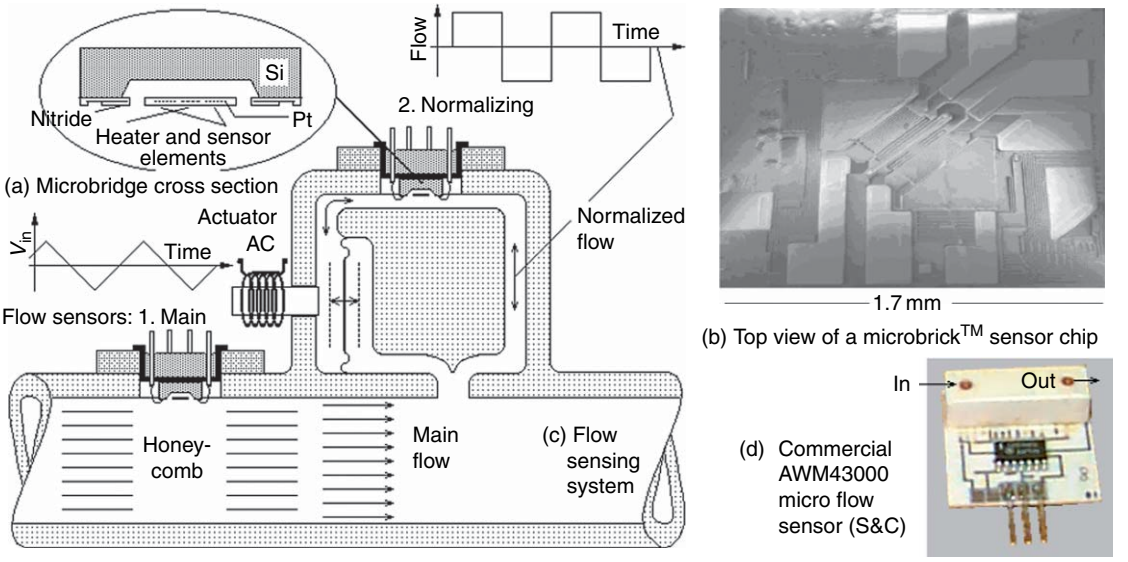

Figure 11 Functional sketch of composition-compensated flow-sensing system. The use of the shown sensor mounting (on TO5 header or on alumina circuit board with flow channel (as in (d)) and thermal flow microsensors is only exemplary. Other types of flow sensors may be used as well. (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *Proceedings GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, © 2002 reproduced with permission from Gas Technology Institute.)

Composition correction factor, C_V: Having demonstrated the ability to measure the small reciprocating flows generated by small membrane actuators, and assuming that the actuator displacement is:

- stable over time, as one is led to believe, given its rugged iron membrane set in motion by the electromagnetic (EM) field (see further details in the discussion on viscosity sensing).
- independent of changes in gas density, pressure, or viscosity.
- generating sensor output signals that are proportional to actuator frequency, to indicate that the actuator is not near conditions or subject to signals distorted by resonance frequency effects as proven in Bonne and Kubisiak (2001a).
- generating sensor output signals that are proportional to absolute pressure and temperature-dependent gas density (because thermal flow sensors are accurate mass flow sensors), and
- generating sensor outputs proportional to the individual gas properties that come into play to cause flow errors due to gas composition changes.

The reciprocating flow sensor signal is then proportional to the composition correction factor, C_V, described in Section 2.11.2.2. This means that C_V can now be directly measured, without the need for the more cumbersome measurement of k and c_p described in Section 2.11.2.2. Furthermore, this general approach is not limited to thermal mass flow sensors. However, for each new sensor one needs to determine whether the used flow sensor is a volumetric or mass flow sensor, so that the pressure and temperature corrections can be applied as appropriate.

The measured data shown in **Figure 15** was also obtained with the setup of **Figure 11**, with N_2 as reference gas and C_2H_6 and He as test gases. The shifts in output for these gases would be much smaller if plotted versus mass flow, but still too large (~100% for C_2H_6 versus N_2, see **Figure 15**) to be negligible. Because of the mentioned 10-fold decrease in signal noise for sine wave versus sawtooth operation, we continued work on flow normalization and composition correction (but not on response time or viscosity measurements) with the former. Additional influences on the quality of the obtained results are as follows:

(1) Proximity of the chosen frequency to the 50- or 60-Hz line frequency, which influences the amount of undesirable pickup.
(2) Drive amplitude, which influences distortion. **Figure 15** was obtained at 60-Hz sine wave and $3V_{p-p}$.
(3) Proximity of the chosen frequency to any resonance frequencies of the speaker membranes.

Figure 12 Comparison of composition-compensated thermal flow sensors, based on sensing: *left*: C_V via actuation-based flow, for maximum flows of 200 (*top*) and 1 l min^{-1} (*bottom*). Right: k and c_p in a dead-ended cavity, also for 200 l min^{-1} package, with circuit-board area of 260 cm^2, compared to 12.6 cm^2 for the C_V-based measurement.

The data points by the sloped lines in **Figure 15** represent the uncorrected main flow experimental data for C_2H_6, N_2, and He, obtained with the 200 l min^{-1} package. The sloped lines represent uncorrected flow data predicted theoretically, relative to reference gas N_2, for which we chose to set the volumetric composition correction factor, $C_V = 1$. As shown, they agree to within ±3%, even before a large effort is made to reduce this number further.

The arrays of approximately constant $\Delta G'$ versus flow data points represent the normalizing sensor outputs, which should not be affected by the main flow, as demonstrated, until turbulence at high flows does seem to exert some influence. C_V now results from a simple ratio:)

$$C_V = \Delta G'_{\text{norm,RMS}} / \Delta G'_{\text{norm,RMS,N}_2} \qquad [2]$$

where $\Delta G'_{\text{norm}}$, RMS, $N_{2=\ 48.5\ \text{mV}}$ as plotted, and represents the nulled signal, i.e., the measured signal, ΔG, without its zero-flow offset, ΔG_o. $\Delta G' = \Delta G - \Delta G_o$. The obtained values of C_V are in good agreement with those "obtained via the "k and c_p" approach" and predicted theoretically: numerically, the actuator-based values for C_V are 1.0 (by definition), 2.1, and 0.112, respectively, while the "theoretical, "k- and c_p"-based" approach according to eqn [3] yielded 1.0, 2.2, and 0.105, respectively. For gases of known k and c_p, the computation of C_V via eqn [3], derived in Section 2.11.2.2, is easy:

$$C_V = C_V = \left(\frac{k}{k_o}\right)^{-0.8827} \left(\frac{C_p}{C_{po}}\right)^{1.110} \left(\frac{\text{Pr}}{\text{Pr}_o}\right)^{-0.333} \left(\frac{T}{T_o}\right)^{m} \qquad [3]$$

but more cumbersome if the k and c_p have to be measured. Measurement of the Prandtl number, Pr, could generally be omitted because of its small

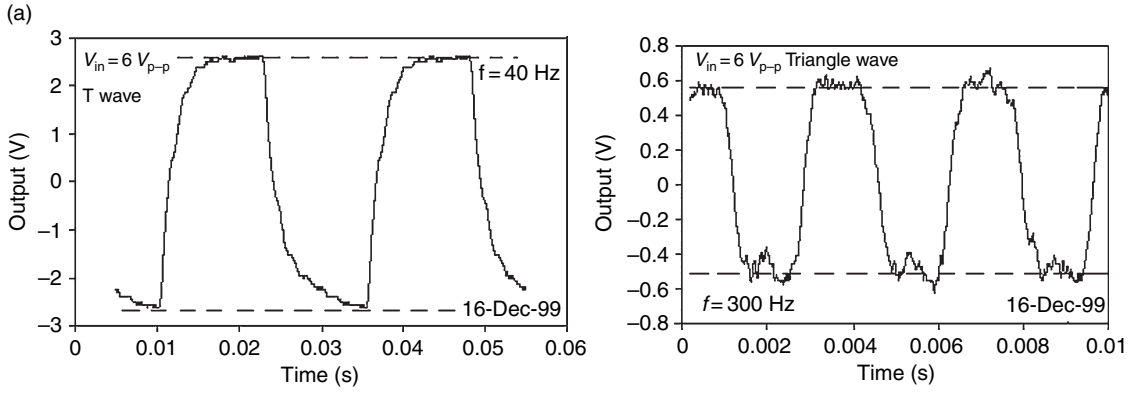

Figure 13 Responses to reciprocating flow generated by triangle wave drive to the earphone speaker, which in turn generates square wave AC flow: (a) microbridge at 40 Hz and (b) Microbrick at 300 Hz (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Struct.* **10**, 1185; reproduced with permission. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, Proceedings; © 2002 reproduced with permission from Gas Technology Institute.)

deviation from $Pr = 0.71$ for a range of gases and because of the smallness of the exponent. The temperature term serves to compensate for a combination of sensor material (Pt in our case) and electronic temperature effects, and may serve to improve accuracies beyond about 1% of reading. Such temperature compensation may need to be added to eqn [1] as well.

To summarize, this new volumetric flow sensor normalization approach:

(1) No longer requires the much more costly measurement of thermal conductivity and specific heat to determine C_V, discussed above, but requires the measurement of absolute temperature and pressure if mass flow normalization is called for; ideally a membrane able to displace and move the same and constant mass flow would be preferred for mass flow normalizations.

(2) The above flow normalization approach is universal and is not limited to composition correction of thermal flow sensors. Although the self-normalizing flow sensor packages in **Figures 11** and **12**, based on the above AC flow modulation, were built with thermal flow sensors (**Figure 11(d)**), other types of flow sensors can be used, such as Δp-based, whereby the two sensors used for the main and normalizing flows and their flow channels would be as similar as possible.

To obtain compensated standard volume flow sensor signals, additional gas pressure compensation is needed, if the actuator is of the constant volume flow displacement type. For compensated mass flow sensing, a constant mass (rather than the above constant volume) flow displacement actuator is needed, which may be a bit more difficult.

Composition sensing via C_V: Easy measurability of C_V begs the question of whether this parameter has any additional advantageous applications. As the parametric comparison in **Figure 16** shows for a binary mixture of CH_4 and C_2H_6, C_V stands out among the other plotted properties (k, c_p, D_T, v, Pr, and M, from software by PPDS/NEL) as showing the strongest signal change versus composition of this mixture. However, no experimental data were available at the time for either gaseous or liquid mixtures. The plotted property data in **Figure 16** were normalized by dividing all data by the value of the property at 0% C_2H_6 or 100% CH_4.

One property not displayed in **Figure 16** is dynamic viscosity, which has values of 91.32 and 108.64 μP for C_2H_6 and CH_4, respectively, or a change of 19% or only slightly stronger than Prandtl number. However, viscosity has other special properties for feedforward combustion control and can be measured with actuation-based sensors, to be discussed next.

Gas viscosity sensing: The measurement of gas properties such as viscosity (Altemark *et al.* 1979, Bonne 1994, Durst *et al.* 1999, Sommers *et al.* 1979, Wakeham *et al.* 1991), density (Altemark *et al.* 1979, Sommers *et al.* 1979, Wakeham *et al.* 1991), thermal conductivity (Bonne 1992, 1994a, 1996), and specific heat (Bonne 1992, 1996) has been under study for some time in order to enable the combustionless determination of fuel gas properties such as heating value, oxygen demand, and Wobbe number via correlation with those properties. In accurate viscosity measurements via vibrating quartz crystals, wires, or Lamb waves, sensor outputs typically provide combinations of viscosity and density (Wakeham *et al.* 1991). Most importantly, such property measurements, if they are to be widely used in small combustion systems, need to be affordable in that market, i.e., manufacturable at a cost of $5–10 or less.

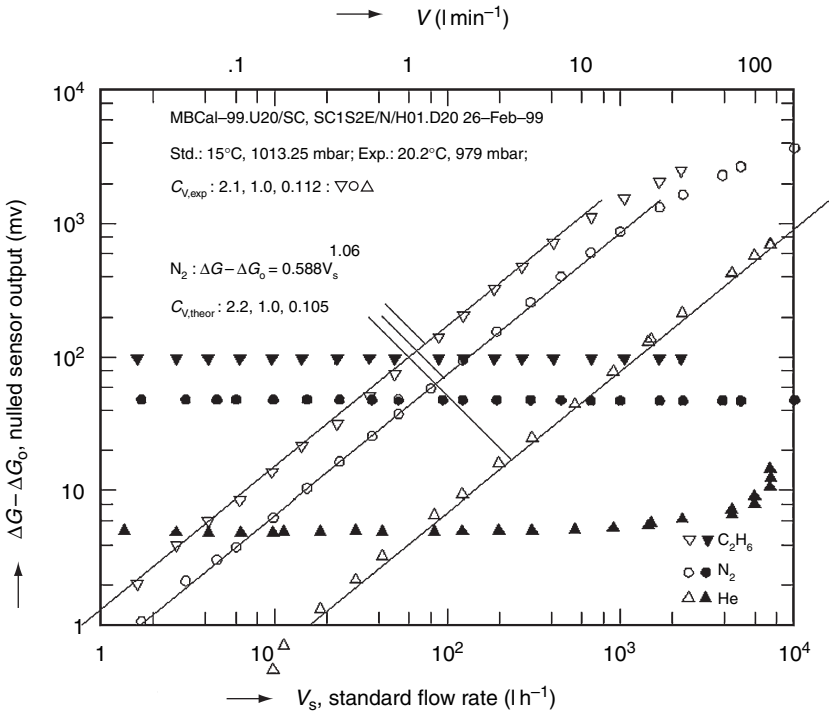

Figure 15 Demonstration of composition correction via the oscillatory sensor approach with N_2 as reference gas, C_2H_6, and He. Actuator driven with 3 V_{p-p} at 60 Hz. As intended, the oscillatory sensor signal is unaffected by the flow rate (for He up to ~1000 l h^{-1}). Measured with the 200 l min^{-1} flow sensor system. ΔG_o: 1027.6, 1029.0, and 1035.0 mV for N_2, C_2H_6, and H_2, respectively. (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *Proceedings GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, © 2002 reproduced with permission from Gas Technology Institute.)

Such affordability had not been achieved before by the approaches based on sensing viscosity and density via flow through a capillary and an orifice, respectively, as proposed by the Ruhrgas group (Altemark *et al.* 1979, Sommers *et al.* 1979), by our own attempts based on the use of quartz crystal oscillators (Bonne 1994a), or by the specially designed micropump to drive gas through a capillary as practiced at the University of Erlangen (Durst *et al.* 1999). Our early 1997 experiments with thermal-expansion-based gas pumps or drives were encumbered by the associated thermal gas properties and long thermal response times.

Figure 17 shows the actuator-based setup 3, designed and built to sense viscosity, using the same EM speaker (see left-hand side) as in **Figure 11**, but is now used to drive fluid through either capillaries or porous frits. The resulting AC pressure signals were then measured by a differential pressure (Δp) sensor, for which we used a piezoelectric (PE) speaker (Bonne and Kubisiak 2001, 2003, 2004; see right side of **Figure 17**), because of its higher S/N ratio and lower cost when compared with silicon-based Δp sensors available at the time (the PZT actuator by itself was only \$0.12 in volumes over ~50 000 units). In order to maximize the signal, we minimized the volume of the cavity between the driver and sensor membranes shown to either side of the frit.

We had calculated that we should be able to generate AC Δp signals on the order of 0.2–2 cm WC, with the setup shown in **Figure 17**, and obtain pressure signals shaped as in the curves shown in **Figure 18**. These were obtained first via numerical integration and later analytically from Poiseuille's law of capillary flow (Bonne 1994a)

$$\frac{dV}{dt} = \frac{\pi \Delta p r_c^4}{8 L_c \eta} \qquad [4]$$

where dV/dt is the laminar volumetric flow, and Δp is the pressure drop in a capillary of radius r_c and length L_c. Because we assume the displacement rate, time ($\Delta t = 1/(2f)$, with f as the frequency), and volume

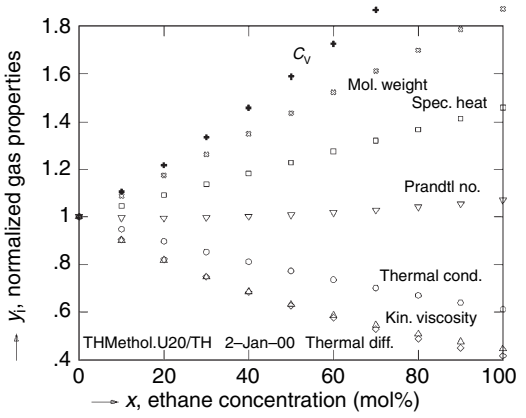

Figure 16 Comparison of relative physical property signal strength for the determination of the composition of the gas binary mixture, C_2H_6–CH_4 at 15°C and 1 atm. The large change in C_V shows it to be the most effective indicator of this mixture, whereas the Prandtl number is the parameter least affected by changes in that composition. (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, Proceedings; © 2002 reproduced with permission from Gas Technology Institute.)

ΔV_c of the actuator for any gas to be constant, we may rewrite eqn [4] with $dV/dt = 2f\Delta V_c$ in the form

$$\eta = \frac{\pi \Delta p r_c^4}{4 \Delta V_c f L_c} \qquad [5]$$

which confirms that η is proportional to the measurable steady-state differential pressure signal. The calculated curves of **Figure 18** show that:

(1) Steady Δp values can be achieved toward the end of each sawtooth period, when flow through the capillary or frit is exactly balanced by the movement of the actuator membrane and therefore provides a direct and linear measure of viscosity.
(2) The increasing values of such steady Δp periods are proportional to the viscosities of the indicated gases C_3H_8, N_2, and Ar (83, 178, and 224 μP, respectively, at 20°C and 1 atm).
(3) The $\Delta V_c/V_c$, r_c, and L_c values need to be and can be chosen to both achieve a steady Δp period and a laminar flow in the capillary, as indicated by the Reynolds number, $Re = 2r_c v\rho/\eta < 2300$ for the gas with the lowest η/ρ ratio (ρ is the gas density), which was propane in this case.
(4) The peak output shows no significant dependence of absolute gas pressure, but the time constants to reach the steady Δp period are longer for higher-viscosity fluids and lower-pressure gases. This is consistent with an expression for this rise time constant, τ_p, which can be derived from eqn [4] for the final ambient pressure in the cavity, p_1:

$$\tau_p = \frac{8\eta L_c V_c}{\pi p_1 r_c^4} \qquad [6]$$

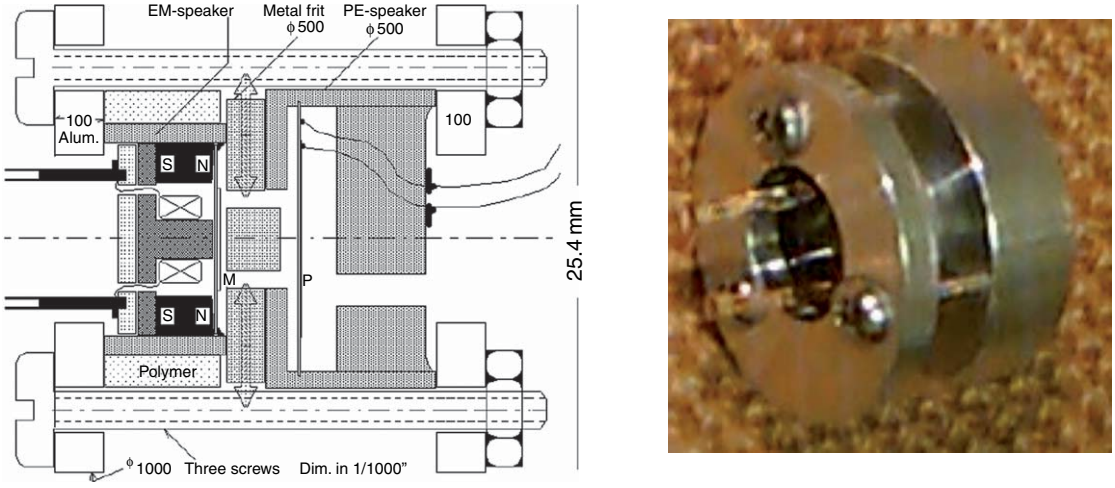

Figure 17 Gas viscosity sensor drawing and photograph, showing the electromagnetic (EM) earphone speaker membrane, M (*left*), generating pressure fluctuations sensed by the lead zirconate titanate (PZT) bimorph pressure sensor, P (*right*), while the fluctuations are partially damped by gas escaping through the metal frit pores between the speaker and the pressure sensor, as indicated by the arrows (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *Proceedings GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, © 2002 reproduced with permission from Gas Technology Institute.)

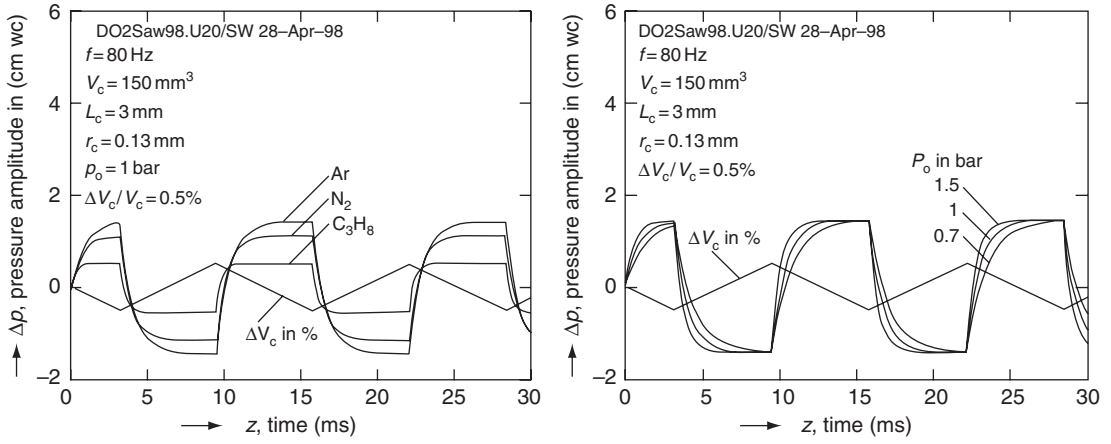

Figure 18 Calculated gas viscosity pressure signals versus time for various gases and pressures. After a few milliseconds of equilibration time, the linear change in cavity volume is balanced by the gas escaping through the frit pores via laminar flow, resulting a steady-state pressure signal, which is largely independent of gas pressure, as shown at right for three pressures of argon. (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *Proceedings GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, © 2002 reproduced with permission from Gas Technology Institute.)

As mentioned previously, the mathematical model assumes that membrane displacement rate and stroke is constant and not affected by the relatively negligible gas mass, or by changes in gas composition or pressure. Manipulation of the parameters in the above equations taught us that for reasonable choices of f, L_c, V_c, and r_c, we can simultaneously achieve laminar flow, measurable Δp values, and fast enough time constants to fit within the linear range of the actuators.

Figure 19 presents early experimental data using absolute gas pressures from ~1 to 7 bar and gases He, N_2, CH_4, and C_3H_8. They verify the fundamental sensing approach, but also point to the fact that additional phenomena are influencing the signal: there are gas-dependent EM speaker resonances, 60-Hz line voltage pickup and frequency-dependent Δp sensor sensitivities. The storage scope data on the left side were obtained with an early setup using a combination of EM driver/0.17-mm ID capillaries/electret microphone as Δp sensor, and show significant overshoot. However, the viscosity dependence on gas type (top left set of traces in **Figure 19**) and pressure independence of the signal after stabilization (bottom left) are evident. On the right side, the setup consisted of a combination of EM driver/porous metal plate instead of the capillaries/PE speaker as Δp sensor. This porous plate or frit resulted in less overshoot and better stability at high gas pressure, and was then adopted as a preferred approach.

Choosing between capillary and frit for the laminar flow restriction is to make a trade-off between service life, sensitivity, linearity, damping, and cost, which for operation with clean gases would favor the frit. Another choice entails fastening the components of **Figue 17** with epoxy (lower cost) rather than via screw-based clamping (greater flexibility for R&D). The PE–PZT-based Δp sensor was chosen over an EM speaker or a silicon-based piezoresistive sensor due to its high immunity toward electromagnetic interference (EMI) from the solenoid driver and higher S/N ratio. **Figures 20–22** show measured Δp data at 80 Hz for several gases versus time and temperature. We found that plotting signal versus time (see **Figure 20(b)**) reveals details of a sensor's performance that would be lost by simply reporting a S/N value, and will be further discussed in Section 2.11.5. The position of the N, M, and E letterpoints included in **Figure 21** represents the temperature dependencies of viscosity expected theoretically and show that additional temperature effects, such as thermal expansion, peak actuator displacement, and electronic offset and gain, contribute to the measured dependencies.

In order to provide a user-friendly sensor output, we electronically compensated all the temperature contributions to signal error by selecting CH_4 as a reference gas and interpolating the temperature correction from a lookup table version of the experimental data (diamond-shaped points) of

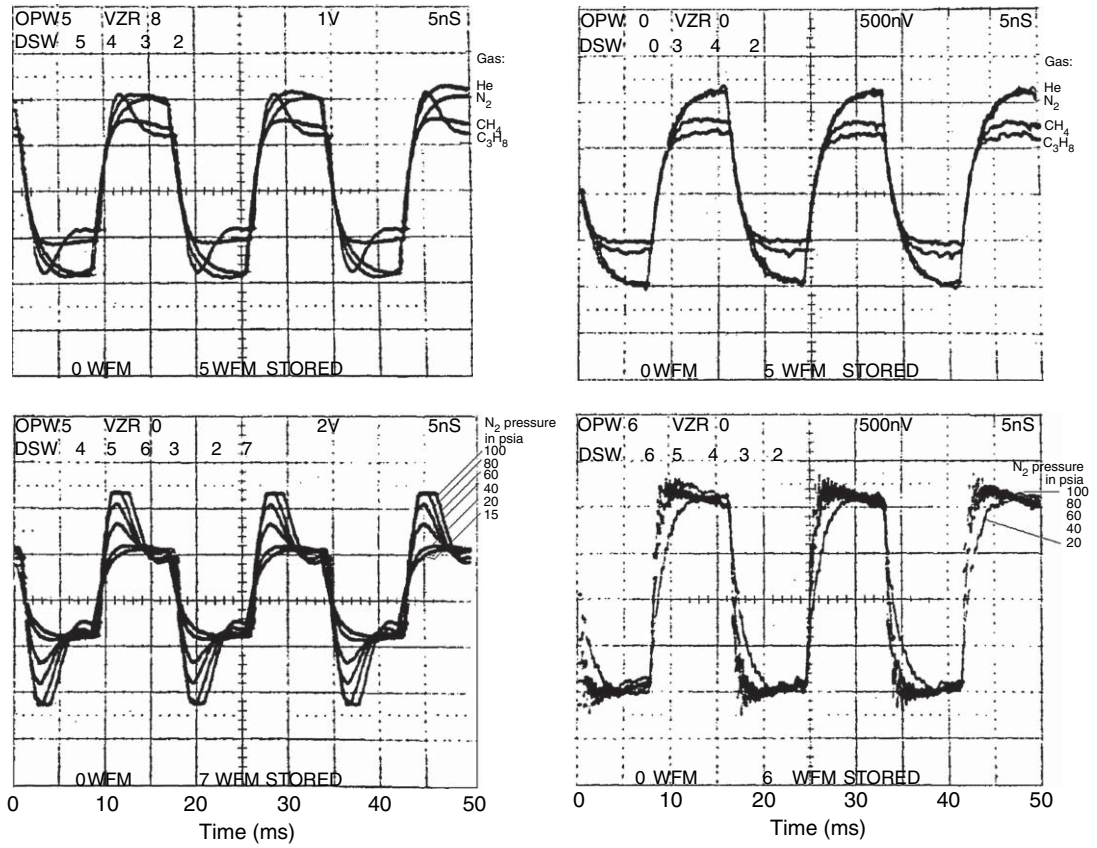

Figure 19 Experimental gas viscosity pressure signals versus time for various gases (He, N_2, CH_4, and C_3H_8) and pressures (20–100 psia or 1.3–7 bar). *Top left:* electromagnetic (EM) driver/0.275-mm capillary/electret microphone. *Top right:* EM driver/porous metal frit leak/lead zirconate titanate (PZT) pressure sensor. *Bottom:* all bottom pressure data were obtained with N_2 at the indicated pressures. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *Proceedings GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, © 2002 reproduced with permission from Gas Technology Institute.)

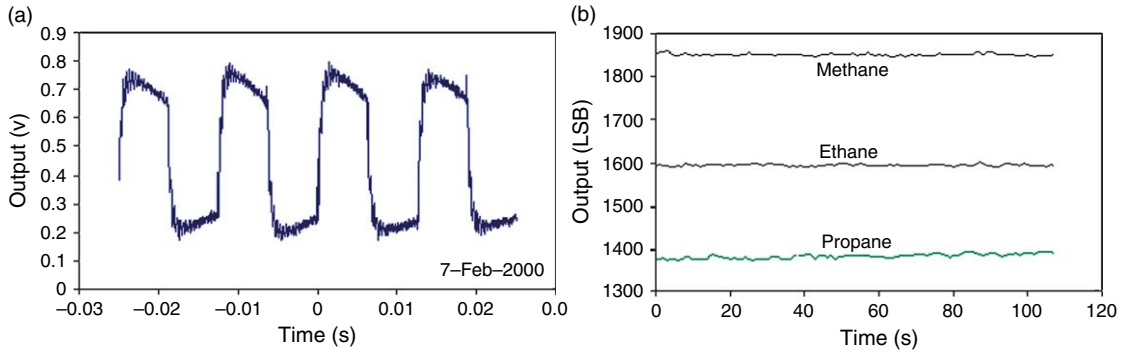

Figure 20 Experimental gas viscosity sensor digital outputs versus time and type of gas; $f = 80$ Hz. (a) The shown noise level may largely be due to driver resonance at 2.3 kHz and the lack of signal plateau flatness may be due to speaker distortion. (b) The sensor outputs versus time reveal S/N levels and remaining drift rate. (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *Proceedings GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, © 2002 reproduced with permission from Gas Technology Institute.)

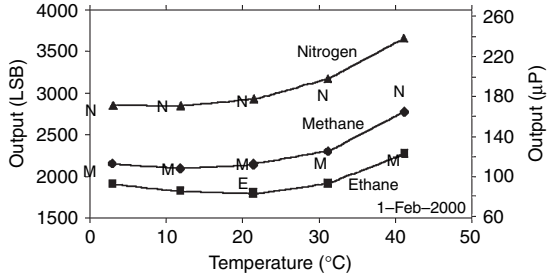

Figure 21 Experimental gas viscosity sensor digital outputs before temperature compensation versus ambient temperature and type of gas. (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission. Bonne U, Detry J, Higashi R E, Rezacheck T, Swanson S 2002 New gas composition and trace contaminant sensors. *Proceedings GTI Gas Technology Conference*, Orlando, FL, USA, September 30–October 2, 2002, © 2002 reproduced with permission from Gas Technology Institute.) The letters represent the intrinsic temperature dependence of N_2 (N), CH_4 (M), and C_2H_6 (E), indicating the presence of other effects.

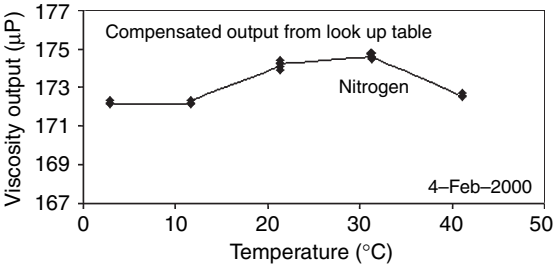

Figure 22 Measured gas viscosity sensor sensitivity to temperature changes, after the implemented temperature compensation. The temperature error is ±0.013% ($^\circ C^{-1}$). (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission.)

Figure 21. The remaining temperature sensitivity is plotted in Figure 22, showing that it decreased to about 0.026% ($^\circ C^{-1}$), which is about 10× lower than the theoretical temperature dependence of N_2 (0.25% ($^\circ C^{-1}$)) and 27× times lower than the experimental temperature sensitivity of Figure 21 (0.71% $^\circ C^{-1}$). The measured pressure sensitivity of 3.4% bar^{-1} for N_2 is much higher than the one predicted by the PPDS/NEL data of 0.14 and 0.09% bar^{-1} for CH_4 and N_2, respectively, so that some fine-tuning and adjustments would be in order. However, many near-ambient-pressure applications not requiring operation over a pressure range larger than 100–200 mbar or accuracy below ±1% may be well served by the simple sensor described above, without further refinements (Figure 23).

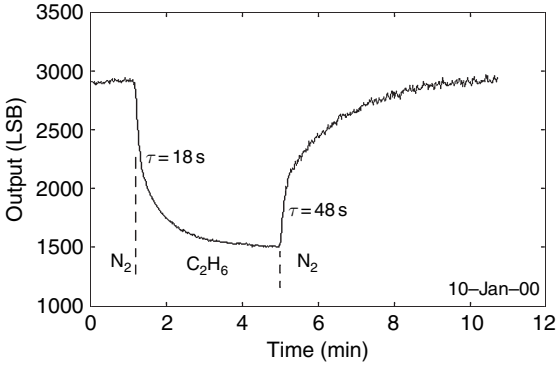

Figure 23 Measured response time of the gas viscosity sensor based on exposure to N_2, C_2H_6, and back to N_2. The 18–48 s was much longer than anticipated and may be due to the time needed for residual gas to diffuse out of the small pores of the used frit, which is associated with a longer time than the few milliseconds needed for pressure equilibration in the viscosity sensor. (Source: Bonne U, Kubisiak D 2001a Actuation-based microsensors. *J. Smart Mater. Struct.* **10**, 1185; reproduced with permission.)

Table 2 summarizes the data on the present performance of the developed viscosity sensor performance. It includes data on the significance of measured noise (∼30× lower at 80 than at 60 Hz) expressed in terms of a viscosity reading (±0.3%) as well as in terms of a feedforward combustion control signal in which a change in the composition of a hypothetical ($CH_4 + C_2H_6$) fuel gas mixture needs to be controlled (±2.3%). However, all other sensitivities in Table 2 are given in terms of viscosity sensitivities. Also listed are the measured response time (30 ± 15 s) resulting from rapid switching from N_2 to C_2H_6 and back; voltage sensitivity ±0.07% over the range from 8 to 23 V; and the p and T sensitivities discussed above.

2.11.2.5 Conclusions

The above results and demonstrations indicate the feasibility and cost-effectiveness of coupling fluid motion induced by simple, available, and affordable membrane actuators to thermal or pressure microsensors to provide advantageous means to determine:

(1) Accurate, submillisecond response times of different flow-sensor structures and at different flows. At flows of up to ∼1 m s^{-1}, the MB sensor flow response time decreases to 0.8 ms, but the value for the more rugged Microbrick drops to 0.3 ms, and lower still at higher flows.

Table 2 Gas viscosity sensor performance data

Sensitivity[a]	~300 LSB signal for CH_4–C_2H_6. Linear with viscosity, η
Noise	±7 LSB or ±0.3% of viscosity reading, or ±2.3% of a CH_4–C_2H_6 signal
Response time	~30 ± 15 s (63%) by switching from N_2 to C_2H_6 and back to N_2
Signal stability	
Versus temperature with compensation	$\leq \pm 0.0.16\%\ ^\circ C^{-1}$ over 2–42°C range
Versus temperature cycling	≤ ± 0.7% after six temperature cycles between 0°C and 40°C
Versus absolute pressure	$\leq \pm 1.7\%$ of η bar^{-1}, or 5 LSB psi^{-1} from 10 to 80 psia
Versus input voltage	$\leq \pm 0.07\%$ of η, or $\leq \pm 0.5\%$ of *Bn*, for $8 \leq V_{in} 23$ V
Versus EMI	TBD
Versus shock and vibration	Output did not change after tapping the sensor with a wrench from any side

[a]For reference gas

Methane	2100 LSB	≅108.6458 μP	≅2.000 B*n*
Ethane	1750 LSB	≅91.3274 μP	≅2.556 B*n*
% change	−12.5	−16	27.8

Bn or Bonne number is defined similarly to the Wobbe number, except for using volumetric or molar oxygen demand, D_{O_2}, rather than the heating value in the numerator, and CH_4 MW rather than the air density as reference in the denominator:

$$\mathrm{Bn} = \frac{D_{O_2}}{\left(M_{gas}/M_{CH_4}\right)^{0.5}}$$

The optimal correlation between *Bn* and viscosity is gas dependent as shown below. For a small set of US and European natural gases, plus test gases as defined by Gasunie in the Netherlands, the correlation

$$Bn = 10.068 - 0.7192\eta^{0.507014}$$

was found useful. However, we have found that the viscosity exponent can vary from 0.3 to over 2.3 for the optimal correlation, depending on the chosen set of gas compositions for the fit.

Conservatively, this means that these sensors can be operated in oscillatory flows at frequencies of up to ~200 and 530 Hz, respectively. Application: Defining the actuator frequency range for the measurements discussed below, and generic response time limitations of such microstructure flow sensors.

(2) Affordable composition correction factors for thermal and other flow sensors. The laborious approach used previously for thermal anemometers, based on the measurement of thermal conductivity and specific heat, can now be replaced by one simple flow measurement to determine the volumetric composition correction factor, C_V, with a comparatively negligible effort for calibration and electronics, that achieves at least ±3% accuracy. Application: Flow sensing of fluids like gaseous or liquid fuels, whose multicomponent composition can vary versus time, grade, and source.

(3) The composition of binary and higher-order mixtures. The determination of the correction factor, C_V, adds one easy-to-measure parameter to the choice of parameters available to characterize the composition of gaseous or liquid mixtures.

(4) Viscosity and other physical properties of fluids. With the laminar flow induced by a simple oscillatory membrane (EM rather than PE earphone speaker) operated below 100 Hz, we demonstrated a compact, light weight, and affordable approach to viscosity measurement. The measurable AC pressure drop signal serves indeed as a linear indicator of viscosity according to Poiseuille's law for viscous flow, which is density independent if operated at low kinetic energy conditions and also pressure independent to the extent that the measured viscosity is pressure independent (~0.1% bar). One driver for this development was to correlate viscosity (by itself or in combination with other parameters) to oxygen demand or Wobbe number.

Two other classes of thermal sensors, also demonstrated with MB sensor chips, represent a result of efforts to minimize sensor drift by shifting sensor readout from being dependent on analog changes in some physical sensor property, to frequency or digital changes in such sensors. But here they shall only be mentioned in passing:

(1) Those geared to induce electronic RC type of self-oscillations by leveraging the temperature-dependent changes in the thin-film resistance of the sensor and the capacitance of the circuit. Such oscillations then change the sensor's output frequency signal as a result of changes in flow, thermal conductivity, or specific heat. Consistent with the thermal response time, frequencies of up to 1000 Hz were generated (Bonne and Kubisiak 2001b). The generation of a frequency output may be appealing, although does not eliminate the dependence of the underlying analog change in sensor resistance.

(2) Those based on measuring the variable time delay associated with the change in heat transfer between the sensing elements involved in the measurement of the above thermal properties. Such digitally measurable delay, if primarily dependent on changes in flow rather than in the analog resistances of the sensor elements, would bring us closer to the ideal digital sensor (Bonne and Kubisiak 2000, Bonne *et al.* 2000b, 2001b). In this promissing approach, one should still check and verify that the influence of the sensor analog resistances may still play a role in the overall sensor operation.

2.11.3 Gas Composition Sensors

2.11.3.1 Introduction

Composition sensors may be grouped into many kinds of categories, classes, or types. Because of the impact of the availability of sample mass on MDL, the two types discussed below are sensors that are either mass flow dependent or independent. This grouping has special relevance to microanalyzers because of ultimate S/N limitations when sample mass flow becomes very small. Examples for the former are those based on MS, catalytic beads, paper tape, and amperometric electrochemical (AEC), which actually consume the analyte; examples for the latter are based on nondispersive infrared (NDIR), thermal conductivity detection (TCD), and potentiometric electrochemical (PEC) sensing.

Whenever possible, we strive to report concentrations and MDLs in mole or volume fractions, such as in percent, ppm, or ppb, rather than as a minimum detectable mass flow, such as $\mu g\ s^{-1}$ or $pg\ s^{-1}$, which researchers of mass flow-dependent sensors are known to do. Concentration is a direct measure on how a compound affects our well-being – beneficially (we like to breathe 21% O_2) or adversely (e.g., when exposed to 100 ppm CO). Occupational Safety and Health Adminstration (OSHA) and material safety data sheet (MSDS) safety instructions are also issued in terms of concentrations and not mass flows.

Without unduly dwelling on how to report MDLs, it may be helpful to compare the two units for conventional (and micro) sensors with specified capability to sense a level of 1 ppm of analyte (at a $S/N = 3$). In mass flow sensor terms, sampling at $0.5\ cm^3\ min^{-1}$ to a sensor with a response time of 1 s (or 0.01 s) and an analyte pulse of 0.010-s duration, the 1 ppm MDL would correspond to an MDL of $1\ ng\ s^{-1}$ (or 0.01 $ng\ s^{-1}$ or $10\ pg\ s^{-1}$) in mass flow terms, respectively assuming an analyte MW near that of air.

The sensor composition topics selected for discussion cover a small fraction of the vast field of such sensors and only represent those that the author had some recent involvement with, i.e., it is an arbitrary selection, but one with which we hope to highlight some generic insights. In the conclusions, some typical sensitivities (**Table 3**) and relative advantages and disadvantages for a bit broader range of composition sensors are considered (**Table 4**), including widely used infrared and catalytic bead monitors (Honeywell Analytics 2006, Kramer and Mangieri 2006).

2.11.3.2 Film Sensors – Capacitive, Resistive, and Colorimetric

When thin polymer films are exposed to gases other than dry reference air, a new adsorption equilibrium establishes itself between the gas and the film phase (or stationary phase in GC terminology), whereby a fraction of the new gas component or analyte in the air carrier gas diffuses into the film. This process is reversible when the analyte disappears from the gas phase. However, while present, the addition of the analyte to the film may cause measurable changes in its physical (swelling, mass (Lu *et al.* 2005, Manginell *et al.* 2003)), electrical (resistivity (Doleman *et al.* 1998) or dielectric constant (Patel *et al.* 2003)), and optical (color) properties. Sensors based on such changes are used to sense analytes in applications such as home safety, environmental, homeland security, and regulatory compliance. Surface acoustic wave (SAW) sensors make for a preferred approach for sensing the small change in mass, especially if the film is made thin enough for the equilibration to happen fast enough, and serve as stand-alone or GC detectors (Lu *et al.* 2005, Manginell *et al.* 2003). By

Table 4 Comparison of single-channel gaseous analyte-in-air sensors

Gas	*Advantage*	*Disadvantage*
Electrochemical solid	Highly specific to O_2. Potentiometric. Not sensitive to mass flow. Nondestructive. Can also be run as amperometric.	Requires <750°C, flame arrester for safety and high input power for operation. Operation down to 300°C is possible but yields poor performance/stability.
Catalytic bead	Simple, measures flammability of combustible gas–air mixtures. Low cost, proven technology.	Can be poisoned by lead, chlorine, and silicones that remain as unrevealed failure mode. Requires oxygen or air to work. Require high input power for operation, <400°C.
Metal oxide semiconductor	Mechanically robust, works well in constant high humidity/temperature conditions. Very low cost. Can give fail-safe behavior with poisoning.	Semispecific. Susceptible to contaminants and changes in environmental conditions. Nonlinear response prompts complexity (electronic correction). <300°C. Too slow (~1 s) for micro-GC application.
Thermal conductivity	Measures approximately volumetric concentrations of analyte(s) in reference gas. Nonspecific, thus good for GC detector.	High gas concentrations only. Limited range of gases. Cannot measures gases with conductivities close to air. Nonspecific. High humidity dependence.
Polymer film, change in *R*, *C*, *f*	Semispecific. Low-power operation. Easy fabrication. Sensitive as SAW	Semispecific. Slow. Frequent recalibration needed. Relatively high drift.
Electrochemical liquid (no consumable)	Measures toxic gases in relatively low concentrations. Wide range of gases can be detected.	Failure modes are unrevealed unless advanced monitoring techniques used. Requires oxygen to work.
Electrochemical liquid (consumable anode) oxygen sensor	Linear response to oxygen. Selective.	Limited lifetime (typically 2 years) due to consumable lead anode. Trade-off between sensitivity and lifetime.
Nonfocusing NDIR absorption	Nondestructive analysis to ppm level. Can be used in inert atmospheres. Optical alignment not critical. Small size.	Higher power requirement than electrochemical. Can only detect IR-active species.
Multiple-pass NDIR cavity absorption	Nondestructive analysis to ppb level. Can be used in inert atmospheres. Easy alignment.	Requires high-tech mirrors (<99.99% reflectivity) to achieve <3000 passes and drift-free operation.
NDIR-absorption with frequency modulation	Nondestructive analysis to ppm level. High reliability due to frequency modulation; % abs. immune to source or detector drift.	Requires sophisticated λ-dither mechanism. Fabry–Perot cell fabrication demands tight tolerances and alignment.
Paper tape	Cumulative/dosage sensor signal. Highly sensitive and selective for toxic gases. Leaves physical evidence of the gas exposure No drift. New sensor for easy measurement.	Can require sample conditioning and extraction systems. High sample flow needs. Requires refills of consumable paper.

controlling the temperature of the films, the desired trade-off between speed of response and sensitivity may be achieved.

The availability of a temperature-controlled platform for metal oxide films of SnO_2, WO_3, In_2O_3, etc. (with or without doping of Pt and other metals) served to fabricate sensors that respond with a measurable change in their semiconducting properties to the change in the concentration of oxidizing or reducing analytes. Such sensors were introduced in the 1960s based on thick films of SnO_2 by Figaro. Tin oxide is still the most commonly used metal oxide gas sensing material. In the 1990s, thick-film sensors based on chromium titanate were introduced commercially by Capteur (Dawson *et al.* 1995, Niemeyer *et al.* 2002), offering improved stability and reduced humidity interference.

Metal oxides have been further developed as thin films by researchers at Carnegie Mellon (Clifford and Tuma 1982–1983, Hoffheins *et al.* 1986, Siegel 1989) and Tübingen Universities (Kleine-Benne *et al.* 2005), NIST (Boger *et al.* 2005, Cavicchi *et al.* 2000, Dable *et al.*, 2004,

Meier *et al.* 2004, Tiffany *et al.* 2000), and more recently at ETH Zurich (Barrettino *et al.* 2004), Motorola and MicroSense, in the form of single and arrays on micro-hotplate sensors, leveraging temperature-dependent sensitivity and doping to reduce response time, and increase selectivity and baseline stability.

Less well known is the use of films of chromium titanate by CTL Capteur (Dawson *et al.* 1995, Niemeyer *et al.* 2002), which claim better stability. Stability may be further improved via a differential sensing approach (Visser *et al.* 1994, Zanini *et al.* 1995), as used with other sensors (NDIR, TCD, etc.), and has successfully been implemented with the hot catalytic bead sensor (Honeywell Analytics 2006), in which the reference bead is identical to the sensing bead, except for not having been provided with the metallic doping for the catalytic response. Both these and handheld infrared detectors (Honeywell Analytics 2006, see Table 3) are used to monitor fuel gas concentration and degree of flammability.

Another method of improving the stability, response time, and/or selectivity of metal oxide sensors makes use of high temperatures to reset the sensor to a known state and then monitor the transient behavior when responding to gas at a subsequent lower temperature. **Figure 27** illustrates such an approach with semiconducting WO_3-based O_3 sensors. Such approaches are used in commercial sensors by Figaro (Massok *et al.* 1995) and Capteur (Aliwell *et al.* 2001, Pratt *et al.* 2001).

For all the above sensors, one expects that the physical changes induced by the analytes are reversible. However, as with other sensors, drift erodes reversibility, so that periodic recalibration is needed, unless one can afford to use a new sensor for each measurement.

But this is exactly what paper tape-based sensors do. Rather than emphasizing reversibility, as with some polymer films (Daws *et al.* 1997), one widely used category of paper-film sensors leverage color change with time that is irreversible, i.e., cumulative, and can directly relate to doses, e.g., doses that workers are exposed to during some working period. **Figure 28** shows the working principle of such a system. The porous paper supports the reagent that turns color when the targeted analyte is present in the sample. Everyone is familiar with the classical litmus paper to gauge the pH of liquid samples, but few would have heard about other such paper spots for sensing chemical agents in water (M8 paper used by the military) or for sensing analytes in air, which is more relevant to the subject at hand (see Chemcassette analyzers used for air monitoring in the semiconductor industry (Honeywell Analytics 2006)). In this case, the sample is drawn through the pores of the paper, as for measurements of stack gas soot concentration with the classical Bacharach smoke spot test. If the intended analyte is present in the sample gas and comes in contact with the reagent in the paper, the color of the paper changes and is quantified via change in the reflected light intensity. Such color change can be highly specific to analyte categories such as hydrides, acids, halogens (Honeywell Analytics 2006), and may be used in the form of personal badges or central monitoring stations. **Table 3** presents a partial list of compounds presently detectable with less than a dozen types of reagents embedded in the paper.

2.11.3.3 Electrochemical Sensors – Potentiometric and Amperometric

The simplest form of an EC cell sensor is of a two-electrode design, as used in potentiometric, solid-state electrolyte (YSZ) oxygen sensors, with porous Pt electrodes, now widely used for air/fuel ratio control in stationary and automotive combustion systems. The basic output signal is a log function of the available analyte (oxygen) in the sample gas, relative to the concentration in the reference gas, typically air, which is represented by the classical Nernstian cell potentiometric output of

$$E = \frac{RT}{nF} \ln\left(\frac{[O_{2,\text{sample}}]}{[O_{2,\text{ref}}]}\right)$$

where the square brackets represent concentractions or partial pressures, R is the universal gas constant, T is the absolute temperature, F is the Faraday constant (96 500 C mole^{-1}), and n is the number of charges per ion. Later innovations leveraged this basic EC cell mechanism to provide sensor outputs that are linear with absolute partial pressure of oxygen, and are based on either closed cells or cells with a purposely added leak. With the closed cell, oxygen is pumped in and out by changing the polarity of an applied fixed DC voltage, so that the time for a complete cycle becomes the linear, absolute measure for the oxygen partial pressure present outside of the cell in the sample gas (Kroot *et al.* 1990). With the leaky cell, one simply obtains the sample gas oxygen from the current input into the cell, which just uses up all the oxygen entering into the cell by diffusion, while the

applied potential drives the oxygen out via ionic oxygen conduction through the YSZ. However, ionic conduction of YSZ requires operating temperatures of $\geq$750°C. While the hazard of using such potential ignition source as a sensor can be managed via classical flame arrestors, in the form of metal frits, its high power consumption has limited its use in portable devices, despite attempts to microminiaturize (MM) such sensors (Bonne *et al.* 1995b, Cole *et al.* 1986) or to further reduce the size of the already small, 2 × 2mm × 2mm cells.

Regarding the MM effort, future researchers may benefit from our experience with fabricating unsupported thin films of YSZ, by ion sputtering thin films of YSZ onto a Si_3N_4-coated Si wafer before etching away the silicon, resulting in the films shown in **Figure 24(a)** (Cole *et al.* 1986). Severe buckling of the compressively stressed films led to breakage if the thickness was increased beyond ~400 nm, yet at that small thickness, the measured output potentials (with also-deposited thin films of Pt) did not achieve the desired stability, although temperaturewise (see **Figure 24(b)**), the resistively heated films showed lifetimes of over 2000 h at ~800°C, with input powers of only 60–70 mW during the on-periods of 10 Hz pulsed DC, to simulate and check duty cycling (50%) to extend sensor life (Cole *et al.* 1986).

In any case, the choice of solid-state, ion-conducting materials to make specific potentiometric gas sensors is much more limited than the availability of liquid electrolytes. This has led to the development and availability of a great variety and number of low-cost AEC cell sensors, with the simplest again being of a two-electrode design (Application notes by City Technology Ltd. (Div. of Honeywell)). Such an EC cell consists of a semipermeable diffusion membrane, a reservoir of acid electrolyte, a sensing electrode and a counter electrode. The electrodes generally consist of a polytetrafluoroethylene (PTFE) substrate coated with a catalytic mixture, usually platinum, which significantly accelerates the sensing gas reaction. In most cases, any gas diffusing into the cell reacts at the surface of the sensing electrode producing, as a by-product, a number of ions (H^+) and electrons (e^-). The ions travel through the acid electrolyte to the counter electrode while the negatively charged electrons travel to the counter electrode via the external circuit. Combining the electrons and ions at the counter electrode completes the reaction without any of the cells components being consumed. The amount of electrons produced by the reaction is directly proportional to the amount of gas present and measuring the current flowing through the external circuit is a basic gas monitor.

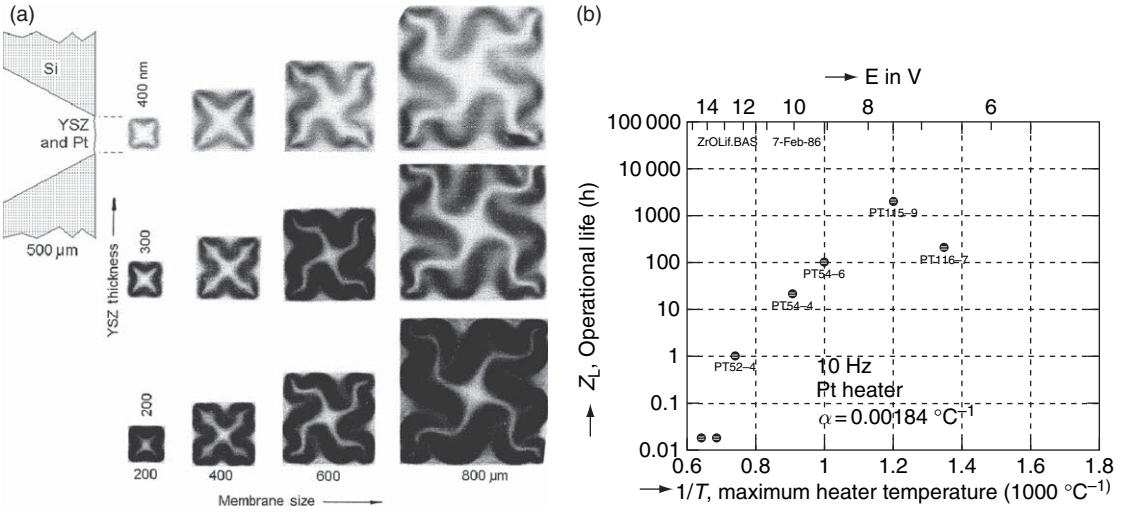

Figure 24 (a) Top-view micrograph of buckled yttria-stabilized zirconia (YSZ) thin-film membranes (with Pt thin-film heaters and electrodes), supported by a silicon chip (drawn to scale in cross section at left), showing increased buckling with membrane size, but with little dependence on film thickness. (Source: Cole B, Ule E, Schuldt S, Bonne U 1986 Oxygen microsensor development. Final Report to GRI, Contract No.: 5084-234-0984, GRI-86/0190 and -90/0170, Honeywell Labs, Plymouth, MN, March 31, 1986, revised July 21, 1986; reproduced with permission.) (b) About the life time of thin-film, self-heated YSZ sensors. (Source: Cole B, Ule E, Schuldt S, Bonne U 1986 Oxygen microsensor development. Final Report to GRI, Contract No.: 5084-234-0984, GRI-86/0190 and -90/0170, Honeywell Labs, Plymouth, MN, March 31, 1986, revised July 21, 1986; reproduced with permission.)

A key feature of this EC sensor design is the gaseous diffusion barrier (see (1) and (2) in **Figure 25**), which may take the form of such small openings, permeable membranes, or a combination of the two (Hogan 2006) that limit the flow of gas to the sensing electrode. This feature permits the electrode to react to target gases as it reaches its surface, and still has EC activity in reserve and thus a long life. The electrolyte reservoir even allows the sensor to operate for a short time in dry conditions without drying out and can contain a reserve of dissolved oxygen allowing the sensor to operate for a short time in the absence of oxygen. The diffusion barrier reduces typically large EC sensor temperature coefficients to the relatively small and predictable diffusion temperature dependence of $D = D_o(T/T_o)^{1.5}$.

Figure 25 shows details of the makeup of such a related, but a three-electrode cell, as well as its drive and sense circuit, representing a potentiostatic circuit, widely used for EC measurements. Besides the two main electrodes, sense (W in **Figure 25**, for working) and counter (C) electrodes needed for basic operation, the reference electrode (R) is added to achieve greater stability and thus lower MDL. The reference electrode is held in an environment in which it will not react with the analyte; it plays no part in the reduction/oxidation reactions in the sensor and is able to maintain a constant potential. In operation, the measurement is taken between the sensing and the reference electrodes, allowing the potential of the counter electrode to change as necessary without affecting that of the working electrode. Therefore, the performance of a three-electrode sensor is more stable, generally has a higher output than that of a two-electrode device, and can be used to monitor a wider range of analyte concentrations.

The circuit in **Figure 25** shows that the signal is generated by converting the cell current between W and R to an output voltage (bottom op-amp), while the top op-amp controls the reference potential. For the shown circuit:

- V_{OUT} = analyte concentration × cell current × R_F. If $R_F = 100\ \text{k}\Omega$, cell output is $50\ \text{nA ppm}^{-1}$ and gas concentration is 100 ppm then $V_{OUT} = 100 \times (50 \times 10^{-9}) \times (100\,000) = 0.5\ \text{V}$.
- The output polarity depends on the redox properties of the analytes being sensed.
- R_L is the cell load resistor (typically 5–50 Ω). A small value of R_L will increase noise, but give a faster speed of response; and *vice versa*.
- C_1 and C_2 help to reduce sensor signal noise and EMI susceptibility. Typical values are $C_1 = 4.7\ \text{nF}$ and $C_2 = 47\ \text{pF}$.
- R_B stops the sensor from polarizing when the circuit is powered off (typically 1–10 kΩ).

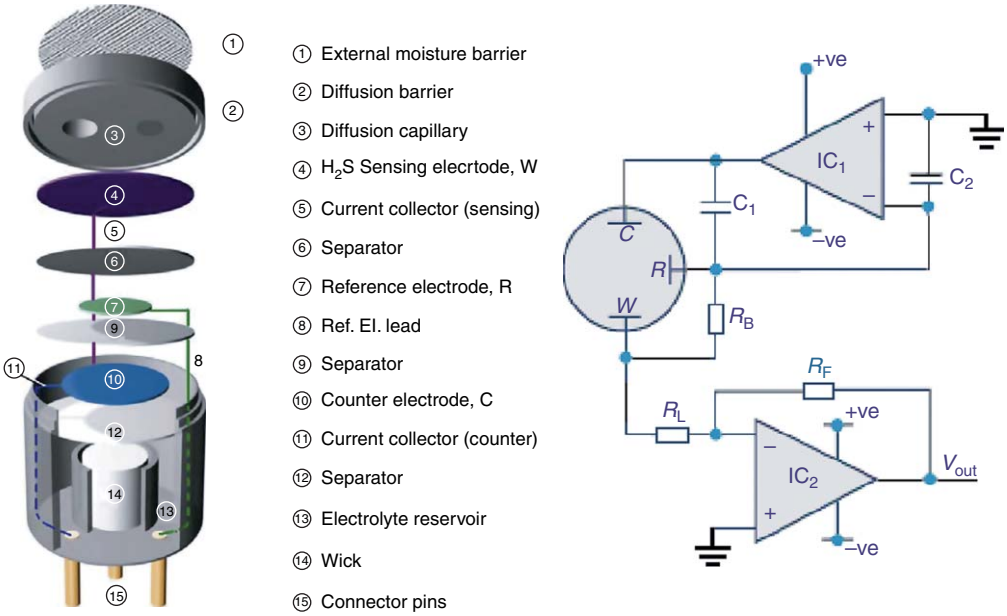

Figure 25 Component view of a three-terminal WO_3-based sensor and its circuit. The reference electrode provides greater stability than a two-electrode sensor. (Source: Application notes by City Technology Ltd (Div. of Honeywell), Walton Road, Portsmouth, Hampshire, PO6 1SZ, UK; reproduced with permission.)

- Some EC sensors require special features, such as temperature compensation circuitry for CO sensors and a small bias voltage for CO_2 sensors.

Due to the highly active nature of the catalysts used in EC sensors, such catalysts can oxidize or reduce gases other than the target gas. In these cases, the sensor exhibits a cross sensitivity, which can, on occasion, be used to extend the measurement capability of the sensor. For example, chlorine sensors exhibit a significant cross sensitivity to chlorine dioxide (ClO_2), bromine (Br_2), and ozone (O_3) and can therefore be used as a suitable sensor for detecting these gases when none of the others are present. The effect of interfering gases may be reduced by catalyst selection, use of on-board filters, or by applying a bias voltage between the working and reference electrodes.

Given the low power consumption of such sensors, intrinsic safety (IS) certification should be easy to obtain. Theoretically, it is possible for an EC sensor to produce up to 1.25 V during an open circuit, but as most of the reactions are irreversible the full potential is never reached. Sensors of Honeywell Analytics will not produce a voltage greater than 1.3 V and a current greater than 1.0 A (Application notes by City Technology Ltd. (Division of Honeywell)).

2.11.3.4 Conclusions

By way of summary, **Table 3** provides a partial list of the variety of analytes sensed by just a few of the sensors discussed above, along with sensitivities (Honeywell Analytics 2006). Paper tape-based sensors have the advantage of leveraging their cumulative, nonreversible color spot, and can therefore increase their sensitivity by increasing the sampling time. For the listed sampling times in the 10- to 60-s range their MDL is in the 2–5 ppb range, which is ~10–30× higher for the EC sensors and typically higher for the portable NDIR type, with the exception of optical cavity approaches, which have achieved NH_3, H_2O, and acetylene (Bamford *et al.* 2003, Gupta 2004) detection in the low ppb range.

Table 4 presents advantages and disadvantages of a number of individual channel sensors, beyond the above discussion, but in use today by us and others on both productized and developmental bases, borrowing heavily from and expanding on inputs received from experts at Honeywell Analytics (Hogan *et al.* 2006) and others such as B Warmack at ORNL, T Mlsna at Seacoast Science, and S Semancik at NIST-CSTL. The rows are arranged in decreasing temperature of operation, starting at the top with the YSZ O_2-sensing cell, which requires operating temperatures above ~750°C. Nonspecificity is a desirable feature (e.g., thermal conductivity) if the sensor serves as a detector with a GC, for the range of gases to be detected (ideally combined with insensitivity for the gases not of interest), as discussed in Section 2.11.4. Such joint operation eliminates a large part of the drift problem, as the GC provides a new baseline at every analysis.

Users may be willing to forgive some reversible temperature and humidity dependence, insensitivity, limited (fail-safe) service life, and cross sensitivity, but not unpredictable drift or unreliable operation. After having accepting the fact that all sensors drift, the chemical processing industry achieves the needed reliability by having test gases available for automatic calibration for their online process analyzers, as further elaborated in Section 2.11.4. Carrying calibration gas tanks with and or portable or handheld sensors for an 8-hour day can be quite burden some, although practiced in some cases as, e.g., with (hydrogen) flame ionization detectors (FIDs) for natural gas leak detection.

AEC sensors have made a virtue of their unavoidable mass flow dependence and leveraged it to generate a pulsed output from regular to zero, in accordance with periodic sample flow interruptions (Pratt *et al.* 2003), as illustrated for an ozone sensor in **Figure 26**. Of course, the pump flow rate needs to be repeatable and the stoppages need to last long enough time to allow the EC sensor to consume the analyte over its dead space, and thereby to drop its output signal to near zero. The sensor has a modest response at low gas flow rates; at intermediate flow rates the response is approximately proportional to the gas flow rate, while above the critical flow rate the response is fully developed.

To overcome drift, optical nondispersive absorption sensors (e.g., NDIR) have resorted to the dual-beam approach or, better yet, to a single beam with a chopper wheel transmitting at least two narrow wavelength bands corresponding to on and off band transmission of the analyte of interest. Such frequency modulation approach can be achieved via a Fabry–Perot interferometric scheme (Barrett 1976, 1977, Jerman *et al.* 1990, Raley *et al.* 1992), which eliminates the effect of drift in the source intensity, detector sensitivity, and/or

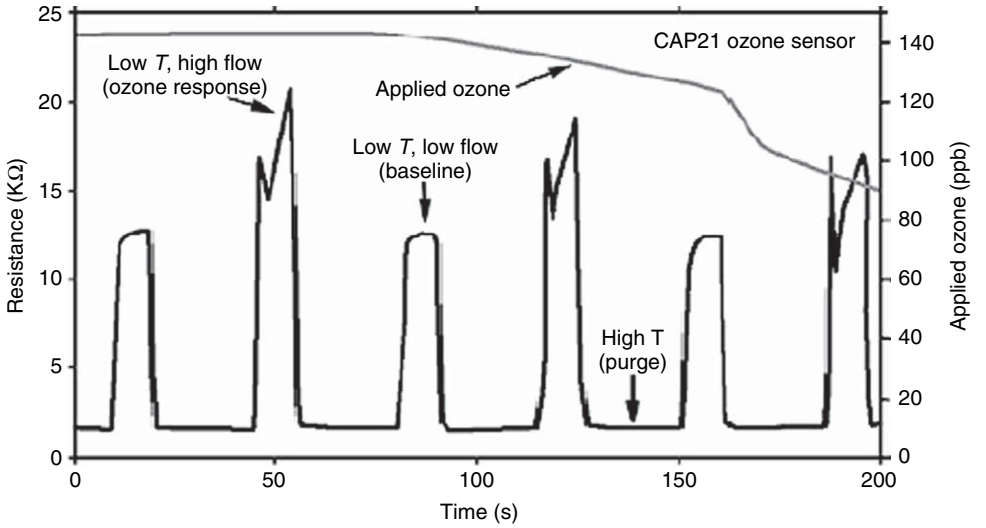

Figure 26 Measured WO_3-based ozone sensor output as its sample flow rate is periodically interrupted to reveal the signal baseline level, and thus to reduce drift and uncertainty. Also demonstrated is the benefit of periodical high-temperature (600°C) cycles to restore the sensor to reference conditions. (Source: Pratt K *et al*. 2003 The effect of flow rate on cap21 ozone sensitivity. Capteur Division of City Technology Ltd, Walton Road, Portsmouth, Hampshire, P06 ISZ, UK, June 2003, Website at http://www.citytech.com/PDF-Datasheets/MMDS_Cap21_t2ops.

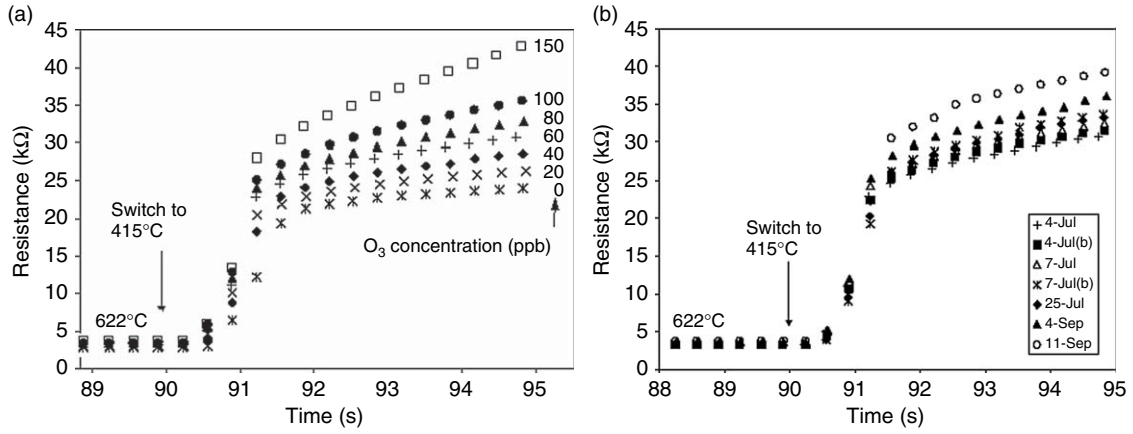

Figure 27 Calibration responses of an O_3 sensor based on a film of semiconducting WO_3, in a sample gas flow rate of 1 l/min, versus time, when switched from 622°C to 415°C. (a) For the listed O_3 concentrations. (b) After the listed days of operating time with an O_3 concentration of 60 ppb. At the higher temperature, O_3 decomposes before reaching the sensor and effectively provides a zero-O_3 baseline, thus reducing signal drift. (Source: Aliwell S R, Halsall J F, Pratt K F E, O'Sullivan J, Jones R L, Cox R A, Utembe S R, Hansford G M, Williams D E 2001 Ozone sensors based on WO_3: A model for sensor drift and a measurement correction method. *Meas. Sci. Technol.* **12**, 684–900.); reproduced with permission.

transmission of the optical surfaces, and is used, e.g., in the Vaisala CO_2 sensors (CARBOCAP CO_2 Transmitter).

The dual or differential sensing approach is used also with the popular and low-cost catalytic bead sensors, where only one of the beads is provided with the small mass fraction of catalyst, but both are exposed to the same sample gas environment (Honeywell Analytics 2006).

Last but not least, and ranking high in terms of reliability, is the paper tape sensor mentioned earlier, whereby a fixed volume of sample is drawn through a reagent-impregnated, porous paper and the irreversible color change is monitored as a measure for the amount of analyte present in the sample. After a measurement, the tape is advanced to a new and fresh paper spot location, thus providing an inherently stable reference baseline (relying on carefully

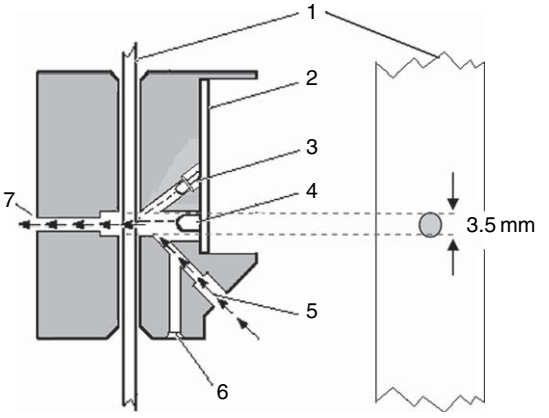

Figure 28 Cross-sectional schematic drawing of a paper tape-based gas-sensing system. Analyte reaction with the reagent in the paper results in a change in color (color spot), which is detected photoelectrically. 1, Paper tape; 2, PCB; 3, LED light source 4, detector; 5, sample gas inlet; 6, pressure-transduced port; 7, sample outlet. (Source: Honeywell Analytics 2006 *Gas Book*, May 2006, and webpage at http://www.honeywellanalytics.com, *Product Range, Analyziers and Sensors*: Honeywell-City Technology at http://www.citytech.com/technology/pellistors.asp and http://www.citytech.com/technology/irsensors.asp)

controlled paper and reagent uniformity), while the previous one remains as a permanent record (Honeywell Analytics 2006) (**Figure 28**).

Another way to provide that stable baseline is by scanning an independent variable such as wavelength, mass, temperature and time as optical spectrometers, MSs, DTAs, and GC analyzers do, respectively, which are to be discussed next.

2.11.4 Multichannel Micro Gas Analyzers

2.11.4.1 Introduction

This section focuses on advanced state-of-the art development of micro gas analyzers (MGA). As defined earlier, we view analyzers as representing multichannel sensors, which are therefore able to identify and quantify the concentration of more than one or two analytes. The larger the number of such independent (or orthogonal, see Section 2.11.5) channels, the better such analyzers can perform their identification job. Sensitivity or MDL of each channel is clearly a separate analyzer performance parameter, but equal to the MDL of single-channel sensors.

Today's commercial micro gas chromatographs or micro-MSs typically entail packaged systems of a half to one shoe box in volume or 5000–9000 cm^3, i.e., portable but still outside the range one would expect for handheld devices of below ~500 cm^3. The discussion below shall be about such analyzers, down to the 50-cm^3 level or cell phone size level, which would serve in applications of first responders, homeland security, medical and breath analyses (Sanchez and Sacks 2003), environmental emissions, and industrial *in situ* process stream sampling (shorter sampling lines and no analyzer sheds).

We shall further narrow the scope of the discussion below, by limiting it to multidimensional microanalyzers, then in Section 2.11.4.4 to using GC as the first-dimension analyzer or analyte separator, and then engage polymeric (chemical impedance detector (CID)) and optical or mass/ion mobility spectrometry (MS/DMS (differential mobility spectroscopy)) for the sample analysis in the second dimension. GC has the unique capability among all other analyzers, to make available for further analysis significant quantities of separated analytes, which then enables the use of multichannel second dimension analyzers to do a better job with analyte quantification and identification, than if that GC stage was not available. Clearly, second dimension analyzers (such as MS, ion mobility spectroscopy (IMS)/DMS, microdischarge detector or device (MDD), CID, and surface-enhanced Raman spectrometry (SERS)) are successfully being used as stand-alone detectors as well.

Venture capital and government-sponsored R&D has recently spawned a number of micro-GC-based developments falling into the 50- to 500-cm^3 range (Bonne *et al.* 2004, 2007, Lehmann *et al.* 2005, Lu *et al.* 2005, Manginell *et al.* 2003, Masel 2004, Pau *et al.* 2006, Polla and Nguyen 2004, Simonson *et al.* 2004), with the goal of achieving even further compactness and low power for battery operation and portability. The need for such MGAs and involved trade-offs were well described in Polla and Nguyen (2004), Bonne *et al.* (2007), and Bonne *et al.* (2003). Some general insights gained there were as follows:

- MM is an enabler to achieve better MGA performance in terms of response time, sensitivity (because of the enabled integration of rapid micropreconcentrators (micro-PCs)) selectivity (because of the affordability of a larger and multidimensional channel capacity), FAR (because a larger and more multidimensional channel capacity, despite the smaller time-channel capacity of a shorter micro GC column than that of a longer column of a desk-top GC), size, weight (from 50 lb to 50 g),

energy per analysis (reduction by 1000–10 000×), and cost (reduction by 10–100×).

- Optimal performance of MGAs would be achieved with units which separately optimize the preconcentration (PC), selectivity, and quantitation functions, and then closely couple them, rather than integrating them into one operational step as for example in a system comprising an array of chemiresistors or a fixed laser as light source for optoacoustic detection.
- Sample gas transport: MGA operation depends on reliable sample (or carrier) gas flow control, which is now dependent on failure-prone mechanical pumps. Alternatives to present mechanical gas pumping and flow control need to be developed, to provide low power and reliable service life (Bonne *et al.* 2003). Pumping based on thermal gas expansion and contraction (Bonne 2007, Bonne *et al.* 2006a, Gokhfeld 2006), ion drag (Garimella *et al.* 2004, Madhan *et al.* 2003, Roth 2003), as well as fluidic–diode effects (Morris and Forster 2003) are worthy of further study. The review by Laser and Santiago (2004) may be another good starting point.
- Manufacturability considerations: Beyond R&D successes, ultimate success in the eyes of potential users requires that researched MGA designs and capabilities can translate into manufacturable, high performance, and economically viable products. Wafer-level fabrication and assembly needs to be leveraged as much as possible, and is enabled by MGAs.
- The GC–MS combination is viewed as the Gold Standard for chemical analysis, because it combines the separation of analytes – with their MW identification (Bonne *et al.* 2007). Proponents of Raman spectroscopy (Haynes *et al.* 2005) would argue that MS cannot distinguish organic isomers (Heaps and Griffiths 2005) and that fragmentation during the MS ionization step, despite assisting with analyte identification, unduly complicates the mass spectrum when several analytes need to be sensed simultaneously. Thus the GC–SERS combination is clearly an analyzer of interest (Carron 1997, Carron and Kennedy 1995, Haynes *et al.* 2005, Heaps and Griffiths 2005).

2.11.4.2 Optical Spectral Absorption and Emission

Among gas analyzers to determine the concentration and identity of single or mixed analytes, NDIR, visible, and ultraviolet optical absorption analyzers and RLGAs (Rich 2001) are commercially available to measure analytes down to a 20–100 ppm range. To reach MDLs below that level with absorption analyzers requires large optical path lengths and associated bulkiness, maybe with the exception of analyzers based on optical absorption cavities featuring thousands of internal reflections (Bamford *et al.* 2003, Gupta 2004), including CRDSs but which have a limited spectral range dictated by the laser source while requiring relatively large sample volumes, polar analytes and sophisticated mirror technology. Such absorption limitations of path and wave-length, and analyte polarity are not hindering Ramas scattering approaches such as RLGA and SERS, besides exhibiting great selectivity, 10-ppm-level sensitivity and 50 ms response time, as demonstrated by ARI's analyzer (Rich 2001).

Also, the optical spectrochemical emission approach bypasses the above problems, while, of course, also having to cope with its own. It is an outgrowth of classical methods based on arc discharges (still used today as high-power atomic emission detectors (AEDs) for GCs) and modern plasma display technology using noble gas fillings. Such microglow discharges output spectral emission of lines and bands indicative of the elements and molecules in the sample. To achieve such glow discharges, well-documented conditions of applied voltage needed for breakdown, electrode spacing, gas type, and gas pressure are described by classical Paschen curves (Raizer 1991). At first, such MDDs only operated in He or Ne at subatmospheric pressures, for only a few minutes in air. But a recent effort by Herring *et al.* at Caviton Inc. resulted in extended (>5000 h of continuous and stable) operation in ambient pressure air, optional operation in 100- to 200-μm ID channels, i.e., using extremely small dead volumes, a few milliwatts of input power, and yielding emission lines and bands over the whole UV, visible, and IR spectrum. Photodetection may consist of individual channels provided by narrow ($\Delta\lambda \sim 2$–5 nm) band pass filters, or, preferably, by small spectrometers with photodetector arrays and CCD readout, as offered by, e.g., Ocean Optics, or more compact ones by Headwall (measuring less than 1 cm × 2 cm × 5 cm) and maybe others. Clearly, such MDDs are attractive detectors:

(1) By themselves, having demonstrated sub-ppm MDLs.
(2) As fast-responding and low dead volume detectors for micro-GC analyzers, as discussed in Section 2.11.4.4.

This is illustrated as follows.

- **Figures 29** and **30** present configurations of recent use for MDDs, with provision for sample gas flow, protection of the optical fiber end (leading to the PD or spectrometer) or window from metallic electrode sputter depositions, and maximum collection of optical emission intensity (Bonne *et al.* 2006a, Herring 2006b). Discharge excitation is preferably with AC in the 20- to 200-kHz range and between ~250 V for the configuration in **Figure 29** (Herring 2006b, Fiona *et al.* 2002) and 1000–2500 V_{p-p} for the one in **Figure 30** to overcome the AC impedance presented by the dielectric barriers.
- The photographs in **Figure 31** are of actual MDD discharges, with the one at left taken after logging over 4300 h of continuous operation in air, and at right an MDD operating in a channel with N_2 flow (Bonne *et al.* 2006a).
- To illustrate what the lowest operating voltages for an MDD might be, **Figure 32** presents a reproduction of classical Paschen curves (Raizer 2001). As shown, the minimum breakdown voltage requirements without the dielectric barrier are just under 200 V for Ne and under 400 V for air.
- MDD emission spectra in **Figures 33** and **34** were taken to reveal the presence of 2.5 ppm traces of Ar, and of CO and CO_2, respectively, in He with observation times of 1 s. Note that the reference He gas spectrum also shows the presence of some Ar and O_2, demonstrating the sensitivity of such spectral emission, but also hinting at the fact that heating the sample lines is needed, even for work with the above high vapor pressure gases, to minimize purge times and concentration reading errors.
- To better visualize and separate emissions of targeted analytes from background emission lines and bands, the formation of spectral differences is helpful, or as **Figure 35** shows an even more effective approach may be the formation of spectral ratios.
- If an MDD is fitted to the output of a GC, wavelengths of special interest may identify the analyte peaks as they elute, as shown by the traces in **Figure 36**, which demonstrates the 2D approach of a GC–MDD combination. The MDD had been placed at the exit of a temperature-ramped, 5-m/100-μm-ID/400-nm DB-5-coated column of a Hewlett-Packard HP 6890 GC, with He as carrier gas.
- **Figure 37** compares the speed of response and detection limit of a standard GC FID and MDD emission by CN at 388.34 nm of a similar set of analytes as in **Figure 36**, but now carried by N_2 flow. Further processing of the data shown revealed MDLs at and below the 1 ppm range. The speed of response of the MDD limit was not taxed in this experiment; it was determined separately that the MDD response time may be even shorter than the 1- to 2-ms timescale available with that setup.
- As analyte concentration increases, so does generally its emission. **Figure 38** shows this for increasing concentrations of CH_4 in N_2, by monitoring the emission at 388 nm due to the formation of CN from N_2 and CH_4 in the discharge plasma. As shown, the increase is less than linear with concentration, and may be caused by the particular chemical kinetics taking place in the plasma.

Recorded with an Ocean Optics USB2000 spectrometer. (Source: Herring C M 2006a Caviton Inc., Private communication, June 2006.)

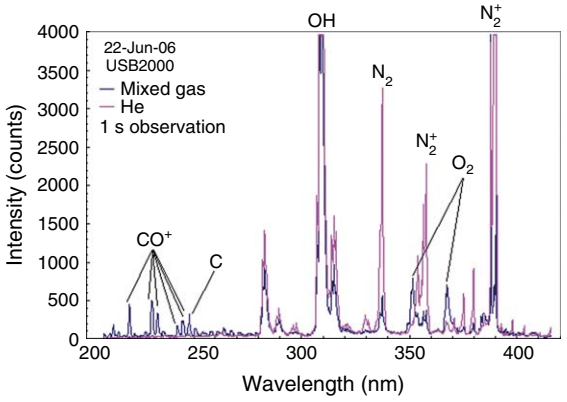

Figure 34 Microdischarge detector (MDD) emission spectrum to reveal the presence of 2.5 ppm CO and CO_2 traces in the He sample gas mixture, compared to pure He reference gas. Recorded with an Ocean Optics USB2000 spectrometer. (Source: Herring C M 2006a Caviton Inc., Private communication, June 2006; reproduced with permission.)

The above points show the versatility, speed of response, sensitivity, multichannel, small dead volume, and compactness of MDDs. Stand-alone detection of NO_x, and ppb level detection of Hg and other metals have been demonstrated (Herring 2006a). Future R&D effort is needed to better understand glow plasma kinetics, which often results in emission output sensitivities to the uncontrolled change in the concentration of gases such as O_2 and H_2O, which at present, are worked out empirically.

2.11.4.3 Mass Spectrometry

One of the most attractive aspects of mass spectrometry is its ability to provide the user with the direct identification of the analytes by way of their MW. The most problematic aspects (preventing their use in portable or handheld gas analyzers) are the requirement of operating at absolute pressures below a millitorr (or below $\sim$1 dyne cm^{-2}, 1 μbar or 0.1 Pa) and the bulkiness (size and weight) of present pumps. Among the different types of MSs in use today (magnetic deflection, time-of-flight, quadrupole, and ion trap) only ion trap MS (ITMS) shall be discussed in more detail, because of its selection to develop a chip-level GC–MS, based on ORNL's ITMS technology (Bonne *et al.* 2004, 2007, Pau *et al.* 2006).

The principle of operation of such ITMSs can be briefly described as follows: after ions of the sample gas are created by any of a number of approaches (electron beam, corona discharge, charge transfer, etc.) and ion groups (small enough to avoid space charging) or pulses are transported into the cavity such as the one shown in **Figure 39**, they are trapped by the quadrupole electric field obtained by the application of just the right AC + DC field amplitude to the end caps and the fundamental radio frequency (RF) signal applied to the ring electrode. The mass spectrum results from scanning the amplitude of this fundamental RF signal, V, which causes sequential ejection of trapped ion masses, whose trajectories become unstable, through the holes in the end-cap

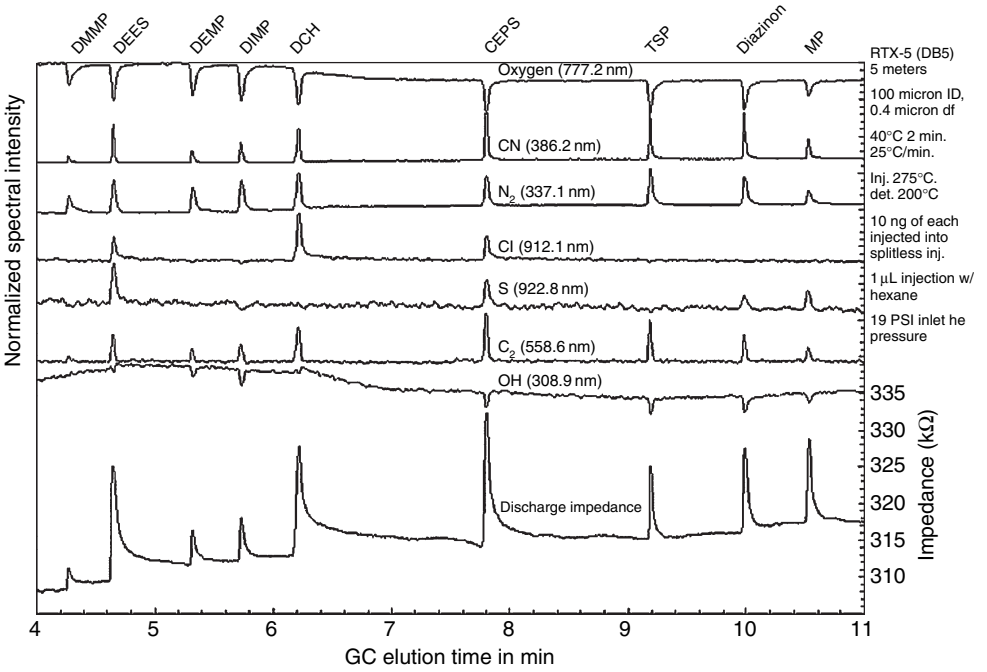

Figure 36 Microdischarge emission outputs of a mixture of analytes, with seven optical wavelength channels, in addition to an electronic channel monitoring microdischarge detector (MDD) impedance, all downstream of a commercial gas chromatagraph (GC) (5-m/100-μm/400-nm DB5 with He carrier gas). (Source: Herring C M 2006a Caviton Inc., Private communication, June 2006; reproduced with permission.)

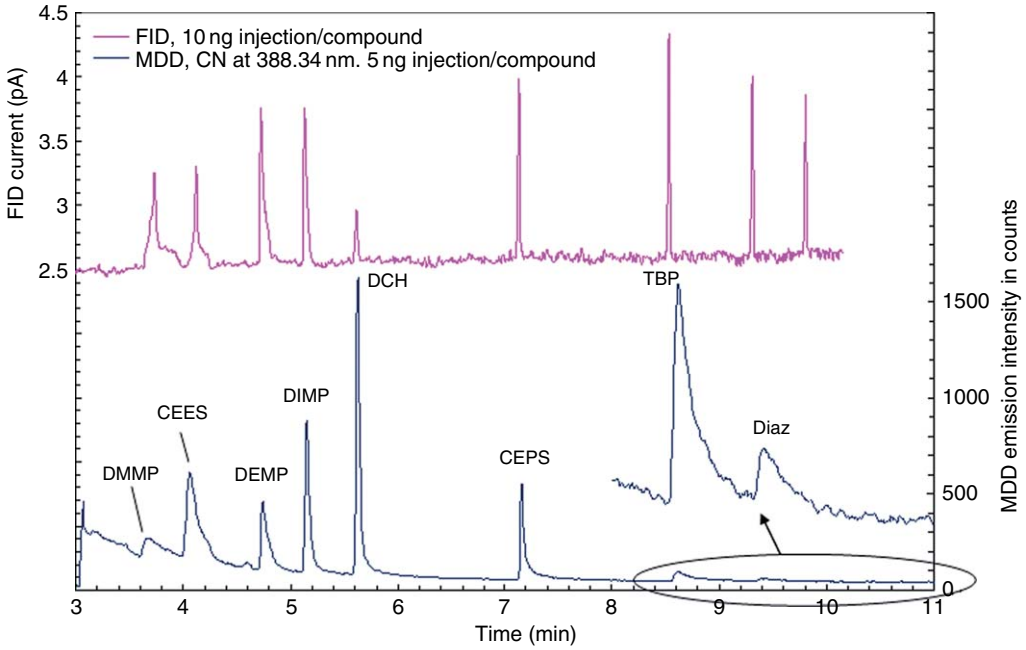

Figure 37 Comparison between flame ionization detector (FID) (*top*) and microdischarge detector (MDD) (*bottom*) outputs for a mixture of analytes separated by a commercial gas chromatagraph (GC) (5-m/100-μm/400-nm DB5 with N_2 carrier gas). Figure 38 (a) Calibration curve of microdischarge detector (MDD) emission from CH_4 in N_2 in the form of the CN band at 388 nm, demonstrating ppm level detection of CH_4, and (estimated) sub-ppm level for pentane at $S/N > 3$. Observation time: 100 ms. Also shown is N_2 emission at 319 nm for reference. (Source: Herring C M 2006a Caviton Inc., Private communication, June 2006; reproduced with permission. Kunze K 1997 Miniaturized discharges – Prospects and limits for quantitative analysis. Ph.D. thesis, University of Dortmund, Germany; reproduced with permission.)

electrode. The end cap is close to a Faraday cup or electron multiplier (not shown in **Figure 39**), which counts the ejected ions as V is scanned. Textbooks and websites abound with more details, which need not be repeated here.

Achieving mass resolution of 1 atomic mass unit (amu) is generally expected of and achieved by the above-mentioned MSs. A resolution of $\leq$0.25 amu was achieved with a 1-mm ID trap ITMS (see **Figure 39**, which also details the structure of such an analyzer). Such resolution sets ITMSs apart from ion mobility and differential (ion) mobility spectrometry (IMS and DMS), which have achieved the equivalent of mass resolutions of 20 amu (Eiceman *et al.* 2004) and a shorter mass range, although operating at ambient pressures and excelling with achieving low ppb levels of detection of large MW and low ionization energy compounds, which are characteristic of those of interest to civilian security and defense. The size reduction has been and continues to be addressed by many researchers (Akinwande 2004, Blain *et al.* 2004, Ferran and Boumsellek 1996, Pai *et al.* 2005, Pau *et al.* 2006, Whitten 2004), and is tied to mitigating the pressure issue, because increasing pressure reduces the mean free path and forces a reduction of internal MS structures and molecular paths. The increase in gas density associated with increased pressure may increase ionization efficiency for IMS (Eiceman and Karpas 1994) and for ITMS, at least partly making up for the reduced number of ions trapped in the smaller ion trap, besides enabling the fabrication of trap arrays to generate higher S/N outputs, as being pursued by the ORNL–UNC–UA team (Pau *et al.* 2006). Theoretically, an array of n traps with $d = d_o/n$ should give the same performance as an individual trap with a trap diameter of d_o, provided the ring frequency is increased by the same factor of n and yielding an overall reduction of MS volume by a factor of n^2. However, producing the same RF voltages while increasing the frequency has practical limits; yet lower RF voltages and higher frequencies may be used to produce a viable ion trap MS with some distinct advantages (Witten and Ramsey 2002–2006).

To illustrate the ITMS micromachining approach taken by this team, **Figure 40** presents the design and

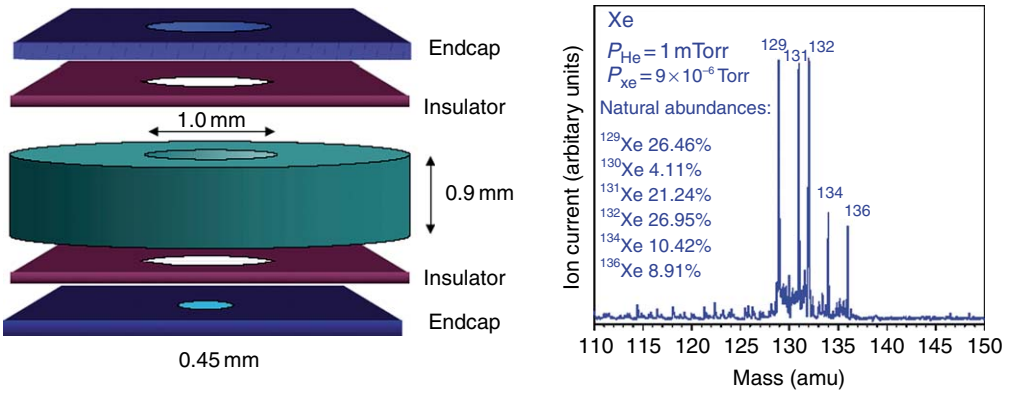

Figure 39 Assembly of a 1-nm ID cylindrical ion trap for an ion trap mass spectrometry (ITMS) (*left*) and obtained resolution of 0.1–0.25 amu of Xe isotopes in 1 mtorr of He, using electron impact ionization and a single scan of ~5 ms for data acquisition. (Source: Kornienko A, Reilly PTA, Whitten W B, Ramsey J M 1999 *Rapid Commun. Mass Spectrom.* **13**, 50; reproduced with permission from Wiley-VCH Europe Ltd.)

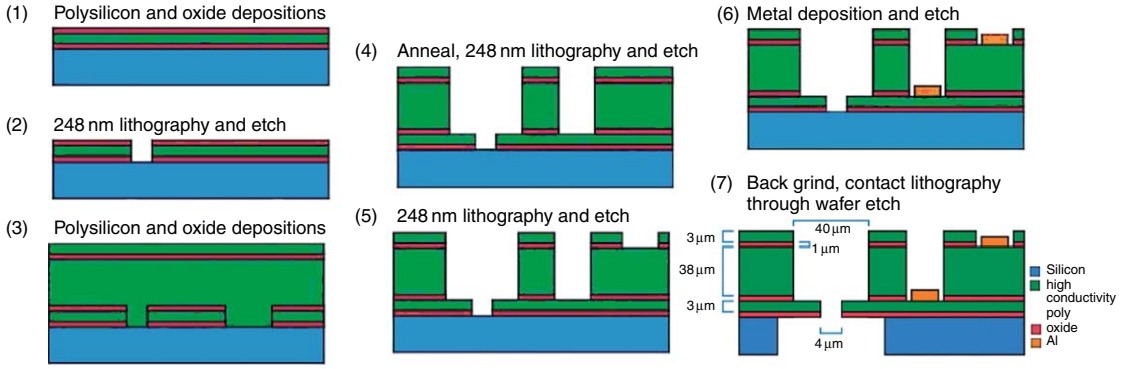

Figure 40 Design and fabrication steps of a 40-μm ID ion trap array, consisting of open cap cylindrical traps. Step 7 also shows the dimensions of the completed trap. (Source: Raizer Y P 1991 In: Allen J E (ed.) *Gas Discharge Physics.* Springer-Verlag, Berlin, Heidelberg; reproduced with permission.)

micromachining steps of a 40-μm ion trap array, which has resulted in measurable ion currents but still exhibits undesirably high capacitance, that lead to impractically high displacement currents (Witten and Ramsey 2002–2006).

The limit in ITMS size reduction and associated pressure increase appears to be governed by the ability to fabricate well-defined and uniform ion traps in the 1- to 10-μm range, and operate in the trapping frequency range of gigahertz (at trap potentials above those corresponding to thermal energy) without incurring excessive displacement currents resulting from the smallest possible capacitance of the ion trap array (Pau *et al.* 2006). If we can assume that the relations between mean free path, trap diameter, 1/(pressure), and 1/(trapping frequency) hold when extrapolating from the millitorr range to ambient pressure, and taking experimental evidence of 1-torr operation with a 1-mm trap at 6 MHz (and 1.7 amu, 3 ppm Xe in He, and 20 amu ms^{-1} scan rate performance) (Witten and Ramsey 2002–2006) as a guideline, one can begin to appreciate the challenges that may still lie ahead. **Figure 41** presents the overall trends in graphical form, showing that operation at

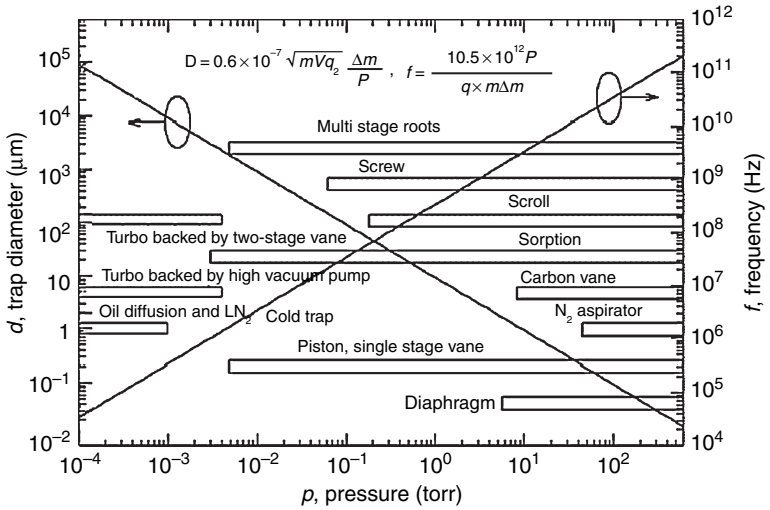

Figure 41 Relationships between ion trap mass spectrometry (ITMS) operating pressure, field frequency, trap radius, and pump capabilities. *m*, atomic mass; *V*, applied trap voltage. Wiley-VCH, Weinheim, in press; reproduced with permission from Wiley-VCH Europe Ltd.)

76 torr might require an operational frequency of 30 GHz; however, this frequency would drop to ~460 MHz if one were to extrapolate from the 6-MHz data point at 1 torr.

2.11.4.4 Gas Chromatography and Multidimensional Analysis

To illustrate the essential functions of the type of GC analyzer to be discussed in this section, **Figure 42** shows how in a most general industrial setting, sample gas is conditioned for the analyzer: a filter removes particles and a flow sensor verifies that sample gas from the process is flowing. A pump draws a small fraction of the sample flow through the analyzer, at a rate controlled by the analyzer and not by the main sample flow.

In an effort to standardize on such sample conditioning, an initiative at the Center for Process Analytical Chemistry (CPAC) has led to guidelines for NeSSI (New Sampling and Sensing Initiative) systems, which consist of devices (filters, on–off and modulating valves, flow sensors, and composition sensors and analyzers) mounted on ANSI Std. SP-76 building-block substrates that are networked and in its Generation-2 certified for IS, so that their replacement can be made in the presence of flammable gas mixtures (Bonne *et al.* 2005b, 2006b, NeSSI 2006).

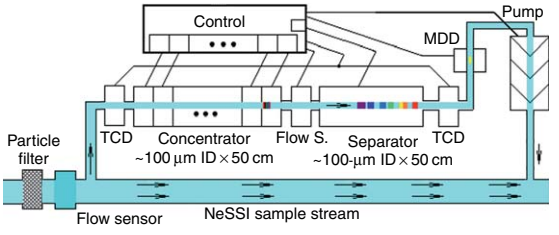

Figure 42 Micro gas analyzer (MGA) functional block diagram, showing a preconcentrator, gas chromatography (GC) separator, detectors, and pump to draw a small flow from the sample stream. (Reproduced with permission from Wiley-VCH Europe Ltd.)

The analyzer itself may consist of a PC (see further details below and Tenax PC tables from Scientific Instrument Services), a GC separation column (or channel in the case of a micromachined GC), its own flow sensor, differential TCD, or other detectors to be discussed below. Not drawn in **Figure 42** but not to be forgotten is the need for a sample gas injection system, which injects a small sample into the (also omitted) carrier gas stream. Those omissions were intentional in **Figure 42** and reflect the ability of the PHASED MGA heater array structure for enhanced detection (PHASED) MGA (Bonne and Higashi 2002, Bonne *et al.* 2004, 2006b) to operate by using air or other background gas as the continuously flowing carrier gas and to generate the injection via rapid thermal pulse to the last element of the integrated PC of **Figure 42**, which desorbs and thus injects the analyte(s) into the separator, which then functions as a traditional GC.

Whereas traditional PCs were based on a single element of packed Tenax or other materials and required watts of heating power to desorb within ~3–10 s, a simple trap in the capillary sample loop (**Figure 43**) (Staples 2004) can provide subsecond desorption pulses as demonstrated by the portable z-Nose GC. An example of its analytical capability is depicted in **Figure 44** (Staples 2004), obtained for the gaseous signature of paper money, and indicating a high peak capacity for the portable GC. **Figure 44** also presents a creative way to present the GC data to

(Source: Staples E J 2004 Chemical profiling cargo with an ultra-high speed gas chromatograph, olfactory images, and virtual chemical sensors. *3rd Microsensors (DHS-ATF)Workshop*, Scottsdale, AZ, USA, April 19–22, 2004 on website, at http://www.estcal.com/TechPapers/CargoContainerOdors.doc and http://www.znose.com/modelsection.htm (Electronic Sensor Technology, Newbury Park, CA); reproduced with permission from IEEE.)

a user in the form of an angular plot, generating patterns that may be easier to remember and to recognize (Staples 2004). The speed and creativity of the z-Nose GC stands out among the shoe box-size GCs by traditional GC firms such as Agilent, Shimadzu, Varian, and even Siemens and Yamatake, as described on their webpages, but without getting down to handheld size.

In the quest to leverage the benefits of miniaturization pointed out in Section 2.11.4.1, the achieved advances to date enable handheld GC operation and compatibility with a NeSSI plug-and-play sampling system. Noteworthy in this respect are:

- Sandia's μChemLab, the first hybrid micro-GC, with micromachined ~3-m columns and discrete components connected and supported on a ceramic substrate, also using SAW detectors (Manginell *et al.* 2003). It has performed field tests and is ready for productization.
- SLSs hybrid micro-GC on a $\sim 4'' \times 5''$ circuit board, individually supporting the injector, heatable and Si-etched column, TCD, and data processing and control electronics (Bonne *et al.* 2006a), which is commercially available.
- The University of Michigan's hybrid micro-GC (3-m Si-etched columns), with three types of PC materials, and chemiresistors and nanoparticle films as detector (Lu *et al.* 2005), combined many interesting GC technologies during its development, including polymer films on SAW detectors similar to Sandia's (Manginell *et al.* 2003).
- Honeywell Labs' developmental PHASED micro-GC, which may be the first version of a monolithic, Si-integrated MGA. It has integrated a multistage PC, injector, heatable separation column (0.2-, 0.3-, and 0.5-m versions), and flow sensor, differential TCD, and temperature sensors (Bonne and Higashi 2004, Bonne *et al.* 2004, 2006a, b). The sample, which is preconcentrated from the sample stream, is injected via a thermal desorption pulse, so that no mechanical valving is needed.

Before the above micro-GCs can be merged with other analyzer–detectors to form 2D or 3D analyzers, the design and fabrication of several components need to achieve the needed performance: PC gain and pulse width, carrier gas selection, flow control, sample gas transport (pump), stationary-phase film material selection and processing, and detector speed and sensitivity.

In the following we will discuss such a performance, while borrowing heavily from the author's first-hand experience with Honeywell's PHASED MGA development, but using it mainly as an example to illustrate generic insights. As principal investigator (PI) of that effort since its inception in 1998 through 2006, he tried hard to keep the overall MGA structure and operation as simple as possible, in order to facilitate future productization, by enabling as much fabrication and assembly at the wafer level. In that spirit, we decided to rely on air as carrier gas to eliminate the need for managing and controlling the availability of bottled and pressurized

carrier gas. Similarly, the thermal injection idea was appealing as a way to eliminate the need for mechanical valving.

We realized early on that PC would be needed in order to achieve the less than or equal to ppb-level sensitivities needed even for simple environmental applications. To hold down on energy consumption, our experience with thermal microflow sensor membranes naturally led us to use that technology platform to fabricate heatable PC and separation elements. **Figure 45(a)** shows the cross section of the ~1-μm-thick silicon nitride membrane support (with embedded thin-film Pt heaters) of the stationary phase, a SEM photo of one (of 40–100) turnarounds etched in to the channel wafer (**Figure 45(b)**), and a photo (bottom view, see **Figure 45(c)**) of a completed PHASED MGA chip, with the integrated components listed above. In the first version, we had the PC and separator on separate chips (Bonne and Higashi 2002), but quickly realized the advantage of merging the two, despite the associated implication of then favoring the use of the same stationary phase for both PC and separator.

Figures 46–48 show details of the integrated components: **Figure 46** presents a top view of a Generation-2 PHASED chip layout version, in which all the 20 + 20 PC and separator elements reside on one chip and can be heated individually, although for most uses the separator elements are all energized in parallel. **Figure 47** depicts a magnified view of the TCD, hosted by the ~1-μm nitride membrane, which in turn is anchored to the Si chip wall, which influences the response time of ~0.8 ms (shorter than the ~1 ms of an MB in a 1 m s^{-1} flow (see **Figure 14**) and heat loss, which was reduced by ~2× by improving the thermal isolation (Bonne *et al.* 2006b). **Figure 48** shows the heater and sensing elements of the thermal flow sensor. Its elements are like the one from **Figure 1(a)**, but reduced 2.5× in size to fit onto the MGA channel, together with a calibration curve. Its remarkably low-noise performance may be due to the smaller Reynolds number associated with the >25× narrower flow channel. Individual element heating (**Figure 46**) enables the PC operation, which comprises three steps (Bonne and Higashi 2002, Bonne *et al.* 2005b): while the sample gas flows continuously, the following occur:

(1) Analyte adsorbtion up to a maximum concentration in the stationary-phase film or up to saturation at which point it is in equilibrium with the sample gas, and is achieved in a time ranging from 0.1 to 4 s.
(2) Pulsed desorption, with 3- to 10-ms-long heater pulses and in sync with the flow, starting with the first element, which injects desorbed analyte into the sample stream, followed by the second, third, and $(n-1)$th element when the gas from the previous desorption passes by, thus achieving a gas-phase concentration gain of approximately

$2\times$ and up to $(n-1)\times$ relative to using only one PC stage, by the time the flow reaches the nth element (Bonne and Higashi 2002). The total achievable concentration gain (**Figure 49**) may range from $10\times$ to $>1000\times$ (see yellow highlights) depending on the number of elements used, the volumetric gas/film ratio, adsorption, and desorption temperatures, and most importantly, on the heat of adsorption of the targeted analyte (Bonne and Higashi 2002, Bonne *et al.* 2006a). The total time to so desorb 20–50 elements may not take more than 60–500 ms.

(3) Pulsed desorption of the nth element, which injects the total PC analyte(s) into the separator, from where separation proceeds as in a traditional GC, except for one feature.

This unique feature is the PHASED coating, which to date has covered only one of the four walls of the approximately square channel. While it would be desirable to have all four sides coated as others do (Lu *et al.* 2003, Manginell *et al.* 2003, Masel 2004, Simonson *et al.* 2004), the penalty in GC resolution, according to Poppe (2002), is only factors of $2\times$ or 1.41, when comparing between fully coated circular on one hand and one- or four-side-coated square channels, respectively. The effect of the associated channel transverse temperature gradient certainly deserves further study. However, coating only one side eases fabrication, as it enables application of the stationary phase via spin-coating and subsequent patterning, so that problems with thick films in channel corners or in cold spots can be avoided. With PHASED element channels, only the middle ~80% of the heatable membrane is coated with the stationary phase, to also achieve a relatively uniform temperature throughout the width of the coated part of the membrane.

Multistage PC gain is of course sensitive to close synchronization between gas flow velocity and heater pulse timing, as shown in **Figure 50**, which Bonne and Rezachek obtained with a constant set of 5-ms pulses to a 20-stage PC, while sample gas (room air) flow varied from 105 to 117 cm s^{-1}, with the optimal value at 115 cm s^{-1} (Bonne *et al.* 2003b). As shown, a

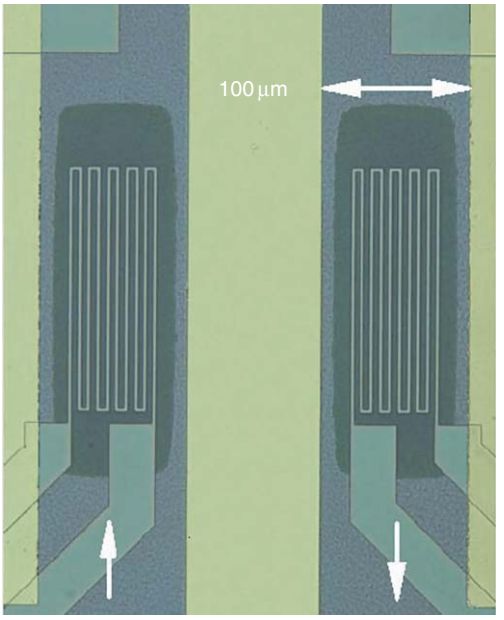

Figure 47 Microphoto of the differential thermal conductivity detector (TCD). (Source: Bonne U, Johnson K, Higashi R, Nusseibeh F, Newstrom-Peitso K, Marta T, Cabuz E, Wang T-Y, Mosher J, Iwamoto N, Lytle N (Honeywell International), Synovec R, Reid V, Prazen B, Gross G, Veltkamp D (Chemistry Department/CPAC, University of Washington, Seattle, WA), Herring C, Kunze K, Kellner D (Caviton Inc., Champaign, IL,) 2005 PHASED*: Development of a µGC-on-a-chip with interface to NeSSI. *Sensors Expo*, Chicago, IL, USA, June 6–9, 2005, Session on 2005 DOE-ITP Sensors & Automation Annual Portfolio Review, http://www.eere.energy.gov/industry/sensors_automation/pdfs/meetings/0605/bonne_0605.pdf; reproduced with permission. Wiley-VCH, Weinheim, in press; reproduced with permission from Wiley-VCH Europe Ltd.)

10% velocity mismatch can lead to a twofold width increase of the PC analyte peak, which was sensed by the integrated TCD and only later was identified as water from the sampled room air with the help of a time-of-flight MS (Leco Pegasus-III).

The PC process steps are clearly shown in **Figure 51**, with a sample gas containing 720 ppm of hexane, which shows as the baseline before and after PC, as sensed by the time-of-flight MS, as indicated in the inset, by recording mass 57, a fragment of hexane. Note that the peak half-width (HW) of 91 ms is wider than the ones in **Figure 50**, and is because of the longer transit time to the nonintegrated MS, and also because of nonoptimal synchronization. Later, optimized operation with gas velocities up to 2.5 m s^{-1} resulted in peak widths down to 3 ms and corresponding increases in PC gains to near 100× with hexane (see bold dots in **Figure 49**), over 400× with nonane (Bonne *et al.* 2006a), and higher yet with analytes of higher adsorption enthalpies or retention indices.

The desorption temperature needs to be high enough to desorb all the analytes, and keep them together through the n stages. As **Figure 52** shows for the calculated example of water and heptadecane ($C_{17}H_{36}$), >160°C is sufficient for water vapor, but $C_{17}H_{36}$ needs a temperature ≥250°C.

The choice of carrier gas has some influence on the separation performance of a GC and on the MDL, and is worth some discussion. The widely used Golay equation (Bonne *et al.* 2005a, Kenndler 2004) well describes the relation between capillary length and diameter, coating thickness, carrier gas velocity, pressure drop, and analyte diffusivities in the mobile phase (carrier gas) and stationary phase (coating). However, less well known is the influence of carrier gas on GC resolution, pressure drop, and HW, which are addressed in **Figures 53** and **54**. According to some opinions, using N_2 rather than H_2 as carrier gas limits the useful gas velocity range. Yet, the relative velocity range is the same for both, as **Figure 53** shows, because the three R^* curves would overlap if just displaced parallel to the x-axis, due to the change in the involved gas diffusivities. Despite the lower viscosity of H_2, relative to N_2, the pressure drop needed to achieve the same resolution with H_2 is almost 2× higher. However, separations with H_2 result in chromatograms with peak widths about 2.2× narrower, which is important if the total analysis time is to be made as short as possible.

Figure 54 shows that the retention factor, k', has a sizeable influence on resolution and HW: As k' and retention time increase, resolution and optimal gas velocity drop while peak width increases.

The key ingredient of separation columns is the stationary phase. It is generally taken for granted, because off-the-shelf capillaries are available in different lengths, inner diameters, and coating types and thicknesses from GC supply houses such as Restek, Agilent, and Supelco. Only when facing the steep learning curve of having to select a film material, its solvent, and the polymerization catalyst; ensuring proper wetting and adhesion; and working out a baking routine does one appreciate the involved developers' work and their reluctance to part with the details of their achievements. At start-up, the Honeywell team were

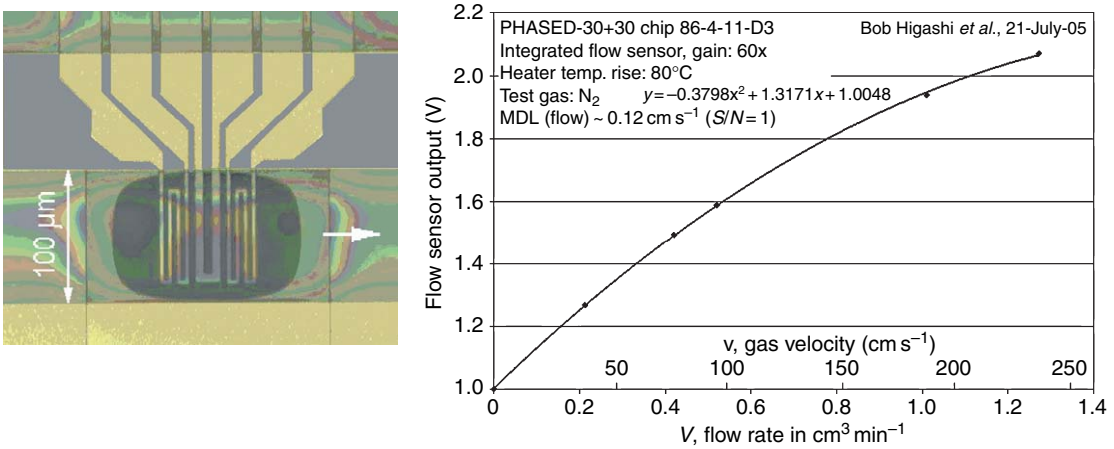

Figure 48 Photo of the integrated flow sensor on a ~1-μm membrane, positioned in the phased heater array structure for enhanced detection (PHASED) micro gas analyzer (MGA) as indicated in **Figure 46**; and its low-noise calibration curve (Source: Bonne U, Higashi R E, Johnson K, Iwamoto N, Sacks R D, Synovec R E 2005a Stationary phase films for microanalytical measurements. *PittCon 2005*, Orlando, FL, USA, February 27–March 4, 2005, Paper No. 420-1; reproduced with permission. Figure 49 Calculated multistage, saturated, and preconcentration (PC) gain versus desorption temperature and adsorption temperature, showing agreement with a few experimental points for hexane, and expected PC gains with dimethyl methylphosphonate (DMMP) and decane, consistent with their standard gas chromatography (GC) retention indices (RI) (Source: Bonne U, Higashi R, Marta T, Nusseibeh F, Rezachek T (Honeywell Labs), Herring C, Kellner D, Kunze K, Castelein M (Caviton Inc.) 2006a Microgas analyzer for NeSSI and DHS: Measurements and simulations. *PittCon 2006*, Orlando, FL, USA, March 13–16, 2006, Paper #2020-6; reproduced with permission.)

fortunate to find an in-house commercial fabrication capability of open-pore, nanoporous organic silicate (Nanoglass™) films intended to serve as low-k dielectric film to fabricate microelectronic circuits. Synovec *et al.* demonstrated that such Nanoglass films also perform well as GC films to separate alkanes (Huseth *et al.* 204), as shown in **Figures 55** and **56**, relative to a commercial DB-5 column, whether used with H_2 and N_2 as carrier gas, respectively, with astounding, subsecond elution times. As processing expertise grows, more materials may be added such as polydimethylsiloxane (PDMS) from

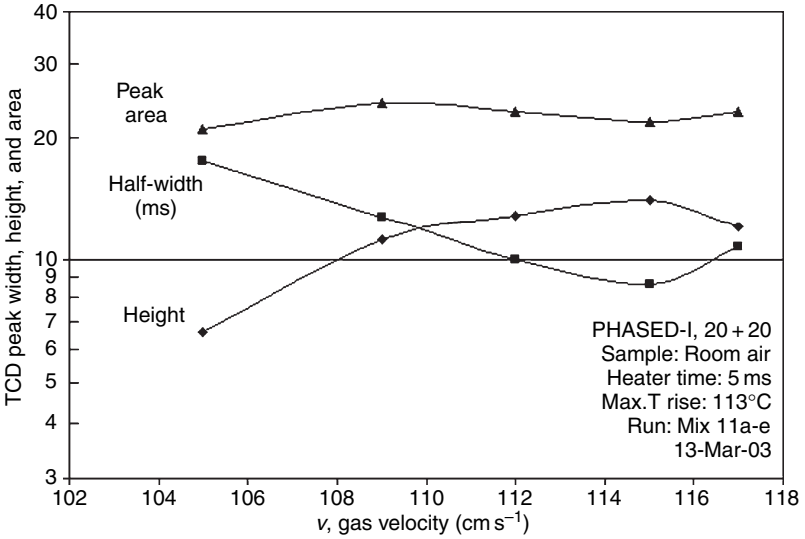

Figure 50 Experimental phased heater array structure for enhanced detection (PHASED) preconcentration peak height and width, showing their sensitivity to proper synchronization between sample gas and heater array pulse progression velocities: the minimum achieved peak half-width is near 8 ms, i.e., excellent, considering the 5-ms widths of the heater pulses, piggybacking desorbed analyte pulses from 20 elements, and peak broadening during separation and thermal conductivity detector (TCD) detection. As shown best with a log plot, the peak area is and should be unaffected. (Source: Bonne U, Higashi R E, Johnson K, Iwamoto N, Sacks R D, Synovec R E 2005a Stationary phase films for microanalytical measurements. *PittCon 2005*, Orlando, FL, USA, February 27–March 4, 2005, Paper No. 420-1; reproduced with permission.)

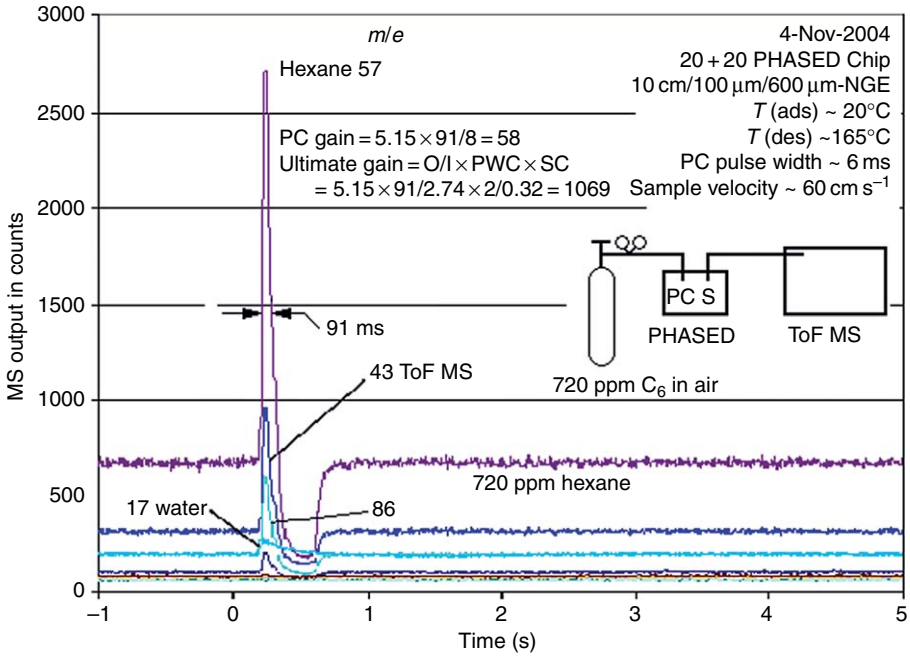

Figure 51 Twenty-stage sampling, desorption, and preconcentration of 720 ppm hexane in air with a phased heater array structure for enhanced detection (PHASED) chip, showing that the adsorption step only takes ~0.3 s or about two sample volumes to refill and saturate the stationary phase with hexane. (Source: Bonne U, Higashi R E, Johnson K, Iwamoto N, Sacks R D, Synovec R E 2005a Stationary phase films for microanalytical measurements. *PittCon 2005*, Orlando, FL, USA, February 27–March 4, 2005, Paper No. 420-1; reproduced with permission from IEEE.)

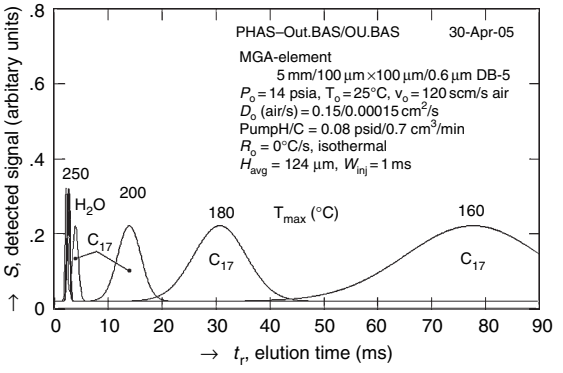

Figure 52 Calculated influence of desorption temperature of a 5-mm phased heater array structure for enhanced detection (PHASED) heater element on the ability to keep all analytes together, represented here by water (H_2O) and heptadecane ($C_{17}H_{36}$). As shown, desorption pulses of ~250°C or higher are needed to desorb and elute heptadecane within the allotted 5–6 ms of each of the 5-mm elements of the multistage preconcentrator, compared to water, for which only a desorption temperature of <160°C is needed. The stationary film thickness was 600 nm of DB-5.

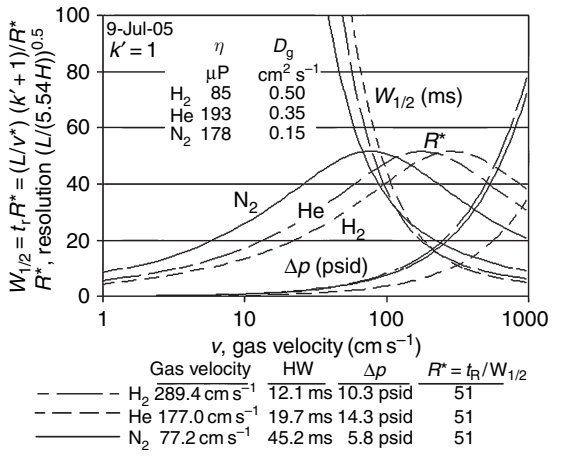

Figure 53 Calculated influence of carrier gas type on best GC separation performance, according to Golay's equation, showing: (1) no change in v-range or resolution, (2) lowest pressure drop for N_2, but (3) lowest half-width for H_2, which is even still 2.2× lower than N_2 at equal pressure drop.

Ohio Valley Inc., carbosilanes from Seacoast Science, and even CNTs (Saridara and Mitra 2005, Stadermann *et al.* 2006). **Figure 57** shows the result of separating alkanes, with temperature ramping, with a first-generation film of ~1-µm-long CNTs grown by LLNL at the bottom of an etched 50-cm-long channel of 100 µm × 100 µm in cross section in silicon, and evaluated by the University of Washington/CPAC (Stadermann *et al.* 2006), who pioneer high-speed GC technology, as needed also for MGAs.

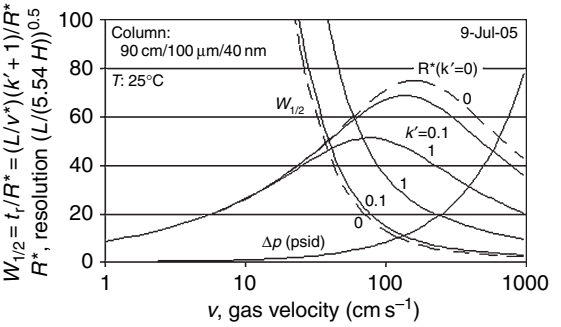

Figure 54 Calculated influence of retention factor $k' = t_R/t_0$-1 on the resolution and half-width of gas chromatography (GC) separation with a N_2 carrier gas stream, according to Golay's equation.

As the quest for a smaller GC analyzer continues, and separation columns shrink below the 1-m length and 100-µm ID size range, it may be good to remember that (Bonne *et al.* 2003):

- Micro-GC peak capacity and analysis time appear as the most important GC performance parameters. As needed analysis times shrink and column lengths shorten below the 1-m mark, peak capacities of only about 20–50 may be achievable with stationary-phase film materials approaching theoretical performance of $H/d = 1$, where H is the theoretical plate height and d is the diameter of the capillary.
- Resolution and temperature ramping: ramping of the separation column increases the range of boiling points of separable analytes but not the full-width peak capacity, C,

$$C = \frac{t_R - t_0}{1.669\, W^*_{1/2}}$$

where the factor 1.669 converts the actual Gaussian (rather than triangular) shape of the GC peaks from average HW, $W^*_{1/2}$, to full-width. Temperature ramping reduces elution time by about 2× for each 16–20°C rise in temperature. The ramp rate should be such that the boiling point temperature of the eluting compound stays in about a constant ratio to the column temperature (Sacks 2004).

- Pressure drop may impose a practical limit to ultimately achievable compactness with ever smaller µGCs, as it limits the column length and thus the achievable resolution (Bonne *et al.* 2003) most of the time. However, pressure drop is predictable via Poiseuille's viscous flow eqn [4], as given in Section 2.11.2.4.

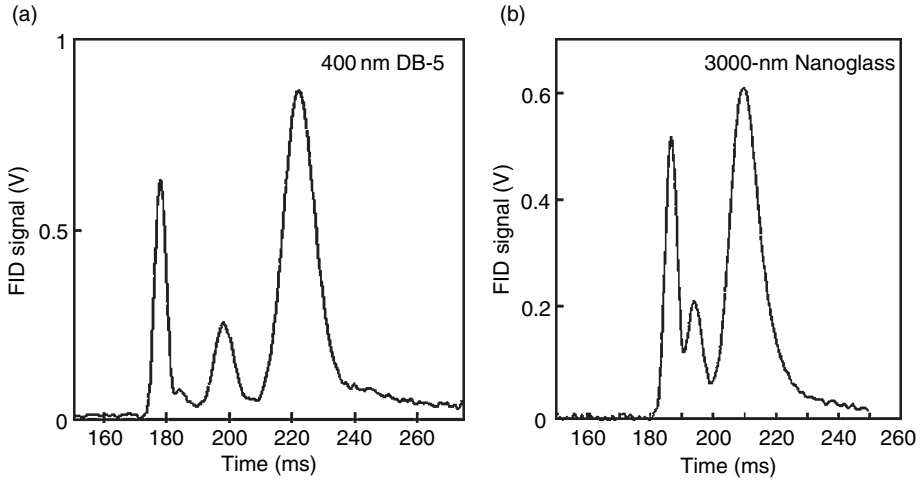

Figure 55 Experimental separation of CH_4, propane, and butane, H_2 carrier gas and flame ionization detector (FID). Comparison between a commercial DB-5 and a developmental Nanoglass film. (a) Column: 1-m/100-μm/400-nm DB-5, ~700 cm s^{-1} H_2 at 25°C. (b) Column: 1-m/100-μm/3000-nm Nanoglass, ~700 cm s^{-1} H_2 at 25°C (Courtesy: G Gross and R Synovec, CPAC; Huseth S, Gonia P, Bonne U 2004 Wireless and sensing solutions advancing industrial efficiency, Part II: PHASED microanalyzer. - Predicting retention time of new analytes is difficult, but approximations may be made on the basis of their vaporization enthalpy or boiling point, as exemplified with **Figure 58** (Bonne *et al.* 2005a). Equating vaporization enthalpy with adsorption enthalpy, ΔH, gets us the retention factor, $k' = (t_R/t_o - 1)$, and retention time, t_R, by leveraging the equilibrium constant, $K = k'\beta$, with $\beta =$ (gas volume/stationary film volume), into the classical relation $\ln(K) = (\Delta H/RT) - (\Delta S/R)$, where, according to Trouton's rule (strictly only for nonpolar compounds), the vaporization entropy is approximately $\Delta S = \Delta H/T_b$ at the boiling point, T_b. From there, the temperature dependence of k' emerges with the remarkably simple van't Hoff's relation, $\log(k'_2/k'_1) = -(\Delta H/R)(1/T_2 - 1/T_1)$, where R is the universal gas constant. Prediction of k' and K may be improved by introducing additional analyte and stationary-phase properties such as their polarizability, dielectric constant (Bonne *et al.* 2005a), and others (Grate 1998, McGill *et al.* 1994).

- Predicting GC peak capacity under given constraints of pressure drop and analysis time may be accomplished iteratively with the help of the expression for HW derived from Golay's

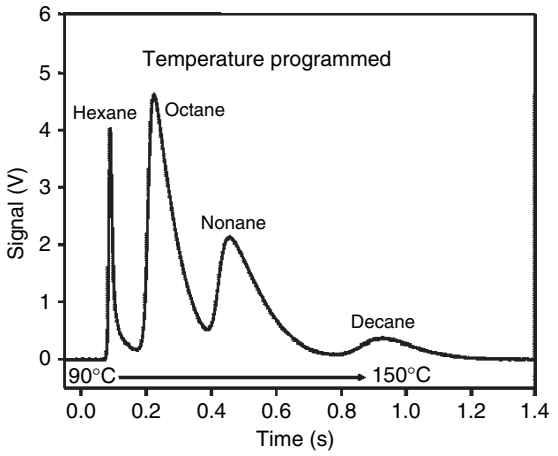

Figure 57 Experimental separation of C_6–C_{10} alkanes on 50-cm/100 μm × 100 μm Si microchannels, coated on one side with single-walled nanotubes (SWNTs) of ~1 μm in length, and temperature ramped from 90°C to 150°C. Achieved peak capacity: ~16 between t_o and 4 s. (Source: Stadermann M, McBrady A D, Dick B, Reid V, Noy A, Synovec R E, Bakajin O 2006 Fast gas chromatography on single-wall carbon nanotube stationary phases in microfabricated channels. *Anal. Chem.* **78**, 5639 (University of Washington and LLNL); © 2006 reproduced with permission from the American Chemical Society. Bonne U, Nguyen T-C, Polla D L 2007 Developments in ultra micro gas analyzers. Wiley-VCH, Weinheim, in press; reproduced with permission from Wiley-VCH Europe Ltd.)

equation, $W_{1/2} = t_R(5.54H/L)^{0.5}$, and the above retention time and pressure drop equations, assuming some ideal or reference conditions of column geometry, temperature, ramping, gas velocity, and injection pulse width. A few examples shall illustrate this approach. **Figure 59** shows the result of using an experimental gas chromatogram to calibrate a physical GC model, by adopting and incorporating measured retention times and their previously determined temperature dependency. This model then served to also visualize the effect of injection pulse width on achievable peak capacity (**Figure 60**), when the analysis up to dodecane was constrained to be completed within 4 s, whereby only column temperature, length, and inner diameter were held to the indicated values, while adjusting film thickness and pressure drop to the gas velocity of the x-axis. When pressure drop and analysis time were also constrained to $\Delta p \leq 5$ psid and 2 s, respectively, while column diameter was stepwise reduced from 95 to 50 μm, **Figure 61** reveals that smaller columns can generate increased peak capacity. This was unexpected and caused by the increase in peak capacity provided by the reduced zero retention time resulting from the reduced column length.

- Stationary-phase film uniformities of transverse thickness and temperature are the key to success and present significant challenges to micro-GC design and fabrication. For example, a systematic 5% thicker film at the center of a (one wall) stationary-phase coating would potentially increase retention time by 5%, which may theoretically amount to an increase in peak width of 5% × R^*, if diffusion cannot even it out, with the resolution, $R^* = t_R/W_{1/2}$. Transverse temperature gradients may have an even greater effect were it

Capillary column: 100-cm/100-μm/400-nm DB-5, isothermal at 125°C, flame ionization detector (FID), 146 cm s^{-1} H_2, and $W_{inj} = 2$ ms.

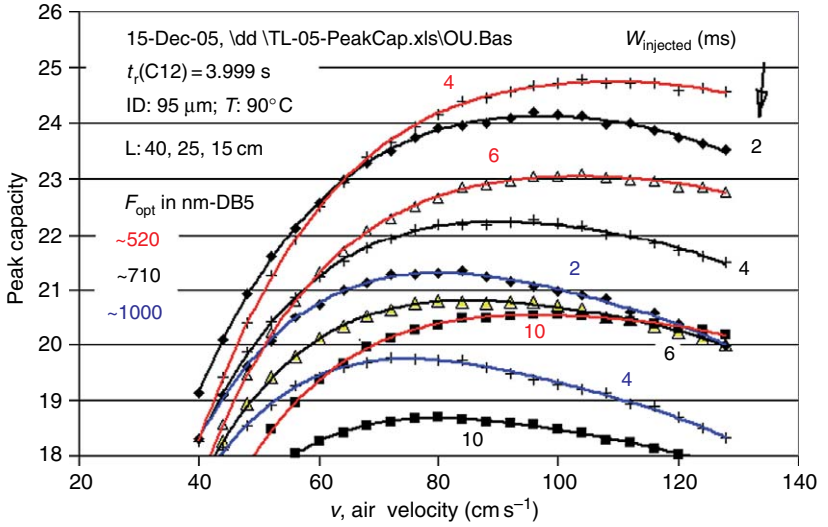

Figure 60 Maximizing peak capacity within the only constraint that analysis time ≤4 s, versus air gas velocity, for four injection pulse half-widths and three column lengths, variable film thickness, and indicated optimal value, F_{opt}. All column diameters at 95 μm at 90°C. DB-5 on one side.

not for the much higher thermal conductivities of the stationary phase and its substrate than that of any gas. **Figure 62** shows that while transverse gas temperature gradients with one-sided column heaters may appear large, the important gradient is the one right at the surface, under the middle 80-μm coating location, which needs to be kept as uniform as possible. Also visualized is the rapid rise in temperature ($\tau \sim 0.8$ ms) of the heater + coating assembly.

As the analytes elute from the micro-GC, they are led to the detectors, single or multichannel, as discussed in Sections 2.11.3, 2.11.4.2, and 2.11.4.3, as rapidly as possible, to minimize peak broadening and loss of concentration and to enable peak identification and quantitation.

As one gathers from the above-mentioned points, new challenges can be tackled with the help of estimates and/or predictive modeling, which all clever developers utilize extensively. **Figure 59** and

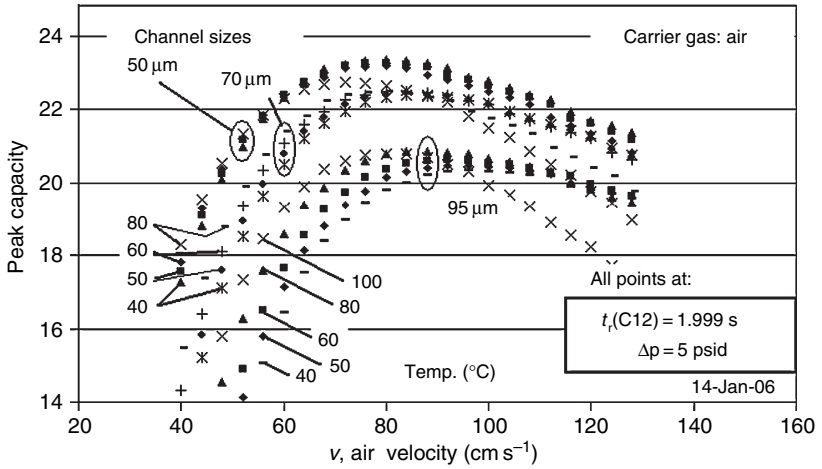

Figure 61 Maximizing peak capacity within the constraints of analysis time $\leq$2 s and $\Delta p \leq 5$ psid, versus air gas velocity, column temperature, and three diameters, variable film thickness, and column lengths. All columns have DB-5 film on one side.

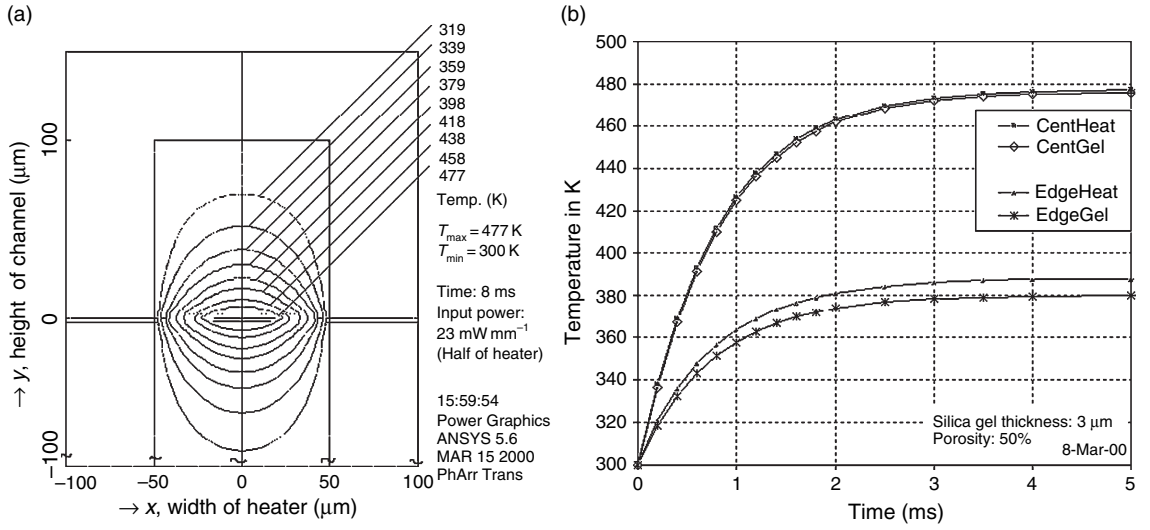

Figure 62 (a) ANSYS-computed transverse gas temperature isotherms in a 100 μm × 100 μm channel over a 100-μm-wide thin-film heater with stationary phase, at zero flow, 8 ms after start from cold, and constant 46 mW mm^{-1} input power to achieve a 200°C steady-state heater temperature. (b) Temperature rise versus time for the same heater, amounting *t* an exponential time constant of 0.8 ms. (Courtesy: Burgass Johnson. additional comparisons between simulations and experiment at other temperatures (Bonne *et al.* 2005a) had further validated the model, so that predictions could be made with confidence, for different geometries, gas types, and temperature programming. **Figures 63** and **64** show two simulated results of PHASED geometries and air as carrier gas, which achieved peak capacities >20, with much shorter channels than the 100 cm simulated in **Figure 59** and achieving shorter analysis times. Whether micromachined GCs will be able to compete with the somewhat higher peak capacity, capillary-based micro-GCs, only time will tell. But those that can leverage the potential cost savings of wafer-level fabrication and assembly would surely increase their odds.

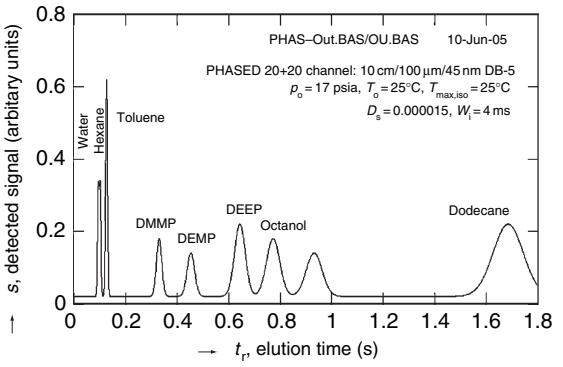

Figure 63 Simulated separation of nine analytes up to dodecane with a 20-element, 10-cm phased heater array structure for enhanced detection (PHASED) channel, over a thin 45-nm film of DB-5, in an 120 cm s^{-1} air carrier gas, eluting in less than 2 s, at room temperature, and with $W^*_{1/2} = 40$ ms resulting in a peak capacity of

$$C = \frac{t_{R,\,C12} - t_0}{1.669\,W^*_{1/2}} = 24$$

2.11.5 Errors, Uncertainty, Self-Calibration, and False Positives

Everyone is familiar with the notion of margin of error or uncertainty, which may be expressed as a ±percentage or absolute peak-to-peak or RMS deviation from a sensor output. However, this deviation may consist of a number of components, such as random white noise or uncertainty, systematic or true error relative to a calibration standard, and drift versus time. Note that precision is often understood to be equivalent to repeatability, while accuracy is in the context of absolute error.

Based on our experience, we recommend that graphical representations of sensor parameter noise and drift be used whenever possible. As mentioned in relation to **Figure 10**, we found it extremely helpful, revealing, and educational to visualize noise amplitude and drift of all relevant inputs and outputs of a sensor system. The use of a $\log(y_i)$ versus time plot is preferred because relative scale for errors, noise amplitude, or uncertainty is the same all along the $\log(y_i)$ axis, as indicated by the error bar of 1% in **Figure 10**. One may use, e.g., factors of $C_i = 10^{0.1i}$ to equally space eight traces within one decade, and magnify the noise and drift, e.g., by a factor of 20× by plotting the parameters of interest, P_i, as $y_i = C_i(P_{i,n}/P_{i,1})^{20}$, where $P_{i,1}$ is the first value of each of the plotted parameters. For easy reference, the dotted line under each trace indicates the no drift level. **Figure 10** shows some drift in the test temperature, but its effect is compensated for and not causing drift in the other parameters, as intended, except maybe in c_{pv}, the volumetric specific heat.

Another helpful measure of the stability of a sensor output signal against variability in its inputs is the notion of log sensitivity (also called gauge factor), which simply indicates the relative change in output as a function of a relative change in one or all of its inputs. This is especially helpful when comparing, ranking, and selecting one correlation from among several possible ones, as is generating the correlation with one set of data (i.e., the training set) and reserving another set for testing the quality of the correlation.

To be sure that measured quantities are trustworthy, all sensors need recalibration after some period of time of operation or even of shelf time, which may be hours or months. In Section 2.11.2.4 we discussed self-normalization of flow sensors via an online, stable, and trustworthy flow–dither approach. The chemical industry cannot afford to manually and periodically recalibrate all sensors and analyzers to ensure proper control of the processes and the quality of product. It therefore adopted automatic recalibration by periodically switching from sample gas exposure of the analyzer to calibration gas and even to span gas. Automatically verifying sample, calibration, and span gas flow, and conditioning it via a standardized, building-block-type, networked, and (soon) intrinsically safe-certified set of components is the aim of the systems being developed with the processing and semiconductor industries (Bonne *et al.* 2006a, Mosher *et al.* 2003, NeSSI 2006). **Figure 65** shows a photograph and illustrates the makeup of such a NeSSI system (Mosher *et al.* 2003), some exemplary devices (Doe 2002–2006), and how it hosts microsensors and microanalyzers.

The above is easy to understand and straightforward, especially when only single or a few known measurands, outputs, or analytes are involved. Defining uncertainty is much more difficult if a sensor output is expected to quantify and to discriminate between the presence and the absence of a target measurand such as a flame in a red-hot combustor (Zook *et al.* 2000), a pathogen in a patient, a type of aircraft from a blip on a radar screen, or one of many possible toxic compounds in air calling for evacuation of a building or processing plant. To generically characterize a sensor's probability to miss a hazardous pattern or its probability to alarm when none is present (FAR) is difficult, especially because of the FAR dependence on the environmental conditions such as temperature, pressure, humidity, and other gases present, as well as the analyte concentration (to be discussed later). Some conceivable approaches to solve this problem of selectivity and discrimination are as follows:

(1) Test the sensor or analyzer under all likely test conditions and experimentally determine FAR for all those conditions.
(2) Test the sensor under a standard set of test conditions and define a FAR under such standard conditions.
(3) Establish a relation between FAR and the analyzer's orthogonal channel capacity (OCC), similar to peak capacity for GCs, except that channels may now not only be resolvable time periods or GC peaks but also resolvable wavelengths, amu, or temperature increments (with DTA) (Bonne *et al.* 2003c, 2007).

None of the above should be confused with MDL. Approaches (1) and (2) may require over 10 000 tests for each analyte, whereas approach (3) is a more rational one, more appealing, and arguably easier to check and recalibrate. Maybe this can also be a more practical approach, if we can define channel capacity in a way that is relevant, i.e., by counting only those channels that can statistically make a meaningful contribution, by, e.g., avoiding to counting wavelength or mass channels that are unlikely to ever detect a relevant photon wavelength or ion mass, other than random noise. Such an approach may then be in line with the work by NRC (Committee on Assessment of Security Technologies for Transportation 2004), in which information content or informing power P_{inf} (in the form of available bits of information) of IMS and MS analyzers was related to transportation security. In comparing OCC and P_{inf}, the latter also assigns capacity counts to each channel for the number of resolvable intensity levels of an analyzer, so that the P_{inf} values are roughly 100× higher than OCC values (Bonne *et al.* 2007).

To relate OCC to FAR (independent on analyte concentration), one might start with a few exemplary OCC values:

- 5–6 for an array of thin-film polymer or SAW sensors (Bonne *et al.* 2003),
- 14–20 for a DMS (Eice man *et al.* 2004),
- 50 for a micro-GCs (Bonne *et al.* 2003), but 200 for a desktop GC,
- 200 for a micro-MS with a 1 amu resolution and a mass range from 20 to 220 amu,
- $50 \times 200 = 10\,000$ for micro-GC–MSs, but 60 000 for desktop GC–MS, the gold standard for analyzers (Polla and Nguyen 2004),

and then consider the possible or likely scenarios in which each orthogonal channel functions as an equation that is part of a system to resolving a problem with n unknowns (analytes and interferents). At its worst, only a fraction of the OCC contributes to solving the problem. But at its best, some combination of channels less than n may uniquely identify an analyte, so that FAR may be much smaller than $1/n$. These and other possibilities involving receiver operating characteristics (ROC) curve calculations are discussed

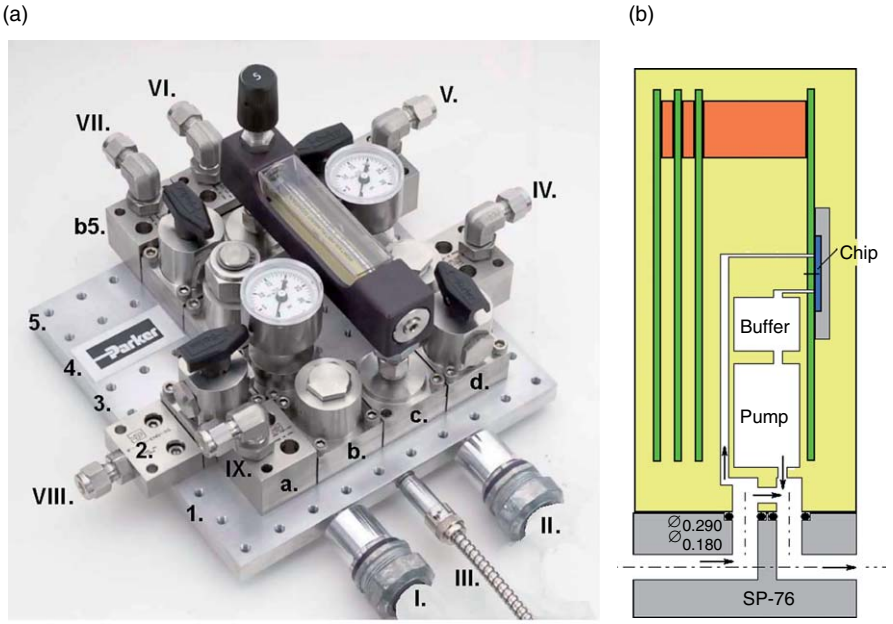

Figure 65 *Left:* Photo of an Intraflow process sampling and sensing system (NeSSi) (New Sampling and Sensing Initiative) (Source: Doe S 2002–2006 Parker Hannifin, private communications; reproduced with permission.), showing standardized devices (pressure gauge, valves, etc.) supported and interconnected on standard ANSI SP-76 substrates of 1.5″ × 1.5″ (38.1 mm × 38.1 mm) footprint. One or more such substrates can host microanalytic devices, such as the analyzer drawn at right. (Source: Mosher J, Nickels R, Bonne U 2003 Networked sampling system (NeSSI-Generation-II) development and field test. *17th Int. Forum Process Analytical Chemistry (IFPAC)*, Scottsdale, AZ, USA, January 21–24, 2003; reproduced with permission.), shown with its own flow control and PHASED MGA chip, corresponding to the block diagram of **Figure 42**. The exemplary devices on the intraflow unit are as follows. Inputs and outputs: 1, sample inlet; 2, sample bypass. Return: 3, from grab sample cylinder; 4, to grab sample cylinder; 5, sample outlet to analyzer; 6, N_2 purge inlet. Devices: a, sample inlet valve; b, check valve; c, sample pressure indicator; d, bypass filter; e, bypass rotometer; f, grab sample cylinder inlet valve; g, grab sample cylinder pressure indicator; h, grab sample cylinder return valve; I, N_2 purge inlet valve.

in Bonne *et al.* (2003, 2007). Together with other plausible considerations, the middle-of-the-road conclusion was a (nonconcentration-dependent) FAR value for the GC–MS gold standard of $\sim 2 \times 10^{-7}$. The above has been based on considering only that part of FAR that depends on the analyte signal clutter contribution, which assumes that enough concentration of analyte is available, so that no MDL effects come into play. But FAR also depends on analyte concentration and therefore on the PC function, which makes a full FAR characterization of a sensor or analyzer more involved. One approach to overcome this problem would be to only accept signals above a set S/N ratio, above the MDL.

Acknowledgments

The author is grateful to the devoted, diligent, and creative sensors and MGA research teams at Honeywell Labs (**Figure 66**), who were active in 2006, and those who participated earlier: Rudy Hegel, Bob Matthys, and Dave Kubisiak led the microbridge product design effort as did Richard Gehman, or supported our MGA effort as external collaborators: Rob Synovec (CPAC/University of Washington), Richard Sacks (University of Michigan), Mike Ramsey (University of North Carolina), Stanley Pau (University of Arizona), Max Lagally (University of Wisconsinn), Peter Griffiths (University of Idaho), Bruce Warmack (ORNL), and Olgica Bakajin and Michael Stadermann (LLNL). Special thanks go to those who directly supported this publication with inputs, support, and encouragement: Patrick Hogan, John Chapples, Keith Pratt and Jerry Evans (Honeywell Analytics), Bill Whitten (ORNL), Cy Herring (Caviton Inc.), Yogesh Gianchandani (University of Michigan), Honeywell management team members Kris Fredrick, Gregg Swenson, and Aravind Padmanabhan as well as Thom Reitz (AFRL) for their permission and clearance to publish, and especially to my family, whose

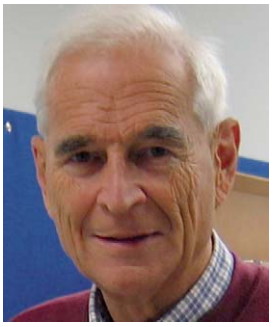
Biography



Ulrich Bonne received an MS in physics in 1960, and a Ph.D. (Dr.rer.nat) in Chemical Physics in 1964 from the University of Göttingen, Germany, with a thesis titled "Optical Studies in the Reaction Zone of (Low-Pressure, Flat) Sooting Flames." Since joining Honeywell Laboratories in Minnesota, he focused on R&D and productization of sensors (of flames, O_2, and efficiency), modeling seasonal system efficiency, and then on devising an annual fuel utilization efficiency (AFUE) test method with NIST, which ASHRAE and DOE later officially adopted. Since the mid-1980s he has pioneered the development of the core micro-bridge sensor technology for environmental, medical, and aerospace applications, and most notably for an electronic, fully compensated natural gas metering system. Since 2002, he has secured funding from DOE and DARPA to model, design, and demonstrate the performance of innovative micro gas analyzers, detectors, and thermal micropumps. His work has led to over 80 US patents and 140 publications. He is a member of the International Combustion Institute; before his retirement in 2007, he served on ASHRAE technical committees DOE and NIST evaluation panels, and was a member of ASHRAE, Opt.Soc.Am., SAE, and ACS.

Glossary

Anodic stripping voltammetry An electrochemical measurement technique that involves a plating step where the electrode is held at a negative potential for a period of time in order to concentrate the analyte by plating it onto the electrode followed by a stripping step where the electrode is switched to a positive potential and the analyte is stripped off the electrode generating a faradaic current, which is measured to determine the concentration of the analyte in the bulk solution.

Chronoamperometry An electrochemical measurement technique that involves applying a potential step to an electrode in solution and then measuring the current generated at the electrode as a function of time.

Cyclic voltammetry An electrochemical measurement technique that involves applying a periodic triangular wave potential to an electrode and then measuring the current generated at the electrode as a function of the applied potential.

Electrical double layer A model used to describe the interaction of molecules at an electrode surface. Currently, the most accurate model of this region is the Gouy–Chapman–Stern model, which includes three distinct regions: the inner Helmholtz plane, the outer Helmholtz plane, and the diffuse layer.

Ion-selective electrode An electrode that has been covered by an ion-selective membrane. The membrane causes the potentiometric response of the electrode to be selective to the concentration of a single ion in the solution.

Linear sweep voltammetry An electrochemical measurement technique that involves applying a potential ramp to an electrode and then measuring the current generated at the electrode as a function of the applied potential.

Polarizable The relative ease with which electrons transfer across the electrode–solution interface defines whether the electrode is considered polarizable or nonpolarizable.

Potentiometry A class of electrochemical techniques that measure the equilibrium potential between two electrodes in order to determine the concentration of a molecule in a solution.

Potentiostat A device that can maintain a fixed potential between a pair of nodes in a circuit by adjusting the current flowing through a second set of nodes in the same circuit. During a voltammetric experiment, a potentiostat can be used to fix the potential between the working electrode and the reference electrode by adjusting the current flowing between the working electrode and the counter electrode.

Reference electrode An electrode that develops a stable and repeatable potential when placed in a solution. Reference electrodes are used to set the relative potential of a solution in an electrochemical cell and are analogous to the ground node of an electric circuit.

Voltammetry A class of electrochemical techniques that involve applying an electric potential between two electrodes and measuring the resultant current in order to determine the concentration of a molecule in a solution.

2.12.1 Introduction

The 21st century will surely be a century of information technology. During the last quarter of the 20th century, computing technology became ubiquitous, moving from mainframe computers in large companies and institutions into the home, classroom, automobile, doctor's office, and telephone. The microprocessor dramatically increased the world's data processing capacity. The limiting factor now in expanding computer analysis and control for clinical, biotechnological, agricultural, industrial, and environmental applications is the interface between electronics and the nonelectronic world. Chemical sensors bridge the gap between chemistry and electronics by transducing chemical concentrations to electronic signals using a variety of transduction methods such as electrochemistry, surface acoustic waves (SAW), and optics. The goal of this chapter is to provide an overview of the theory behind liquid-phase electrochemical sensors, to describe two major classes of these chemical sensors – potentiometric and voltammetric sensors – and to discuss the instrumentation and packaging needed to build a complete chemical sensing microsystem.

2.12.1.1 Motivation for Building Microchemical Sensors

Applications in a number of areas demand tightly integrated microsystems that incorporate a chemical sensing subsystem. Two examples of the significant applications of this technology are implantable

sensors for monitoring biological chemicals such as glucose in the bloodstream (Beach *et al.* 1999, Guiseppi-Elie *et al.* 2005, Koudelka *et al.* 1991) and sensors for real-time monitoring of industrial effluents (Thomas *et al.* 1999). While analytical instruments and laboratory procedures are available for collecting the required data in each of these cases, the demand for faster test results and lower costs is driving research in the area of low-cost, portable instruments (Wolffenbuttel 1996). As these types of instruments become available, they will have an impact on chemical data collection, which can be comparable to the effect that microprocessors have had on data processing.

Small sensors mean smaller sample sizes and an increase in data collection density. Many microscale chemical sensors are also cheaper to mass-produce than their macroscale counterparts. This cost reduction comes in part because the sensors can be batch fabricated with several thousand sensors being fabricated simultaneously on a single substrate. Additionally, many chemical sensors utilize precious metals such as platinum, gold, and silver, and the reduction in raw materials required to manufacture the sensors is also a significant factor.

Calibration and maintenance are also important factors to consider. In virtually every precision-sensing application, periodic calibration is required to ensure accuracy. Chemical sensors are normally calibrated with a calibration solution formulated for the specific test the sensor is designed to perform. Microsystems and lab-on-a-chip solutions with integrated microfluidic handling can store the calibration solution internally and then perform the periodic calibration automatically, making the calibration function invisible to the end user, thereby reducing the complexity of using the device and reducing the cost per test.

Microfabricated chemical sensors can also be designed as small arrays of multiple sensors, where each sensor can be selective to a different chemical. These arrays can be used to measure the concentration of multiple chemicals simultaneously, and by using several sensors having different selectivities and sensitivities the concentration of a single chemical can be determined more accurately in the presence of interferants (Brown 1985). The same process, of course, could be implemented with conventional macroscale chemical sensors, but a large sample would be required and the sensors could not be placed in close proximity to each other for measurements in nonhomogeneous solutions.

There are disadvantages of small size as well. The manufacturing and handling of very small sensors is more challenging than that of macrosized sensors. Additionally, microscale sensors are more susceptible to noise and to variations in manufacturing than are similar macroscale sensors. Although techniques have been developed to mitigate both of these issues, the fixes make the designing and testing of miniature chemical sensors more complex than that of conventional chemical sensors. These disadvantages make microfabricated chemical sensors wholly unsuitable for some applications.

Despite these disadvantages, many applications exist such as the implantable glucose sensors (Koudelka *et al.* 1991) and the effluent monitoring systems (Thomas *et al.* 1999) mentioned earlier that either require miniaturization to be viable or else would be too expensive to be widely deployed without the cost savings derived from batch microfabrication.

Perhaps though, the single most compelling reason for miniaturizing chemical sensors is the promise of complete microsystems that integrate chemical sensors with electronics, microfluidics, and sensors for other physical parameters such as pressure and temperature. In the future, these lab-on-a-chip solutions will provide solutions to problems such as long-term, low-cost environmental monitoring and faster, more reliable monitoring of medical patients.

2.12.2 Electrochemical Theory

A basic knowledge of electrochemical theory is needed to understand or to design liquid chemical sensors. While an in-depth discussion of this topic is beyond the scope of this chapter, the basic concepts of electrochemistry are presented here in sufficient detail to allow the reader to grasp the principles of operation behind these sensors. For those who wish to delve deeper into the electrochemical theory, there are several excellent texts devoted to the subject, including Bard and Faulkner (2000) and Kissinger *et al.* (1996).

2.12.2.1 The Electrode–Electrolyte Interface

All electrochemical measurements rely on the behavior of an analyte in a heterogeneous environment. When an electrode is placed in a solution, a phase boundary exists between the solid electrode and the bulk solution. Additionally, a barrier to charge transfer exists between the two phases due to a difference in charge carriers (charge is carried by electrons in

solid conductors and by ions in solutions). Charge can cross this barrier only when a molecule in the solution is either reduced thereby receiving an electron from the electrode or oxidized by giving up an electron to the electrode.

A generic reduction–oxidation (redox) reaction follows the form as given below:

$$O + ne^- \rightleftharpoons R \qquad [1]$$

where O is the oxidized form of the analyte, R is the reduced form, and n is the number of electrons (e^-) exchanged in the reaction. This reaction has two components, a forward reaction and a reverse reaction, and the reaction can be either reversible or irreversible. If the reaction is reversible, then the reaction can proceed in both directions, and neither O nor R is ever present without the other species being present, although the amount of one of the two reactants may be very small. Reversible reactions eventually reach an equilibrium point where the rate of the forward reaction equals the rate of the reverse reaction. Irreversible reactions proceed in only one direction and given enough time, one of the two reactants (either O or R) will be completely consumed by the reaction. Eqn [1] represents the simplest form of a redox reaction. In practice, more complex reactions involving three or more products with intermediate reactions are often encountered. However, for the sake of simplicity, a discussion of these more complex reactions is omitted in this chapter.

2.12.2.2 The Nernst Equation

A result of the barrier to charge transfer is that almost all electrodes, when placed in solution, develop a surface charge. At equilibrium, the potential difference, E_M, that develops between the electrode and the solution depends upon the electrode material and the concentration of the analyte in the solution. This potential is known as the Nernst potential and is given by the Nernst equation

$$E_M = E^0 - \frac{RT}{nF}\ln\left(\frac{C_O}{C_R}\right) \qquad [2]$$

where E^0 is the standard potential of the reaction, R is the molar gas constant ($8.3145\,J\,K^{-1}\,mol^{-1}$), T is the temperature, F is the Faraday's constant ($9.6485 \times 10^4\,C\,mol^{-1}$), C_O is the concentration of the oxidized form of the species, and C_R is the concentration of the reduced form of the species (Bard and Faulkner 2000). In this form, the Nernst relationship applies only to dilute solutions; in more concentrated solutions, the concentrations, C_R and C_O, must be replaced by their respective chemical activities. For solid-phase reactants (such as a metal electrode placed in solution), $C = 1$. At $T = 298\,K$ the Nernst equation can be rewritten in a simpler form using the common log instead of the natural log as follows:

$$E_M = E^0 - \frac{59.2mV}{n}\log\left(\frac{C_O}{C_R}\right) \qquad [3]$$

The standard potential of the electrode, E_M, needs special consideration. Since direct measurement of the potential of a solution is impossible, all electrode potentials must be given relative to the potential of a second electrode. The electrode normally used for measuring standard values of E^0 is the normal hydrogen electrode (NHE), which has E^0 defined to be 0 V. E^0 values for a few common electrode materials are listed in **Table 1**. For a more comprehensive table of values, the reader is directed to the many extensive texts on the subject such as Bard *et al.* (1985) and Sawyer *et al.* (1995). If an electrode other than the NHE is used, the E^0 value used in calculating E_M must be adjusted to include the additional potential due to the standard potential of the measurement electrode.

The Nernst equation relates the potential between the electrode and the surrounding solution to a simple logarithmic ratio of two species in solution. For metal electrodes, one species is the metal at the surface of the electrode and the other is the oxidized form of the metal ion in solution. For example, when a copper electrode is placed in a solution containing 0.02 M Cu^{2+} the potential difference that exists between the metal and the solution phases can be calculated using the Nernst equation. The following equation describes the redox reaction between the two reactants:

$$Cu^{2+} + 2e^- \rightleftharpoons Cu(s)$$

Table 1 Standard potentials for several common electrode materials

Electrode half reaction	*E^0 for reaction (V)*
$Au^+ + e^- \rightleftharpoons Au(s)$	1.691
$Hg^{2+} + 2e^- \rightleftharpoons Hg(l)$	0.852
$Ag^+ + e^- \rightleftharpoons Ag(s)$	0.799
$Hg_2Cl_2 + 2e^- \rightleftharpoons 2Hg + 2Cl$	0.268
$AgCl(s) \rightleftharpoons Ag(s) + Cl^-$	0.222
$2H^+ + 2e^- \rightleftharpoons H_2(g)$	0.000

E^0 for the reaction is 0.339 V. Using eqn [3] with $n = 2$, $C_O = 0.02$, and $C_R = 1$ the value of E_M can be calculated to be 0.239 V.

The Nernst equation is the basis for the potentiometric and voltammetric sensors described in this chapter. Potentiometric sensors measure the value of E_M and use the measured value of E_M to determine the ratio of C_O to C_R. Voltammetric sensors control the value of E_M, drive the value of the ratio of C_O to C_R to either infinity or zero, and then measure the current resulting from the associated redox reaction.

2.12.2.3 The Capacitive Double Layer

Under equilibrium conditions, no net current flows across the solid–liquid interface and a charge builds up on both sides of the interface in much the same way as charge gathers on the two plates of a parallel plate capacitor. On the electrode side of the interface, all of the charge gathers at the surface of the electrode. However, in the solution, the charge carriers are ions and not electrons, and ions cannot pack as densely as the electrons in a conductor. In order to counterbalance the charge on the electrode and preserve charge neutrality, ions pack as densely as possible forming a dense layer of ions near the surface of the electrode known as the capacitive double layer (see **Figure 1**). The ions forming the capacitive double layer are normally grouped into three distinct regions. The first region, known as the inner Helmholtz plane (IHP), is composed primarily of polar water molecules and specifically adsorbed anions. The second layer is composed mostly of fully hydrated cations and is called the outer Helmholtz plane (OHP). The final region, the diffuse layer, extends from the OHP to the bulk of the solution and is composed of hydrated anions and cations. The capacitive double layer is very thin (normally <1 μm and often <0.1 μm) and functions similarly to a capacitor with a capacitance, C_{dl}, of approximately 10–100 μF cm^{-2} of electrode surface. However, the behavior of the double-layer capacitance varies from that of a true capacitor in that the capacitance of the layer can vary with the external potential applied to the system.

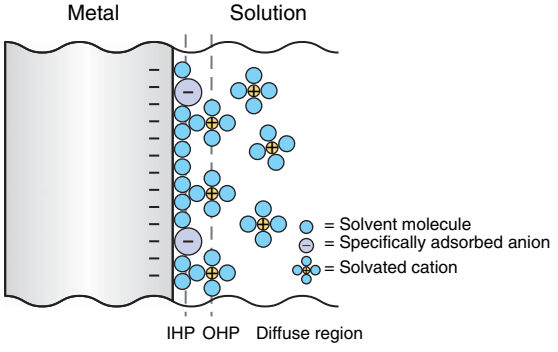

Figure 1 Depiction of the electrical double layer that builds up at the electrode–solution interface when a metal is placed in solution. In the solution there are three distinct layers. The outer Helmholtz plane (OHP), the inner Helmholtz plane (IHP), and the diffuse layer. (Source: Bard A, Faulkner L 2000 *Electrochemical Methods*. John Wiley & Sons, New York, NY.)

2.12.2.4 Polarizable and Nonpolarizable Electrodes

The relative ease with which electrons transfer across the electrode–solution interface defines whether the electrode is considered polarizable or nonpolarizable. Electrodes that utilize very little energy for electron transfer are referred to as nonpolarizable, while those for which the transfer is nearly impossible are referred to as polarizable. No electrode is purely polarizable or nonpolarizable. Real electrodes fall somewhere in between the two extremes; however, close approximations of these ideal electrodes do exist.

Polarizable electrodes pass very little current when a voltage is applied across them. Most noble metals such as platinum and gold are examples of nearly ideal polarizable electrodes. An ideal polarizable electrode behaves like an electrical capacitor with one plate acting as the electrode and the other consisting of the ions and solvent molecules collected near the electrode surface, which form the capacitive double layer.

Nonpolarizable electrodes are characterized by a very fast electrode reaction that allows the electrode's potential to remain close to the equilibrium potential even when current is flowing through the electrode. The most common nearly ideal nonpolarizable electrode is the Ag/AgCl electrode, which is formed by coating a silver electrode with silver chloride. An ideal nonpolarizable electrode behaves like an electrical resistor, with the resistance modeling the difficulty in the transfer of electrons across the interface.

2.12.2.5 The Electrochemical Cell

The apparatus used to carry out an electrochemical experiment is known as an electrochemical cell. Most electrochemical cells consist of either two or three electrodes (**Figures 2** and **3**). Two electrodes are

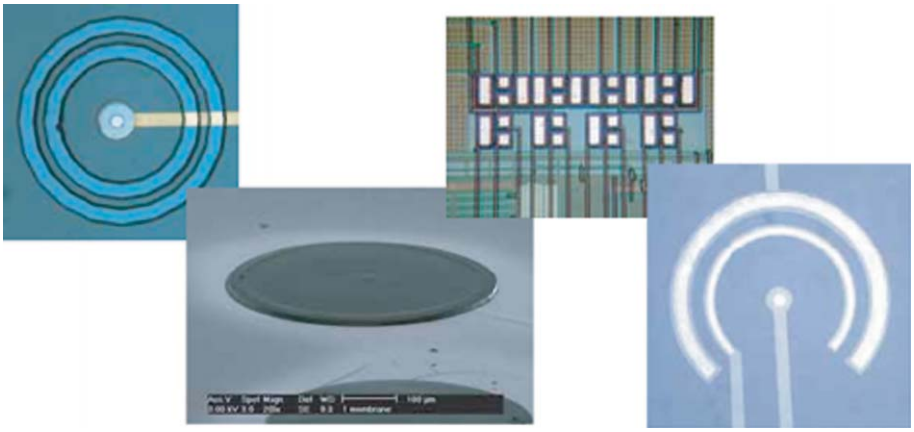

Figure 2 Several example electrodes. *From left to right*: A platinum voltammetric electrode with SU-8 well for enzyme-selective coatings; a Scanning electron micrograph (SEM) of a polymer-based ion-selective electrode (ISE) membrane using an SU-8 ring for containment during membrane dispense (Nam *et al*. 2003); an active voltammetric array with Pt working and counter electrodes and Ag/AgCl reference electrodes fabricated on top of complementary metal oxide semiconductor (CMOS) circuitry (Martin 2005); and a voltammetric sensor with Pt working (inner) and counter (outer) electrodes and integrated Ag/AgCl reference electrode (middle).

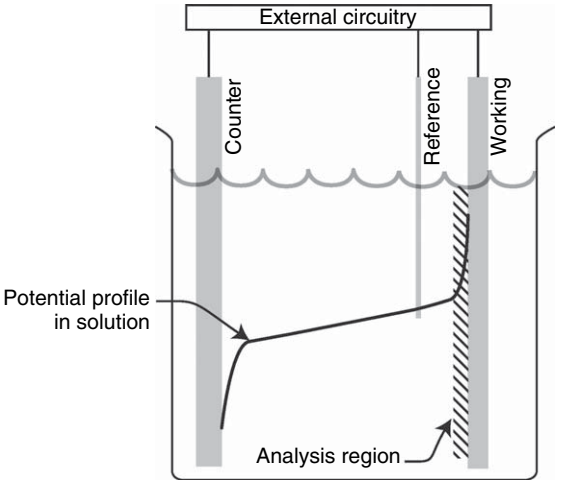

Figure 3 Electrochemical cells normally contain at least two electrodes: the working electrode and the reference electrode. In experiments that draw significant amounts of current, a third electrode, the counter electrode, may be added to the cell. The profile of an applied potential is also depicted. Most of the potential drop occurs at the surface of the electrodes. However, when current is flowing between two of the electrodes, there may also be a potential drop in the bulk of the solution due to the resistance of the solution. (Source: Strong T D 2004 Microfabricated voltammetric neuro-arrays for use *in vitro*. Ph.D. thesis, University of Michigan.)

always present in every electrochemical cell, the indicator or working electrode and the reference electrode. Normally, the reaction at the indicator/working electrode is of interest. The conditions at this electrode are carefully controlled in order to favor detection of a single analyte. If little or no current flows through the electrode as in potentiometry, then this electrode is referred to as the indicator electrode. In cases where significant current flows through the electrode as in voltammetry, the electrode is called the working electrode (McNaught and Wilkinson 1997).

The second electrode, the reference electrode, is designed to develop a well-defined and reproducible potential when placed in solution. A good reference electrode should be stable over long periods of time and should show very little hysteresis when small currents are passed through it or after temperature cycling (Sawyer *et al.* 1995). The NHE, discussed previously, is a reference electrode that is formed by bubbling hydrogen across the surface of a platinum electrode. However, due to the complexity of the NHE, self-contained reference electrodes such as the saturated calomel electrode (SCE) and the Ag/AgCl electrode are more commonly used. These self-contained reference electrodes normally consist of an inner element (either Hg/Hg_2Cl_2 (calomel) or Ag/AgCl) in an appropriate filling solution (often saturated KCl) connected to the external solution by a liquid junction such as a capillary or a porous glass frit (McNaught and Wilkinson 1997). Of these two electrodes, the Ag/AgCl electrode is used almost exclusively in microsystems, and there is an extensive body of literature describing the manufacture and characterization of miniature Ag/AgCl electrodes (Bousse *et al.* 1986, Dendo 1994, Huang and Huang 2002, Strong 2004).

The third electrode, the counter or auxiliary electrode, is normally used in methods that involve a significant current flow through the working electrode. This electrode is normally significantly larger than the working electrode and is made from a polarizable, inert material such as platinum. The only purpose of the counter electrode is to provide a complete circuit allowing the current to flow between the working electrode and the counter electrode as reference electrodes are not normally well suited to sourcing or sinking significant amounts of current.

2.12.3 Potentiometric Sensors

Potentiometric sensors generate an electric potential that is proportional to the activity of a chemical in solution (usually equivalent to the concentration). The most common of these sensors, ion-selective electrodes (ISEs), are used for measuring the concentrations of small ions. Traditionally, ISEs are formed by separating two liquids with a membrane that inhibits or modifies transport between the two phases in such a way that a potential develops across the membrane (Buck 1978). Classical ISE sensors (see ISE electrode body in **Figure 4**, *left half*) have a solution of known composition (the internal solution) on one side of the membrane and the solution being tested on the other side of the membrane (exterior solution). Because the internal solution is controlled, a stable electrical contact can be made to it using a nonpolarizable electrode. A chloridized silver wire in a saturated KCl aqueous solution is commonly used. In coated wire electrodes and some solid-state ISEs, this internal solution is replaced by a direct metallic contact to the membrane.

Transduction of the unknown chemical concentration occurs at the outer surface of the membrane. For measuring this ion concentration-dependent voltage, one must know the potential of the exterior, or test, solution. A reference electrode is normally employed to read this potential. A liquid junction electrode (see reference electrode body in **Figure 4**, *right half*) is commonly used for this application because it can be designed to have a well-defined potential between its connecting wire and the solution over a wide range of chemical compositions and concentrations. Accurate measurements of the membrane potentials can be made only when the membrane is at equilibrium, and so the electronics used in the measurement need to have a high input impedance and the potential of the test solution should be stable, so as to eliminate electric currents from flowing through the cell and driving the cell away from equilibrium.

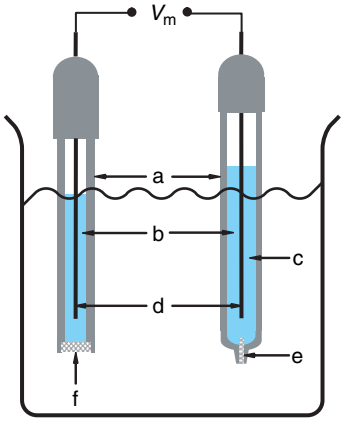

Figure 4 Schematic of a conventional ion-selective electrode (ISE) (*left*) and a reference electrode (*right*) for measuring ionic species in an aqueous solution: (a) electrode body; (b) internal filling solution; (c) reference electrolyte (e.g., 3 M KCl); (d) Ag/AgCl internal reference electrode; (e) liquid junction/porous frit; and (f) ion-selective membrane (glass pellet or polymeric membrane). (Source: Nam H, Cha G S, Strong T D, Ha J, Sim J H, Hower R W, Martin S M, Brown R B 2003 Micropotentiometric sensors. *Proc. IEEE* **91(6)**, 870–80.)

2.12.3.1 Selective Membranes

The ion-selective membranes in conventional ISEs are commonly made of one of the four materials: glass (for pH and alkali ions), pellets of insoluble salts, crystals, or polymers. A brief description of membrane operation is given based on polymeric membranes.

Polyvinyl chloride (PVC) is the most widely used matrix for permselective membranes in conventional ISEs because of its excellent electrochemical properties. PVC, however, exhibits poor mechanical adhesion to the underlying solid passivation layer (usually silicon nitride) of solid-state ISEs. It has been shown that the leading cause of failure in solid-state devices based on PVC membranes is electrolytic shunts around the membrane resulting from the poor adhesion of PVC (Brown 1985). Hence, other polymer matrices such as polyurethane (PU) (Liu *et al.* 1993) and silicone (Malinowska *et al.* 1996) have been developed for use in solid-state chemical sensors (Ryu *et al.* 1994).

Plasticizer, lipophilic salts, and other electroactive ingredients are added to the high molecular weight polymer matrix to give ions mobility in the membrane and to control the membrane's resistivity. The membrane is made selective to a specific ion by the addition of a small weight percent of an ionophore to the membrane. Neutral carrier ionophores (Bakker *et al.* 1997, Buhlmann *et al.* 1998) provide size-selective binding sites for ions of interest, imparting a selectivity to the intended analyte of typically three orders of magnitude over that of interfering ions. Membranes for conventional ISEs are typically formed by mixing the membrane components with an organic solvent, dispensing the membrane cocktail onto a solid surface, evaporating the solvent, and then peeling the polymeric membrane from the casting surface and clamping it into an electrode body. To form coated wire electrodes, the wire can be dipped into the membrane cocktail and the membrane forms as the solvent evaporates. Similarly, microfabricated ISEs are often formed by dispensing the membrane cocktail directly onto a miniature electrode, where it forms a membrane as the solvent evaporates.

Figure 5(a) is an illustration of a membrane cast directly on an electrode; as the membrane contacts the liquid under test and hydrates, water molecules and the analyte ions (in this case, potassium ions) are able to move between the solution phase and the membrane phase. The measured voltage, V_M, includes all the interfacial potentials in the circuit, including the metal–membrane potential. The analyte ions occupy the ionophore binding sites in the membrane, imparting charge to the membrane at the surface. As shown in **Figure 5(b)**, these charges are mirrored by the counter ions in the solution. As in a semiconductor p–n junction, this separation of charge generates a built-in surface potential, E_S, that opposes further diffusion of ions into the membrane. The rates of absorption and desorption of ions are brought into balance at a surface potential that is logarithmically related to the activity of the ions in the solution, as given by eqn [3]. At 298 K, for an ion that exchanges a single electron, the change in E_S in response to changes in concentration of the selected ion is approximately 59.2 mV per decade, i.e., for every 10-fold increase in ionic concentration, E_S increases by 59.2 mV; ions that exchange two electrons generate a potential difference of half this magnitude, i.e., 29.6 mV per decade.

2.12.3.2 Micropotentiometric Sensors

Conventional ISEs have traditionally been about 1.5 cm in diameter and 10 cm in length; they are liquid filled and are expensive and hence must be used for an extended time. Conventional ISEs also require periodic refilling of the internal solution and must be

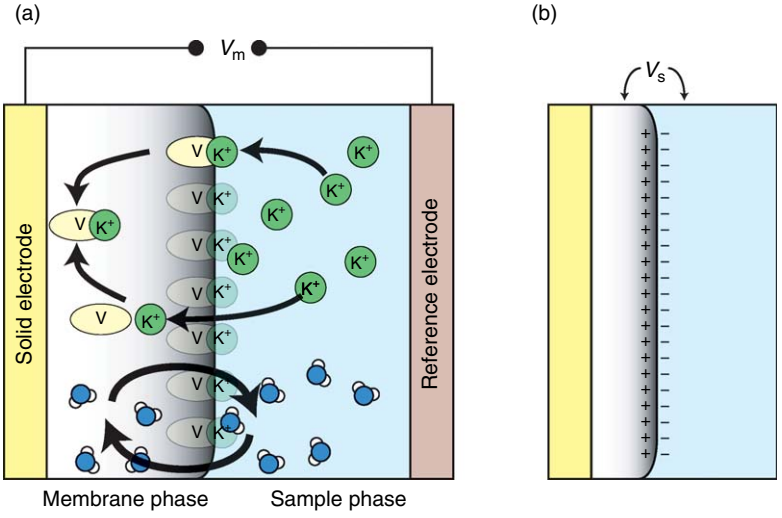

Figure 5 Representation of a potassium ion-selective micropotentiometric sensor having a polymeric membrane with valinomycin (V), a neutral carrier ionophore, in direct contact with the metal electrode. (a) The movement of water and potassium ion between the aqueous and membrane phases. (b) The charge separation that results in the surface potential, which is measured.

stored in the same solution between measurements in order to prevent the membrane from drying.

Microfabrication technologies opened the possibility of miniaturizing ISEs and mass-producing them so that they could be made inexpensively enough to be used only once, or at least used for a short period of time, so that no maintenance is required. The first report of thin-film technology being applied to chemical sensors was Bergveld's (1970) ion-sensitive field effect transistor (ISFET), which is shown in **Figure 6** (*left half*). This device merged the same solid-state electronics technology used to fabricate transistors with chemical sensors by including a field effect transistor (FET) under a chemically selective glass layer. The principles of operation for these devices were clarified over the following decade (Janata and Huber 1980). Researchers have modified the original ISFET by adding metal or polysilicon gates between the transistor channel and the chemical-selective layer (Smith 1982), by incorporating organic polymer membranes instead of silicon dioxide as the chemical selective layer, by coating the ion-selective layer with enzymes, and by using a gate material having a work function that can be modulated chemically (Jakobsen *et al.* 2002, Janata 2004, Shepherd and Toumazou 2005). This whole set of FET-based chemical sensors has been called chemical field effect transistors (CHEMFETs).

An alternative approach for microfabricating ISEs is the use of thick-film (screen printing) technology on ceramic, glass, or plastic substrates (Yoon *et al.* 2000). The dimensional control of photolithography is roughly two orders of magnitude better than that of screen printing, so the thick-film features cannot be as small or as well controlled as features on thin-film-fabricated sensors. However, thick-film manufacturing is very cost-effective, and can form sensors that are small and inexpensive enough to be used just once. The use of a ceramic, glass, or plastic substrates and screen printing to fabricate sensors precludes the option of integrating electronics with the sensors on the same substrate.

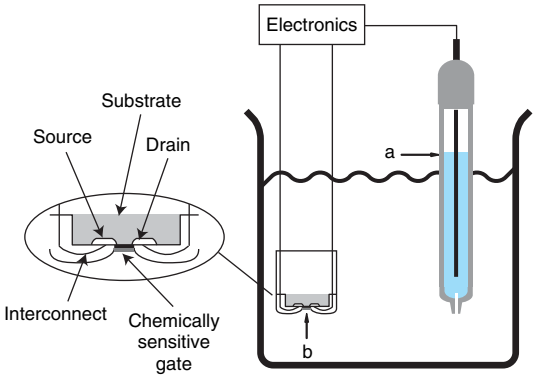

Figure 6 Schematic of an ion-selective field effect transistor (ISFET) in use: (a) reference electrode, as in **Figure 4** and (b) ISFET device. (Source: Nam H, Cha G S, Strong T D, Ha J, Sim J H, Hower R W, Martin S M, Brown R B 2003 Micropotentiometric sensors. *Proc. IEEE* **91(6)**, 870–80.)

The chemical-selective membranes used for potentiometric sensing have high impedances. Reducing the area of the sensor increases the impedance even further. These very high impedances make the sensor system extremely susceptible to noise pickup. Transistor-based sensors such as the ISFETS described above have the advantage of lower output impedance, which should improve noise performance. Unfortunately, MOSFETs (and CHEMFETs) have their own noise susceptibilities, being sensitive to light, temperature, voltage, and semiconductor parameter variations. CHEMFETs have often been used in differential circuits that employ a true MOSFET as the other input device, to compensate for the semiconductor-related noise. Unfortunately, since CHEMFETs and MOSFETs have different gate materials, they are not well matched and the compensation is far from ideal (Hammond *et al.* 2004).

The interposition of a metal or a polysilicon gate material between the chemically sensitive layer and the gate insulator is a substantial improvement to the FET-based devices, as it causes the gate potential to be uniform across the channel. A metal-gate ISFET is exactly analogous to a coated wire electrode driving a single-transistor amplifier (with a very short wire). The next step in the evolution of these active chemical sensors was the use of an operational amplifier (op-amp) instead of the single-transistor amplifier (Brown *et al.* 1985, Lauks *et al.* 1985) (**Figure 7**). With the op-amp configured as a voltage follower, the input impedance is increased by the open-loop gain of the amplifier (typically several orders of magnitude), and the output impedance is reduced by the same amount. The output signal from the op-amp-based sensor is a voltage that tracks the membrane voltage, whereas in the ISFET, the output signal is a current that is quadratically related to the change in gate voltage. The feedback of the voltage follower configuration also improves the stability (insensitivity to a change in circuit parameters) of the electronics by a factor equal to the open-loop gain of the amplifier. The input transistors of the op-amp can be small and well matched for good compensation over temperature, aging, and exposure to light.

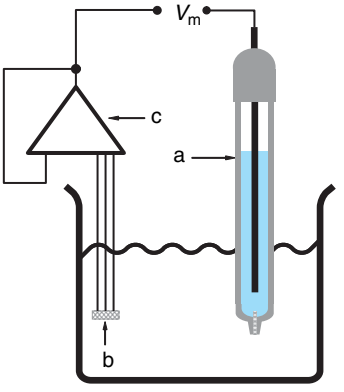

Figure 7 Solid-state ion-selective electrode (ISE) with electronic buffering: (a) reference electrode, as in Figure 4; (b) ISE; and (c) operational amplifier buffer. (Source: Nam H, Cha G S, Strong T D, Ha J, Sim J H, Hower R W, Martin S M, Brown R B 2003 Micropotentiometric sensors. *Proc. IEEE* **91(6)**, 870–80.)

The benefits of integrating op-amps with potentiometric sensors have been realized by placing the sensor directly on top of the amplifier (Brown *et al.* 1985, Milgrew *et al.* 2005) and by integrating the amplifiers on-chip, but separated from the sensors (Lauks *et al.* 1985). As described in more detail in Section 2.12.5, the advantages listed above can also be realized by locating the op-amp very close to the transducer, but not on the same substrate. As noted above, the membrane impedances of microsensors are high, so the leads between the transducer and the amplifier must be either short or well shielded to avoid ambient electromagnetic noise. When a sensor has a long expected lifetime or the application demands a very small size, integration of the electronics with the transducer may be justifiable. On the other hand, when a sensor is disposable or has a short lifetime, manufacturing the sensor and electronics on separate substrates may be more practical and cost-effective.

2.12.3.3 Micropotentiometric Examples

Examples of polymeric membrane-based potentiometric sensors made using thick- and thin-film technology, both with and without integrated electronics, are presented here. Examples of different polymer matrices are given. Some of these sensors are microfabricated, planar coated wire electrodes. Others have hydrogel buffer layers between the membrane and the metal contact to stabilize the membrane-contact potential, and some have integrated op-amps.

2.12.3.3.1 Microfabricated coated wire electrodes

Microfabricated coated wire electrodes might appear to be just miniaturizations of conventional ISEs, but as noted previously, conventional ISEs have an internal solution designed to establish a well-defined Nernstian potential between the solid phase and the liquid phase of the electrode. Coated wire electrodes and ISFETs, on the other hand, lack an analogue to the internal filling solution of conventional ISEs and instead rely on direct contact between the internal electrode and the membrane. This solid contact does not establish a good thermodynamic equilibrium between the two materials and is a source of sensor drift in these devices. Better stability at the membrane–solid interface has been shown when the membrane is adhered tightly to the solid contact. Hower *et al.* (1995) demonstrated that the rough surface of silver epoxy is an effective anchor for the membrane, and Lutze *et al.* (1999) found that the incorporation of a silver ion-containing ligand into the membrane stabilized the membrane-contact potential for some ions, but this approach is not a generalizable solution.

Good examples of micropotentiometric coated wire ISEs are the calcium and chloride sensors described by Hower (2005). These sensors were fabricated on a silicon substrate. A layer of silicon dioxide was grown on the wafer, heavily doped polysilicon was deposited and patterned as interconnect, another layer of silicon dioxide was deposited, and then a silicon nitride layer formed by low-pressure chemical vapor deposition (LPCVD) was deposited as an encapsulant. Contacts were etched down to the polysilicon at the sensing sites and at the bonding pads, and a thin layer of silver was deposited in these openings. A 50-μm-thick layer of silver epoxy was then screen printed as the solid contact at the sensing sites using a Nu-Long microscreen printer. The silver was chloridized, and chemically selective membranes were screen printed directly over the solid contacts and the surrounding silicon nitride surface. The optimized calcium ion-selective membrane was made using 2 mg ETH129 as the ionophore (1 wt.% after solvent removal); 1.5 mg potassium tetrakis(4-chlorophenyl) borate (KTpClPB) to decrease the anionic response; 126 μl 2-nitrophenyl octyl ether (NPOE) plasticizer; 52.8 mg PU and 13.2 mg PVC as the polymer matrix; and 125 μl dimethyl phthalate (DMP) solvent (which is evaporated during membrane curing). As seen in the calibration curve in **Figure 8(a)**, the resulting calcium ISE had a slope of 29.9 mV per decade over a range of

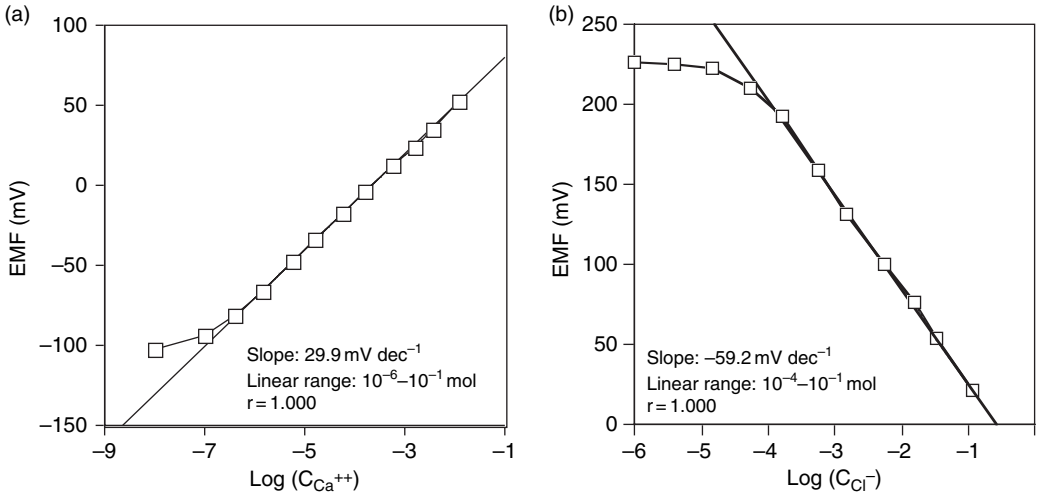

Figure 8 Calibration curves for (a) passive calcium and (b) chloride sensors made on silicon substrates with polyurethane (PU)/PVA membranes, polysilicon interconnect, and silver–epoxy contacts. The ionophores used were ETH129 for calcium and tetradodecylammonium bromide (TDDABr) for chloride. (Source: Hower RW 2005 The integration of potentiometric and optical chemical sensor arrays. Ph.D. thesis, University of Michigan.)

10^{-6} to 10^{-1} mol. The chloride-selective membrane whose calibration curve is shown in **Figure 8(b)** was made using 2 mg tetradodecylammonium bromide (TDDABr) (1 wt.% after solvent removal) as the ionophore and the same components as in the calcium membrane except that it did not include KTpClPB. The slope was −59.2 mV per decade over a range of 10^{-6} to 10^{-1} mol.

2.12.3.3.2 Micropotentiometric sensors with internal layers

As stated previously, the membrane–solid interface in coated wire-type electrodes can be a source of drift in microfabricated ISEs. This is of particular concern for pH sensors or for other membranes that have a secondary pH sensitivity because dissolved carbon dioxide gas and water can permeate the thin membrane and form an unbuffered, slightly acidic intermediate layer at the membrane–solid interface. If either the membrane or the electrode is pH-sensitive, then this can lead to a significant signal drift (Han *et al.* 2001). Hence, buffered hydrogel layers are usually formed beneath pH-selective polymeric membranes, and are often used under all polymeric ion-selective membranes to stabilize the membrane–solid interface. The one serious problem with this approach is that the buffer layer can develop a large osmotic pressure, which can lead to the detachment of the membrane unless design steps are taken to prevent this (Lesho and Sheppard 1996).

An example of sensor arrays made using internal hydrogel layers are those commercialized by Sensicore Inc., Ann Arbor, MI, USA, to monitor pH, ammonia, calcium, and a number of other parameters pertinent to potable water quality. **Figure 9** is the layout of an early version of a sensor array of this type. **Figure 10** is a dynamic calibration curve for pH and calcium taken from a sensor of this type. The Sensicore chips include

passive (i.e., no on-chip electronics) potentiometric, voltammetric, conductivity, and temperature sensors (Sensicore 2006).

2.12.3.3.3 Active micropotentiometric sensors

As mentioned above and described in detail in Section 2.12.5, the integration of amplifiers and other circuits onto the same piece of silicon with chemical transducers is possible. As has also been stated, this technologically elegant approach may not always be the best solution from an economic point of view. However, there is another benefit to placing the amplifier close to the transducer, as in an integrated sensor: having the micropotentiometric sensor and the electronics tightly integrated expands the list of usable membrane materials by allowing the use of membranes with higher intrinsic impedances.

In Section 2.12.3.1, silicone was suggested as an alternative to PVC for membrane matrices because of its adhesion to the surface of solid-state sensors. Single-component silicones, such as silanol-terminated polydimethylsiloxane (Petrarch Systems, Bristol, PA, USA) and room temperature vulcanizing (RTV) silicones (Dow Corning, Midland, MI, USA), have been shown to have excellent adhesion to silicon nitride. The adhesive force holding silicone membranes onto the sensor surface was shown by Yoon *et al.* (1999) to be more than 50 times than that in a PVC membrane. **Figure 11** is a dynamic calibration plot for a potassium-selective RTV 3140 membrane in a conventional ISE body made with 1 wt.% KTpClPB and 2 wt.% valinomycin. Unfortunately, silicone has a very high resistivity, leading to large impedances, slow responses, and poor detection limits. This problem is exacerbated in microsensors because the membranes are small in diameter and impedance is inversely proportional to area.

Integration of complementary metal oxide semiconductor (CMOS) electronics onto the same substrate as in the potentiometric sensors has been shown to alleviate the disadvantages of silicone membranes. Specifically, placing a CMOS op-amp near the sensor reduces the interconnect capacitance between the membrane and the instrumentation, and provides a very high input impedance to the instrumentation. The result is a significantly reduced electrical time constant for the sensing system. **Figure 12** shows the difference in dynamic response among a conventional microsized ISE body, a passive solid-state ISE, and an active solid-state ISE with a CMOS-integrated, unity-gain buffer. Each electrode consisted of identical RTV 3140 membranes with 2 wt.% valinomycin and no lipophilic additives. In this case, the op-amp was integrated on the sensor chip, but nearly the same effect could be achieved by a hybrid sensor having the electronics very near the transducers.

2.12.3.4 Comparison of Potentiometry and Voltammetry

The potentiometric sensors described in this section are used to detect small ions such as hydrogen (H^+), potassium (K^+), and chloride (Cl^-) ions. Ions that need to be detected at very low levels or that have

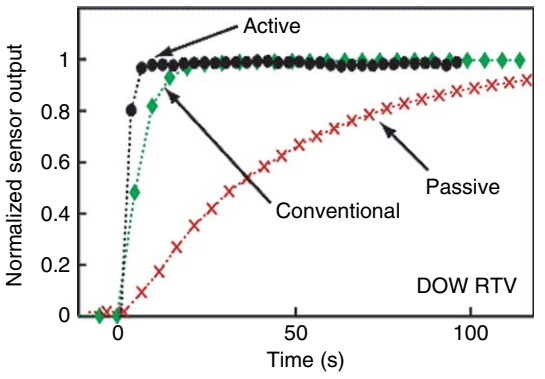

Figure 12 Dynamic response to a ten-fold change in concentration for silicone potassium-selective membranes in a conventional ion-selective electrode (ISE) body, on a passive solid-state sensor, and on an active (op-amp buffered) solid-state sensor. Digest Solid-State Sensor, Actuator, and Microsystems Workshop*, Hilton Head Island, SC, USA, pp. 396–9.)

poor ionophores as well as uncharged species are not usually measured using potentiometric sensors. Many of these analytes such as phenols, nitrate, and the heavy metals, however, can be oxidized and reduced at characteristic potentials so that their concentrations can be monitored with voltammetric sensors, which are described in Section 2.12.4. Solid-state chemical sensors of both potentiometric and voltammetric types can be fabricated with the same photolithographic processes, leading to the integration of both types of sensors in a single device.

2.12.4 Voltammetry

Many chemical species are electroactive and will be either reduced or oxidized when an electric potential is applied between a set of electrodes immersed into a solution containing the species. These redox reactions transfer electrons, generating a current flow between the electrodes through the solution. This current, referred to as the faradaic current, i_f, is related to the concentration of the material undergoing the redox reaction by the following equation:

$$i_f = -nFAD\left(\frac{\partial C(x,\,t)}{\partial x}\right)\Bigg|_{x=0} \qquad [4]$$

where A is the area of the electrode involved in the reaction, D is the diffusion coefficient, and $C(x, t)$ is a function describing the concentration of analyte at a distance x from the electrode at time t.

2.12.4.1 Principle of Operation

To perform a voltammetric analysis, an excitation voltage is typically applied between two electrodes, and the current flowing through the cell is measured. Redox reactions must occur at both the electrodes in order to support the current flow; however, only the reaction at the working electrode is important. In most voltammetric analyses, the working electrode is a polarizable electrode, and the test solution is a strong electrolyte and thus a good ionic conductor. If the test solution is not a strong electrolyte, a background electrolyte such as NaCl may be added to increase conductivity. Under these conditions, the voltage applied to the solution primarily drops across the double layer. Since the double layer at the working electrode is extremely thin ($\ll 1\,\mu m$), large electric fields are developed in this area, providing the energy necessary to cause electron transfer and to drive the resulting redox reaction of the analyte material.

As discussed earlier, a generic redox reaction follows the form described by eqn [1] and the applied potential at which the rates for the forward and reverse reactions are equal and at which no net current flows in the cell is determined by the Nernst equation (eqn [2]). If an external voltage is applied to the cell using the counter electrode, the forward and reverse rates for the redox reaction change, resulting in an increase of either O or R at the surface of the electrodes and a net current flow. Although eqn [2] applies only to a system at equilibrium, when the cell is driven away from equilibrium, the basic relationship described by eqn [2] still holds and the approximate ratio of O to R can be found by rearranging terms to arrive at the following equation:

$$\frac{C_O}{C_R} = \exp\left(\frac{(E^0 - E)nF}{RT}\right) \qquad [5]$$

From this relation it is apparent that the input voltage required to push the reaction entirely to one side would be infinite. However, since the relationship is logarithmic, the change from having nearly all O to nearly all R at the surface is a very small change in voltage. In fact, if the material exhibits a single electron reaction, an E that is only 177 mV greater than E^0 is large enough to make the ratio of a material 1000 times greater than the other at the surface of the electrode (Kissinger *et al.* 1996).

The rate at which the reaction proceeds and the magnitude of the faradaic current that flows are controlled by the following factors: the potential applied between the working electrode and the counter

electrode; the electron transfer kinetics of the redox reaction; adsorption of ions on the surface of the electrode; and mass transfer of the reactant to the surface of the electrode and the product away from the electrode. Mass transfer occurs due to convection, diffusion, and migration. If the cell is mechanically isolated from vibration, mass transfer due to convection can be mostly ignored, and if the background ionic strength of the solution is at least two orders of magnitude larger than that of the analyte, then most of the ionic current will be carried by background ions and mass transfer due to migration can also be ignored. Assuming that mass transfer occurs mostly due to diffusion and that the diffusion of analyte to the electrode surface dominates the other rate-controlling steps, a closed-form solution of eqn [4] can normally be found that approximates the relationship between the concentration of the analyte and the observed faradaic current.

The remainder of this section describes several of the voltammetric methods most commonly used with microfabricated sensors. All these methods adhere to the principles outlined in the preceding paragraphs, but differ in the excitation waveforms applied to the cell. The simplest method, chronoamperometry, which is presented first, consists of a single voltage step. After chronoamperometry is presented, an analysis of more complex methods such as linear sweep voltammetry (LSV), cyclic voltammetry, square wave voltammetry (SWV), and square wave anodic stripping voltammetry (ASV) are presented.

2.12.4.2 Chronoamperometry

Chronoamperometry is one of the simplest voltammetric methods and yet it is one of the most frequently used voltammetric methods. Chronoamperometry, in its most basic form, consists of applying a single voltage step at time t_0 and then measuring the current that results from the applied potential. The simplicity of chronoamperometry makes it an ideal technique to analyze it as an example of a basic voltammetric operation.

Consider a simple electrochemical cell consisting of a working electrode, a counter electrode, and a beaker of solution containing only the oxidized form of the analyte, O, at a concentration of C_O^*. An initial voltage is applied between the working electrode and the counter electrode such that no electrochemical reactions occur at the working electrode surface and no net current flows in the cell. At time t_0, the applied potential is stepped to a new voltage, E_a, that is 177 mV more negative than E^0, causing almost all of the O at the surface of the electrode to be instantaneously reduced to R and causing any additional O that arrives at the surface of the electrode via diffusion to be immediately reacted so that the concentration of O at the surface of the electrode is essentially zero. After a period of time, t_S, the applied potential is stepped back to a voltage that allows the R at the electrode surface to oxidize back to O, and the experiment is concluded.

If the electrode is much larger than the molecules of O and if the volume of the solution is large compared to the exposed area of the electrode, then a 1D solution of Eqn [5] will suffice, and the concentration profile $C_O(x, t)$ in the solution during the period when the applied voltage is E_a will approximate the series of curves illustrated in **Figure 13**. During the experiment, the concentration of O at the surface of the electrode, $C_O(0, t)$, is essentially zero while the concentration of O in the bulk solution, $C_O(\infty, t)$, remains at the original concentration, C_O^*. Unreacted O diffuses down the concentration gradient to the surface of the electrode where it gains an electron. As time passes, the region depleted of O by the reaction at the electrode extends deeper into the solution. The thickness of this depletion region is proportional to the diffusion coefficient, D.

The amount of charge, Q, transferred during the reaction is related to the number, N, of moles of O reduced to R by the following relationship:

$$Q = nFNA \qquad [6]$$

Differentiating Q with respect to time, we arrive at an equation for the faradaic current flowing through the electrode at time t

$$i_f = \frac{dQ}{dt} = nFA\frac{\partial N}{\partial t}\bigg|_{x=0} \qquad [7]$$

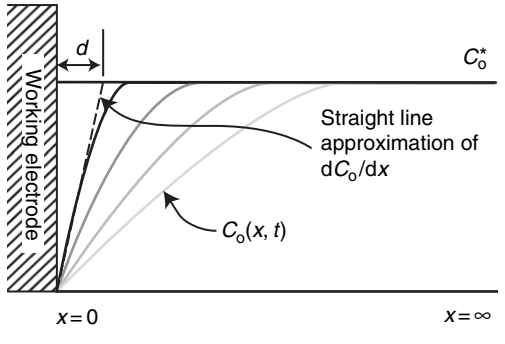

Figure 13 Concentration profile of O at various times after the application of E_S. Note that the slope of the concentration profile can be approximated by a straight line. (Source: Strong D D 2004 Microfabricated voltammetric neuro-arrays for use *in-vitro*. Ph.D. thesis, University of Michigan.)

Material diffuses only along the X-axis, so by Fick's law of diffusion in one dimension:

$$\left.\frac{\partial N}{\partial t}\right|_{x=0} = -D\left(\left.\frac{\partial C(x,\,t)}{\partial x}\right)\right|_{x=0} \quad [8]$$

Substituting eqn [8] into eqn [7] results in eqn [4], which is given in Section 2.12.4.

The important thing to stress in eqn [4] is that i_f is proportional to the slope of the concentration gradient at the surface of the working electrode and not to the applied voltage. As long as E_a is large enough to convert all of the O at the surface of the electrode to R, the current that flows will be independent of E_a. If a straight line approximation for $C_O(x, t)$, as shown in **Figure 13**, is used, then the slope at the electrode will be C_O^*/d. Substituting this into eqn [4] gives an approximate relation for the current, which is as follows:

$$i_f \approx nFAD\left(\frac{C_O^*}{d}\right) \quad [9]$$

While only an approximation, a straight line estimate of a concentration profile is often instructive as to the behavior of a voltammetric system, especially for more complex cases. In this case, however, the actual solution of eqn [4] can be found by applying the boundary conditions $C_O(0, 0) = C_O^*$, $C_O(0, t) = 0$, and $C_O(\infty, t) = C_O^*$, providing

$$i_f(t) = \frac{nFAC_O^*\sqrt{D}}{\sqrt{\pi t}} \quad [10]$$

Eqn [10] is commonly referred to as the Cottrell equation and a plot of this response is shown in **Figure 14**. Note that at time t_0, the current is infinite according to eqn [10]. In real systems, i_f is limited by the rate of electron transfer at the surface of the electrode and by the maximum current supply rate (slew rate) of the electronics applying the input voltage. After time t_0, the current rapidly decays at first and then asymptotically approaches zero.

To determine the concentration of an analyte, the researcher typically chooses a time long enough after t_0 so that the current associated with charging the electrode capacitance is negligible, but soon enough so that the current has not decayed too much to take the measurement. The current at this time will be proportional to the concentration of the analyte.

Although chronoamperometry is a very useful technique, it also has several serious drawbacks.

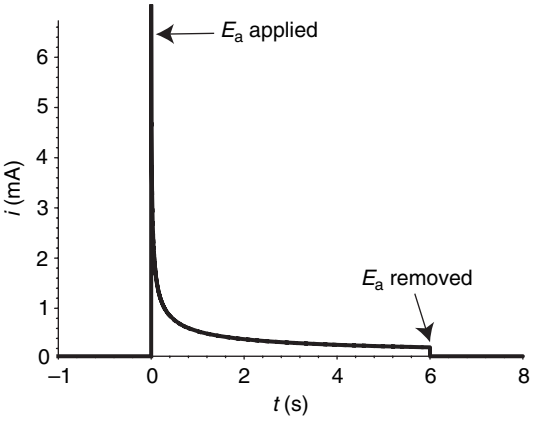

Figure 14 Ideal chronoamperometric current response to step of E_a. Plot assumes a concentration of 1 mM, an electrode area of 1 cm × 1 cm, a diffusion coefficient of 10^{-6} cm^2 s^{-1}, and $n = 1$. (Source: Strong D D 2004 Microfabricated voltammetric neuro-arrays for use *in-vitro*. Ph.D. thesis, University of Michigan.)

The two major drawbacks of chronoamperometry are the following:

(1) It is a relatively slow measurement technique with most measurements requiring perhaps 10 s or longer.
(2) It is not very selective.

The current measured during a chronoamperometric scan is the sum of the faradaic currents produced by all ions in solution that are reduced at a potential more positive than E_a. Consequently, measurement of the concentration of a single analyte in a solution containing several different molecules can be difficult.

2.12.4.3 Linear Sweep Voltammetry

The excitation waveform for LSV is a linear sweep of the applied voltage, E_a, from an initial voltage, E_i, to a final voltage, E_f. E_i is normally selected to be a voltage where no electrochemical reduction of O occurs, and E_f is selected to be a voltage at which so much reduction occurs that $C_O(x = 0) \approx 0$. The analysis from chronoamperometry applies here with the exception that $C_O(0, t)$ is no longer assumed to be zero for the entire time period. Instead, a straight-line approximation of the slope of the diffusion profile

$$\left.\frac{\partial C_O(x,\,t)}{\partial x}\right|_{x=0} \approx \frac{C_O^* - C_O(0,\,t)}{d} \quad [11]$$

can be used to approximate

$$\left.\frac{\partial C_O(x, t)}{\partial x}\right|_{x=0}$$

Combining eqns [4] and [11] gives the following approximation for i_f:

$$i_f \approx -nFAD\left(\frac{C_O^* - C_O(0, t)}{d}\right) \quad [12]$$

The quotient in this equation is the key for understanding the behavior of LSV. As time passes and E_a approaches and then exceeds E^0, the value of $C_O(0, t)$ begins to decrease, causing the numerator to increase. At the same time, the denominator increases as the depletion region extends into the solution. The result is that i_f rises exponentially to a peak near E^0. These conditions apply until the applied voltage is far beyond E^0 so that the surface concentration of O is essentially zero; after that point, the response will resemble a chronoamperometric response, tapering off inversely with $\sqrt{t}$.

The height of the peak is related to how fast both the numerator and the denominator of eqn [12] are changing, and the rate of change in the numerator and denominator is in turn dependent on the rate at which the applied potential is swept. A general linear sweep voltammogram is shown in **Figure 15**. Note that in LSV, rather than plotting the current versus time, the horizontal axis is the applied voltage.

In LSV, the two most important characteristics are E_p, the voltage at which the current peaks, and i_p, the value of the current at that point. If the system is reversible, then the Randles–Sevcik equation applies

$$i_p = 2.69(10)^5 n^{\frac{3}{2}} A C_O^* \sqrt{Dv} \quad [13]$$

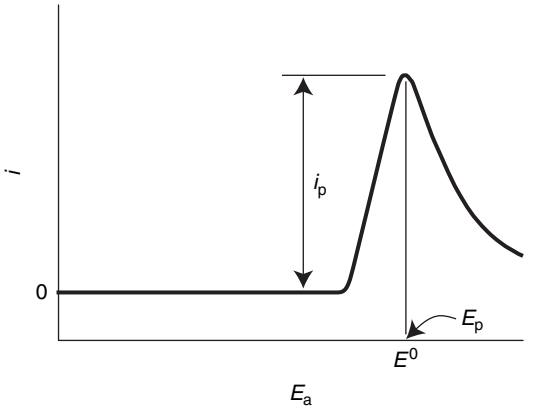

Figure 15 Linear sweep voltammogram. The potential at which the current peaks, E_p, and the current at the peak, i_p, are labeled. (Source: Strong D D 2004 Microfabricated voltammetric neuro-arrays for use *in-vitro*. Ph.D. thesis, University of Michigan.)

where v is the scan rate of the applied voltage (Bard and Faulkner 2000). If the diffusion coefficients for both O and R are approximately equal, then E_p is given by the following equation:

$$E_p = E^0 - \frac{0.029}{n} \quad [14]$$

Since the working electrode has a different E^0 for each ion in solution, each ion in the solution will generate a different current peak at E_p, which is dependent on both the electrode material and the ion. The potentials at which these peaks occur can thus be used with eqn [14] to identify the ions in the solution, and then, using eqn [13], the value of i_p can be used to determine C_O^*. Unfortunately, many chemicals have standard potentials that are close enough to each other that this kind of analysis must be done with caution.

As with chronoamperometry, the above analysis will apply equally well to an oxidation reaction if the voltage is swept in the opposite direction, and the minus sign in eqn [14] is changed to a plus sign. The current will, of course, flow in the opposite direction.

2.12.4.4 Cyclic Voltammetry

Cyclic voltammetry is an extension of LSV. Instead of sweeping the voltage in only one direction, after the linear sweep is concluded, the voltage is immediately swept back to the initial voltage at the same rate. If the analysis starts with a solution consisting of only O, at the conclusion of the first sweep, an amount of R approximately equal to the initial concentration of O will be present at the surface of the electrode, and the reverse sweep will reoxidize (if the reaction is reversible) whatever part of this material has not diffused away from the electrode and produce a current peak similar to the reduction peak, but in the reverse direction. A typical cyclic voltammogram is shown in **Figure 16**. The equations for i_p and E_p are the same as in LSV because the technique is essentially two linear sweeps run back to back.

Cyclic voltammetry has several advantages over LSV. The reverse sweep provides additional information to help identify materials. It also converts material back into its original form, which can prevent the accumulation of unwanted material. Additionally, many facts about the chemical reactions occurring at the surface of the electrode can be inferred from the observed peaks in the voltammogram. For example, if a peak is observed during the forward sweep indicating the reduction of an ion, then on the reverse sweep, a second peak should be observed indicating the reoxidation of the ion back to its original form. If the two

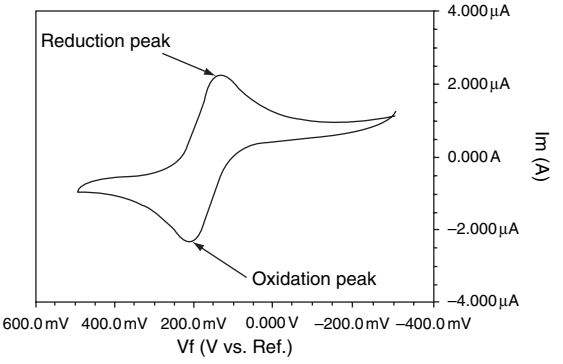

Figure 16 Voltammogram of potassium ferricyanide showing a separation of 50 mV between peaks in the forward and reverse scans. Sweep rate is 1 V s $^{-1}$. Note that the *X*-axis is reversed, the more typical orientation in chemical science texts. (Source: Strong D D 2004 Microfabricated voltammetric neuro-arrays for use *in-vitro*. Ph.D. thesis, University of Michigan.)

peaks are separated by 59 mV then eqn [14] indicates that $n = 1$ for this particular redox reaction and that the reaction is reversible. Likewise, if $n = 2$ for the reaction, then the forward and reverse peaks will be separated by 29.6 mV. Other analyses are also possible and information regarding intermediate products of the reaction as well as transfer kinetics can be observed using cyclic voltammetry. These methods are well documented and information regarding their application can be obtained in the many texts on the subject (Bard and Faulkner 2000, Kissinger *et al.* 1996).

2.12.4.5 Square Wave Voltammetry

The techniques described prior to this point have involved the applications of relatively large potentials. SWV, on the other hand, is a small-amplitude technique that was developed to isolate the contribution from the faradaic signal and the contribution from the parasitic charging currents. Small-amplitude techniques like SWV restrict the changes in the excitation potential to small excursions around a baseline potential. Normally these excursions are typically less than $8/n$ to $12/n$ (mV) for each potential step where n is the number of electrons transferred in the redox reaction, and the baseline around which the potential steps are introduced is often a linear ramp similar to the ones used in LSV. **Figure 17** shows excitation waveforms for three typical small-amplitude voltammetric techniques (Kissinger *et al.* 1996).

In SWV, the faradaic current produced by each potential step is measured at the end of each voltage excursion, and the change in current between potential steps, Δi, is plotted versus the applied potential. The faradaic currents that flow during the positive and negative potential steps are opposite in polarity while the polarity of the charging current, which is mostly due to the ramp voltage, does not change. Thus, the component of the output current due to the faradaic signal is amplified while the component due to the charging current is reduced. Δi is directly proportional to the change in surface concentrations of the electroactive species, and the maximum current difference occurs near E^0 for each electroactive analyte.

2.12.4.6 Square Wave Anodic Stripping Voltammetry

For analytes present in only trace amounts, the peak currents generated using the techniques presented up to this point can be quite small and indistinguishable from noise. To overcome this problem, a technique known as ASV can be used to amplify these currents for heavy metals and other species, which can be electrochemically plated on the surface of an electrode. ASV is a combination of standard voltammetric techniques with a preconcentration phase (Wang 1985). The preconcentration step applies a deposition potential, E_d, on the electrode for a predefined period of time, t_d, as shown in **Figure 18**. The application of E_d reduces O in solution to R, and if R is insoluble in solution, a thin layer of R plates onto the electrode (**Figure 19**). After the plating step, a voltammetric sweep such as SWV or CV is conducted, and the film of R is stripped off the surface of the electrode as it is

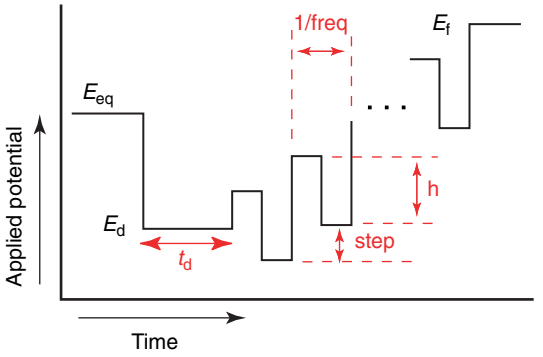

Figure 18 Typical anodic stripping voltammetry (ASV) input waveform. E_{eq} is the equilibrium potential of the solution, E_d is the voltage applied to the solution during the preconcentration step, t_d is the duration of the preconcentration, E_f is the final potential of the sweep, *step* is the step height, *h* is the pulse height, and *freq* is the frequency of the pulses. (Source: Martin S M 2005 CMOS-integrated liquid chemical microdetection systems. Ph.D. thesis, University of Michigan.)

oxidized back to O. The resulting faradaic current is larger than the current produced without plating because the effective concentration of R at the electrode surface is increased. If the voltammetric technique employed during the measurement step is SWV, then the entire process is referred to as square wave anodic stripping voltammetry (SWASV).

2.12.4.7 The Three-Electrode System

The analysis so far has described the use of two electrodes in the solution: the working electrode where the reaction of interest is occurring, and the counter electrode, which completes the electric circuit and allows the application of an external potential. In practice, a reference electrode is often added, as illustrated in **Figure 20**. In a three-electrode electrochemical cell, the applied voltage, v_a, is composed of three parts: v_w, the potential drop at the surface of the working electrode; v_S, the potential drop due to the ionic resistance of the solution; and v_c, the potential drop at the surface of the counter electrode. When performing a voltammetric experiment, only the reactions occurring near the surface of the working electrode are of interest, and in order to measure the quantity of reactants at the working electrode surface, both v_w and i_f must be known. If only a counter electrode and a working electrode are used, i_f can be measured; however, v_w cannot be set independently of v_S and v_v, and only v_a is measurable at the external cell connections.

The unknown contributions from v_S and v_c can be minimized by using a reference electrode such as an Ag/AgCl electrode as the counter electrode in order to obtain a well-defined reference potential for v_c and

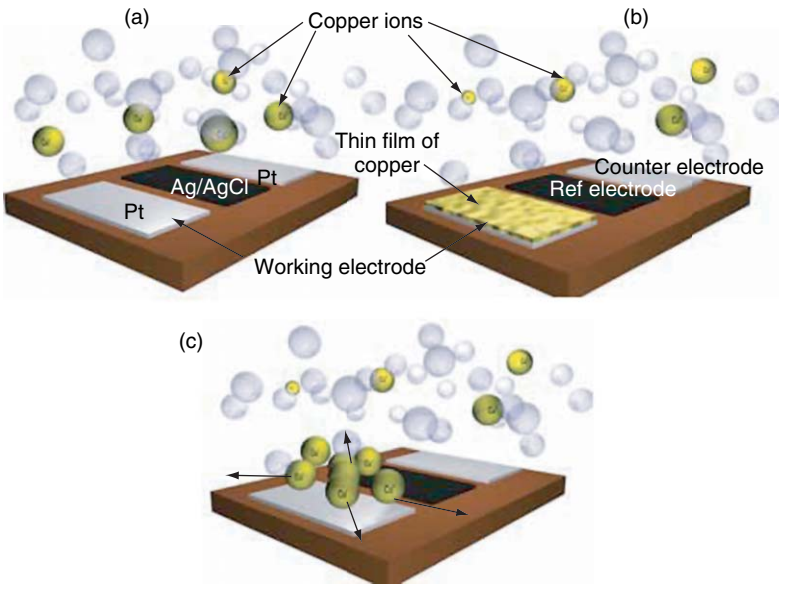

Figure 19 Diagram of anodic stripping voltammetry (ASV). (a) A three-electrode sensor and solution with no cell potential applied. (b) The system during plating with a cathodic potential applied to the cell. A thin film of copper forms on the electrode while the bulk concentration of ions in solution is unaltered. (c) The ions diffusing away from the electrode after a redox reaction has stripped them from the electrode during the voltammetric scan. Figure 20 Figure 3 with all potential drops labeled. The analysis region is the area where the redox reaction under study occurs. Note that the interface voltage drops (v_c, v_w) occur in a region near the electrodes that is typically <1 μm thick. (Source: Strong D D 2004 Microfabricated voltammetric neuro-arrays for use *in-vitro*. Ph.D. thesis, University of Michigan.)

by using a high ionic strength solution to minimize the resistance of the solution, R_{sol}, thereby reducing v_S ($v_S = iR_{sol}$). However, in practice, these approaches may not be practical or possible.

Although reference electrodes are normally nonpolarizable, no electrode is ideal, and any current passing through a reference electrode will shift the electrode's reference potential away from its equilibrium value. Additionally, the most commonly used reference electrode in microsystems, the Ag/AgCl electrode, normally consists of only a thin layer of AgCl grown on the surface of an Ag electrode, and the faradaic reaction that occurs when current flows through an Ag/AgCl electrode consumes the layer of AgCl, greatly shortening the life of the electrode. Adding a supporting electrolyte to a low ionic strength solution is not always desirable either, as the supporting electrolyte may interfere with the measurement (such as adding NaCl to the test solution for a chloride sensor), and for many simple automated test systems (such as the remote rainwater pollution-monitoring station proposed by Martin (2005), the addition of an electrolyte would unnecessarily increase the complexity of the system.

The addition of a reference electrode in close proximity to the working electrode removes most of the measurement errors due to v_S, and completely eliminates v_c from the measurement. This removal of v_c is key in microsystems, as the small distance between the counter electrode and the working electrode in a microelectrode device has already reduced R_{sol} to a nearly negligible value. However, as the counter electrode decreases in size, v_c becomes strongly dependent on the current flowing through the cell, making the removal of its influence important.

2.12.4.8 Nonidealities

During the discussion of the more common electrochemical techniques in the previous sections, several assumptions were made that glossed over nonidealities that the reader should be aware of. Two of these nonidealities are discussed in the following sections.

2.12.4.8.1 Parasitic electrode currents

In addition to the current generated by the redox reaction of interest, parasitic currents are also drawn to charge the electrical double-layer capacitance discussed in Section 2.12.4.3, and additional current is generated by interfering redox reactions at the electrode surface by ions other than those being measured. Sometimes these additional currents can be accounted for through calibration, but often they cannot be easily separated from the signal of interest without using a more complex technique such as SWV. It is important to note that both the current drawn to charge the double-layer capacitance and the peak current measured during a voltammetric scan, i_p, are dependent on the scan rate. The parasitic current drawn to charge the double layer

$$i_c = C_{dl} v \qquad [15]$$

is directly proportional to the scan rate, while the peak current (see eqn [13]) is only proportional to the square root of the scan rate. Consequently, while faster scan rates do enhance i_p, i_c increases at a faster rate, negating at least part of the benefit of increasing the scan rate.

On the other hand, both i_c and i_p are also directly proportional to the area of the electrode. However, as the electrode gets very small (<25 μm) nonplanar diffusion effects which will be discussed in the next section increase the flux of ions to the surface of the electrode, increasing the faradaic current above what is predicted by eqn [10].

2.12.4.8.2 Nonplanar diffusion

Eqn [10] is derived by assuming that the electroactive material diffuses to the electrode in a planar fashion. This assumption holds very well in the center of the electrode as shown in **Figure 21(a)**; however, near the edges of a planar electrode,

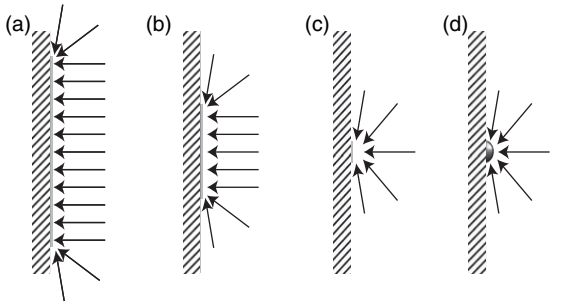

Figure 21 Planar and spherical diffusion to an electrode. Arrows represent material diffusing to the electrode. (a) A large electrode where planar diffusion dominates; (b and c) progressively smaller microelectrodes where planar diffusion no longer dominates; and (d) diffusion to a spherical electrode. Note the similarity between (c) and (d). (Source: Strong D D 2004 Microfabricated voltammetric neuro-arrays for use *in-vitro*. Ph.D. thesis, University of Michigan.)

material diffuses in a nonplanar fashion. As the electrode size is reduced, the contribution from this nonplanar diffusion begins to dominate as seen in **Figure 21(b)** and **21(c)**. Clearly, for these cases, eqn [10] will not hold. If a redox reaction at an electrode has a duration long enough that the electrode's longest dimension is much smaller than $d = \sqrt{Dt}$, the diffusion layer will have extended so far beyond the electrode geometry that the shape of the electrode starts to become less important, and material diffuses toward it in a way that is similar to diffusion toward a hemispherical electrode. For chronoamperometry, the equation for the faradaic current to a hemispherical electrode, such as that in **Figure 21(d)**, is given as follows:

$$i_f - \frac{nFAC\sqrt{D}}{\sqrt{\pi t}} + \frac{nFACD}{r} \qquad [16]$$

where r is the radius of the hemisphere. The first term is the same as in eqn [10], but the additional term is independent of time. Thus the current starts out like in the planar case, but instead of decaying to zero it decays to a steady-state value when the diffusion layer extends much farther into the solution than does r. Absent convection, planar electrodes stimulated long enough will exhibit a very similar current relationship. The case in cyclic voltammetry is similar, with the current being enhanced by the nonplanar diffusion to a higher value. In addition, rather than the current decaying beyond the peak toward zero, it will stabilize at the same steady-state value as in the chronoamperometric case. The enhanced currents of nonplanar diffusion are extremely beneficial, and as a result, in order to reduce charging currents, the electrode is normally made as small as possible without reducing the peak current below the detection limits of the interface circuitry. As the electrodes become very small and the currents generated at the electrodes get even smaller, significant benefits are realized by integrating the chemical sensors directly on top of the CMOS circuitry as described in Section 2.12.5.

2.12.5 Integrated Electronics for Chemical Sensors

Integrating readout electronics with a passive transducer for forming an active chemical sensor can provide many advantages over passive devices. These advantages include a reduction in overall system size; a reduction in system power dissipation; an improvement in sensor detection limit, speed, and linearity; and a more user-friendly interface due to the use of application-specific electronics. Additionally, certain applications where system size and power dissipation are limiting factors, such as implantable devices, might only be viable using active sensors. Integrating circuitry directly with chemical sensors, however, is not without challenges. In general, active sensors are more expensive to fabricate than are passive devices due to the additional manufacturing steps required. This additional cost can be prohibitively large for applications where the chemical sensor is a single-use, disposable device. The integrated readout electronics might also have lower resolution than a bench-top instrumentation system, since the best process for fabricating a chemical sensor might not be the best process for fabricating electronics. Accordingly, thoughtful analysis of the advantages and disadvantages of integration must be considered to decide whether passive or active sensors are a better choice for the application of interest.

Two example applications utilizing active sensors are presented below. Martin *et al.* (2004a) described a system with ISEs and CMOS electronics integrated onto a single silicon substrate. The shortening of the interconnect between the sensor and the amplifier reduced the amount of coupled noise in the system. The percent error of the measured response compared to the theoretical response of the sensors improved from 19% to 5% in moving from passive to active sensors. Schienle *et al.* (2004) demonstrated a single-chip voltammetric DNA sensor that measured faradaic currents resulting from a redox reaction used to identify specific DNA sequences. The chip

included 128 electrodes and in-pixel analog-to-digital converters (ADCs).

In this case, one major benefit of coupling the electronics and sensors was the reduction in off-chip communications achieved by transforming the current into a frequency and encoding this frequency using a digital word.

2.12.5.1 Microelectronic Instrumentation

In the design of active chemical sensors, the microelectronics must be carefully engineered to ensure that the overall system achieves performance greater than or equal to the performance of passive sensors coupled with bench-top instrumentation. This section details the development of a typical microelectronic subsystem for chemical sensing. First, a typical top-level block diagram is presented and then several of the important design considerations of the subcomponents are reviewed.

2.12.5.1.1 Complete microinstrumentation system

Figure 22 shows a block diagram of a typical active chemical sensor. The microelectronics might contain a digital control section that communicates with the data converters in the signal path and the computer or data storage device on the data processing side of the analysis. The signal processing might also be integrated in the digital control block in the form of a microcontroller or a digital signal processor (DSP). In applications where an analog control or stimulus is needed, a digital-to-analog converter (DAC) can be integrated with the system. This analog stimulus is sent to a sensor interface block, which can produce a specified condition on the transducers, provide calibration, or actuate additional components. The transducers may consist of any of the chemical sensors previously discussed. The output of the sensor connects to the sensor interface block. The signal may be amplified in the interface block or may be passed on to a dedicated preamplifier. This amplification helps improve the signal-to-noise ratio (SNR) of the transducer's signal. Further amplification or filtering may be implemented in a signal conditioning block. These circuits drive an ADC, and the digital output code is conveyed to the digital control section. Integrated sensor systems may include only some of these components, and may incorporate other electronic functionality.

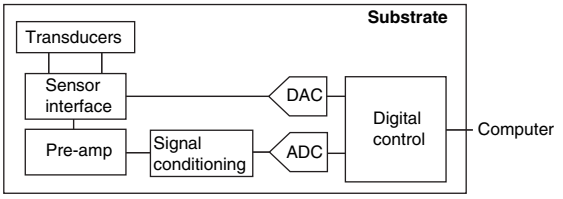

Figure 22 Block diagram of a generic active chemical sensor microsystem.

2.12.5.1.2 Digital-to-analog converter

Voltammetric sensors require a stimulus signal to induce the reduction or the oxidation of a chemical species. These signals can be generated using specialized analog circuits such as triangle wave generators or pulse generators, but a DAC is more versatile in that it can produce any arbitrary waveform such as the complex stimulus signals required by SWV and sinusoidal AC voltammetry (Kissinger *et al.* 1996). A DAC might also be used to generate a calibration or offset cancellation signal. There are many different DAC architectures and the best choice for a given design depends on the application. The output range, resolution, linearity, and power dissipation of the DAC are of primary concern. The glitch time and glitch amplitude as the DAC switches codes is an equally important specification in chemical sensor applications. It is desirable to have a continuous stimulus signal. Fortunately, the low-bandwidth nature of many chemical sensors helps filter glitches in the output of the DAC. The interested reader is directed to Razavi (1995) for a discussion of performance metrics and an analysis of design trade-offs in DACs.

2.12.5.2 Sensor Interface Circuits

The chemical sensor generally dictates which type of interface circuit is used. The following sections detail a variety of sensor interface circuits currently used in modern sensors. The following is not meant to be an exhaustive list.

2.12.5.2.1 Ion-selective electrodes

ISEs are high-output-impedance devices that require high-input-impedance circuits in order to avoid drawing current through the ISE, as even small currents will drive the ISE away from equilibrium. Consequently, the output voltage of an ISE needs to be buffered, which provides an impedance transformation transitioning the signal from a high-impedance to a low-impedance signal. This buffering is commonly accomplished with a CMOS op-amp that uses the gate of a MOSFET as the input terminal

of the amplifier and therefore has an almost infinite input impedance (Gray *et al.* 1993). Nonideal leakage currents through the gate, source, and drain connections of the input transistor, however, must be carefully analyzed to ensure minimal leakage current. Compounding the problem is the fact that gate leakage currents are increasing as process technologies scale (Henson *et al.* 2000).

Two op-amp configurations provide the large input impedance necessary for ISE applications. These two architectures, the unity-gain configuration and the noninverting gain configuration, are shown in **Figure 23(a)** and **23(b)**, respectively. The noninverting gain configuration can be used in applications requiring immediate signal amplification while the unity-gain configuration can be used as a simple buffer. The ISE's output voltage must be referenced to the potential of the solution, which can be obtained from a reference electrode. It is usually advantageous to ground the solution. This can be done through the reference electrode, or the physical connection to ground can be provided through some other solution contact and the reference electrode can be used to measure the solution potential. If, for various reasons, the solution cannot be grounded, an instrumentation amplifier (**Figure 23(c)**) can be used to reject the signal common to both the ISE and the reference electrode. One must ensure, however, that the common-mode level of both signals is within the common-mode range of the amplifier.

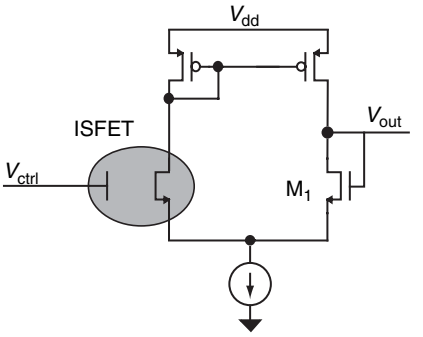

Figure 24 Simplified schematic of a readout circuit for ion-sensitive field effect transistors (ISFETs). (Source: Martin S M 2005 CMOS-integrated liquid chemical microdetection systems. Ph.D. thesis, University of Michigan.)

2.12.5.2.2 Ion-selective field effect transistors

Under a constant gate bias voltage, a change in concentration of analyte will modulate the current in an ISFET. Lauwers *et al.* (2001) provide a detailed schematic of an ISFET interface circuit. **Figure 24** shows a simplified interface circuit for an ISFET. The circuit operates by steering more or less current into the output node, depending on the ISFET's current conducting capability. V_{ctrl} can be set during operation by the DAC to reduce the offset errors presented by the difference in the nominal current-carrying capability of the ISFET and the transistor, M1. ISFETs are more susceptible to changes in operating point, temperature, and charge distribution than are the purely electronic transistors. Consequently, the offset voltage in this circuit is more difficult to eliminate than in the op-amps used with ISEs, and therefore, more sophisticated offset correcting techniques (Razavi and Wooley 1992) are needed for ISFET implementations.

2.12.5.2.3 Voltammetric sensors

Compared to the other types of electroanalytical chemical sensors, voltammetric sensors have the most complicated interface. A specialized circuit, known as a potentiostat, was developed to interface to voltammetric sensors. The standard potentiostat (Bard and Faulkner 2000) is shown in **Figure 25** and functions as follows: The potentiostat ensures that the voltage across the reference and working

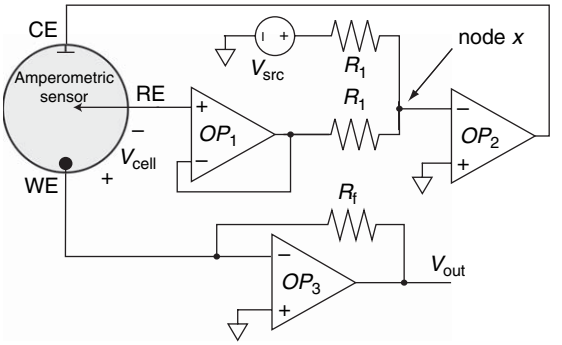

Figure 25 A potentiostat for readout and control of voltammetric sensors. (Source: Martin S M 2005 CMOS-integrated liquid chemical microdetection systems. Ph.D. thesis, University of Michigan.)

electrodes, V_{cell}, tracks an applied source voltage, V_{src}, under varying current-loading conditions. The negative feedback around op-amp OP_3 creates a virtual ground at the working electrode. Thus, V_{cell} is given by the following equation:

$$V_{cell} = -V_{RE} \quad [17]$$

The potential of the reference electrode is buffered by OP_1 to ensure that no current is drawn through the reference electrode. The negative feedback around OP_2 (which is connected via the voltammetric cell) forces node x to ground. The voltage seen at node x is one-half of the sum of V_{src} and V_{RE}. It follows that node x is equal to zero (ground) only when $V_{src} = -V_{RE}$ or by eqn [17] when $V_{src} = -V_{cell}$. Thus, the negative feedback of the potentiostat ensures that V_{cell} tracks V_{src}.

The other function of the potentiostat is to amplify the sensor's faradaic current. This is accomplished with OP_3. The current of the sensor flows through R_f (which is referenced to virtual ground) to provide an amplified current-to-voltage conversion such that:

$$V_{out} = -I_f R_f \quad [18]$$

Many variations on the standard potentiostat have been published. Wei and Lin (1992) demonstrated a chopper-stabilized potentiostat to improve DC offset. Kakerow *et al.* (1995) used switch-capacitor techniques to improve the measurement accuracy. Martin *et al.* (2005a) implemented a pseudo-differential potentiostat to enable real-time subtractive stripping voltammetry, and demonstrated a fully differential potentiostat (Martin *et al.* 2004b) that allowed potentiostats to operate in low-voltage processes. Narula and Harris (2004) demonstrated a potentiostat that enhanced the dynamic range of chemical sensors in low-voltage processes by dynamically translating the sensor signals into time-encoded values. Bandyopadhyay *et al.* (2002) implemented a distributed potentiostat system for neural applications.

Of critical importance in the design of a potentiostat is the noise performance of the signal amplification path. The SNR of a voltammetric sensor increases as the area of the electrode decreases, but the magnitude of the signal decreases as the electrode area decreases (Bard and Faulkner 2000). The electronic readout, however, also introduces noise into the signal. In fact, for microelectrodes, the electronic noise typically dominates other noise sources, as shown in **Figure 26** (Martin 2005). The graph depicts the total output noise of a voltammetric sensor and the current-to-voltage (or transimpedance) gain stage of the potentiostat for a SWV experiment. The data reveal that for typical ranges of electronic noise, the total system noise is relatively flat except when transimpedance amplifiers with gains approximately 10^5 or greater are used. This implies that the sensor noise is about five decades smaller than the electronic noise. Thus, in most scenarios, the electronic noise will dictate the sensor parameters. In an electronic noise-limited regime, an actual optimal electrode area can be found, as shown in **Figure 27** (Martin 2005). Clearly, as electronic noise is decreased, the optimal sensor area decreases and more devices can be fabricated on a single substrate. The bulk of the electronic noise originates in the op-amp, OP_3. The noise performance of this op-amp must be optimized within the context of the other design constraints. Section 2.12.5.5 describes op-amp optimization for chemical sensor applications.

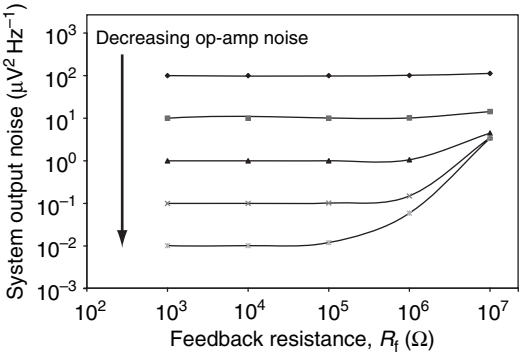

Figure 26 Total output noise of an active chemical sensor with various current-to-voltage gain settings obtained by varying the size of the feedback resistor. (Source: Martin S M 2005 CMOS-integrated liquid chemical microdetection systems. Ph.D. thesis, University of Michigan.)

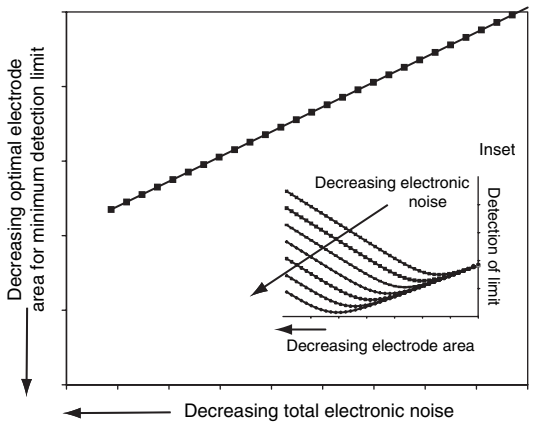

Figure 27 Optimal electrode area of a chemical sensor versus the total electronic noise in the system. (*Inset*) Detection limit of an active sensors versus electrode area and noise used to find the optimal electrode area. (Source: Martin S M 2005 CMOS-integrated liquid chemical microdetection systems. Ph.D. thesis, University of Michigan.)

2.12.5.3 Preamplifier and Signal Conditioning

If the sensor interface circuit does not provide a gain stage, then a preamplifier can be included to raise the signal amplitude. The preamplifier is often followed by a programmable gain amplifier (PGA). The PGA is advantageous in that the dynamic range of the sensor's signal might be so great that a high-gain amplifier would saturate under certain conditions, or a low-gain amplifier might not sufficiently amplify the signal to utilize the full dynamic range of the subsequent ADC. Low-pass or band-pass filters are also commonly used to limit the bandwidth of the signal and to improve its SNR. The signal must also be filtered before it is sampled with an ADC to prevent aliasing due to high-frequency components. Passive filters generally exhibit lower noise performance than do active filters, but some signal attenuation can occur and circuit loading must be carefully analyzed. A single-ended differential converter might also be included in the signal conditioning section as many modern ADC architectures use a differential input stage.

2.12.5.4 Analog-to-Digital Converter

Like DACs, ADCs come in many varieties and the proper ADC architecture often depends on the application of the sensing system. Since many analytical applications demand high precision but are low-bandwidth measurements, integrating ADCs (Breten *et al.* 2000, Reay *et al.* 1994), successive-approximation ADCs (Ryan *et al.* 1995), and oversampled ADCs (Kraver *et al.* 2001) are typical choices for chemical sensing. Important parameters to consider when choosing an ADC architecture include power, area, effective resolution, linearity, and sampling rate. The intricacies of ADCs are well beyond the scope of this work and the reader is referred to Rabii and Wooley (1999) and Razavi (1995) for more details.

2.12.5.5 Operational Amplifiers

Op-amps are the basic building blocks in most of the circuits previously described. The design of op-amps is more than adequately covered in numerous texts on the subject (Gray *et al.* 1993, Johns and Martin 1997). This section highlights some important op-amp parameters with respect to chemical sensing. Many transducers utilize op-amps in unity-gain and noninverting gain configurations to buffer signals. The common-mode range of the op-amp is an important parameter in these situations, as the inputs of the op-amp track the input signal, as opposed to being forced to a virtual ground, as in an inverting gain configuration. Rail-to-rail input op-amps are a common choice for these configurations. The charging currents that occur in voltammetric sensors have the potential to draw a significant current from the op-amp's output. Accordingly, the maximum output current and the slew rate of an op-amp become important. Fortunately, the charging currents scale with the area of the electrode, and the output current of the op-amp is less important for small electrodes. For precision applications, op-amps with high open-loop gains are necessary. The equation for the gain of a unity-gain buffer is given by the following equation:

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{A}{1+A} \qquad [19]$$

where A is the open-loop gain of the op-amp. Clearly, a finite open-loop gain will cause the buffer's gain to be <1.
