When optimizing the detection limit of the sensor, the noise of the op-amp plays a critical role. At low frequencies where chemical sensors typically operate, the dominant noise source is the flicker noise. Flicker noise is inversely proportional to frequency and is often referred to as $1/f$ noise. **Figure 28** shows the measured noise spectral density of an op-amp used in the potentiostat presented in Martin *et al.* (2005a). The strong $1/f$ dependency of the noise is evident from the data. Flicker noise is inversely proportional to transistor

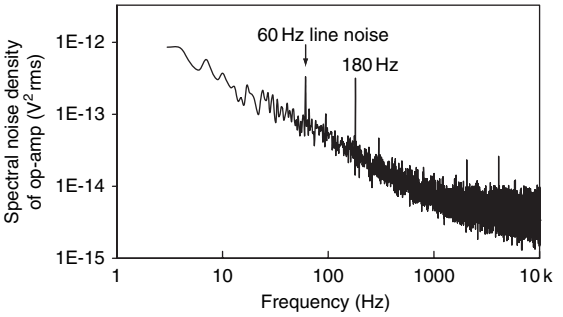

Figure 28 The noise spectral density of a complementary metal oxide semiconductor (CMOS) op-amp over the frequencies of interest in most chemical sensing applications. (Source: Martin S M 2005 CMOS-integrated liquid chemical microdetection systems. Ph.D. thesis, University of Michigan.)

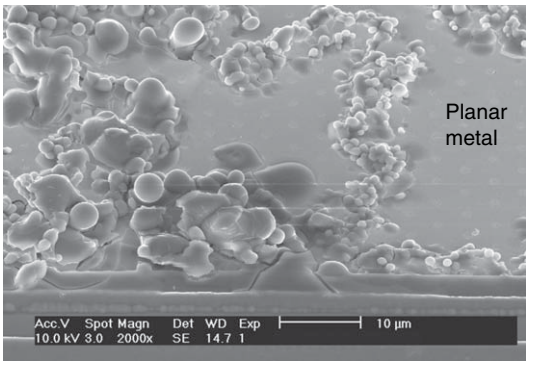

Figure 29 Scanning electron micrograph (SEM) of the surface of a platinum film over an aluminum film after heating, showing the expansion of the metals.

size and bias current. Thus, flicker noise can be reduced by using large input transistors and large bias currents, but the noise performance of an op-amp must be traded off with other design parameters such as device area, power dissipation, and input capacitance.

2.12.5.6 Active Sensor Post-CMOS Fabrication

One method of fabricating active chemical sensors is to postprocess (via thin-film fabrication) the necessary sensor layers on the same silicon substrate as the CMOS electronics. This forces the chemically sensitive layers to be postprocessed after the initial CMOS fabrication is complete and requires that the additional processing steps do not adversely affect the underlying electronics. This method generally allows for the smallest possible device and the shortest interconnect between the electronics and the sensors. Post-CMOS fabrication can be economical as hundreds of devices can be batch-fabricated on a single silicon wafer, but yield will degrade as the fabrication process grows more complex. The fabrication methodologies for many passive sensors can be amenable to post-CMOS fabrication. There are, however, certain aspects of the fabrication process that must be carefully designed to ensure a functional and long-lived device.

In commercially available CMOS processes, the top-level metallization is typically aluminum. The first desired metal in sensor fabrication can be platinum or gold or a similar metal. Unfortunately, aluminum and platinum (and similar metals) are incompatible. At standard fabrication temperatures, the metals interdiffuse and expand in volume (Hwan *et al.* 1998). The expansion (shown in **Figure 29**) causes the normally planar metal to bubble, often fracturing the passivation layer and destroying the device. While some have successfully bypassed this problem by substituting a compatible metal in the place of aluminum during electronics fabrication (Schienle *et al.* 2004), this can alter the performance of the electronics and requires a custom fabrication process for the electronics. An alternative, which continues to use foundry-standard fabrication methods of electronics, is to deposit a metal compatible to both aluminum and platinum as an intermediate step. Titanium tungsten (TiW) is one possible choice, but was found to be incompatible due to film stress by at least one researcher (Strong 2004). Titanium nitride (TiN) is another suitable diffusion barrier for these two metals (Hwan *et al.* 1998).

The passivation layer that is used to protect the electronics, the sensor interconnect layers, and the sensitive substrate from the liquid under test is also important. Many materials have been investigated for this purpose, including thermally grown silicon dioxide and silicon nitride; deposited films such as plasma-enhanced chemical vapor deposited (PECVD) silicon dioxide, silicon nitride, and parylene, and spun-on films such as polyimide and SU-8 (Martin *et al.* 2005b, Nolan and Kounaves 1998, Schmitt *et al.* 1999, Sudakov-Boreysha *et al.* 2004). The thermally grown films are typically the best choices for passivation, but the high temperatures used during their processing (1000°C) are incompatible with the metals used during the CMOS electronics fabrication. Concerns with the other films include adhesion to the substrate, solution uptake, and pinholing in the film. Additionally, most of the problems with these films are exacerbated around nonplanar surface features over metals where stress in the film may induce additional fissures

(Schmitt *et al.* 1999). Reducing surface features via etchbacks or chemical mechanical polishing (CMP) may be necessary in applications where extremely long-use life is required. Additionally, if the active sensor is to be used as a biomedical implant, the coating material must be biologically compatible.

Adhesion of the sensor layers can also be a problem. In most thin-film processing steps where a metal is deposited on a substrate, an adhesion-promoting metal (such as titanium) is first deposited to ensure good mechanical contact. Sometimes, this adhesion promoter (along with the desired electrode material) might have intimate contact with the solution under test. Standard adhesion promoters can be incompatible with the solution, and more exotic materials must be used (Strong 2004).

The openings through the passivation layer to the sensors or from one interconnect layer to another are generally performed using dry etching techniques such as reactive ion etching (RIE). In the RIE steps, charged particles are accelerated toward the surface of the chip and can charge the gates of the CMOS transistors. An excessive charge buildup can destroy the transistor. This phenomenon (along with others) can be classified as process-induced damage (PID). One solution is to use electrostatic discharge (ESD) protection circuits fabricated as part of the electronics to limit the amount of PID that occurs. Care must be taken to properly size these devices as they present a leakage path for the sensor's signals, and the noise from this leakage may be so large in some cases as to completely mask the desired signal.

As an example of a post-CMOS process, **Figure 30** shows the cross section of an active ISE (Martin *et al.* 2005b). The process methodology used to fabricate this device was based on a four-mask, passive sensor process as outlined in Poplawski *et al.* (1991) and Strong *et al.* (2000). Platinum (Pt), gold (Au), and silver (Ag) layers serve as sensor electrodes. A PECVD silicon nitride layer (Si_xN_y) serves as the passivation layer. High aspect ratio SU-8 rings serve as dams for stopping the flow of the bond wire encapsulant unto the surface of the sensor and can alternatively be used to contain the polymer membranes of specific sensors (Hower and Brown 2004). The wirebonds are sealed in a two-part process. They are first coated with MED4211 medical-grade silicone silastic (NuSil Silicon Technology, Santa Barbara, CA) and then with RTV 3140 silicone (Dow Chemical, Midland, MI). An in-depth description of the fabrication is given in Martin *et al.* (2005b). The process is capable of producing many different sensors including voltammetric, potentiometric, and temperature sensors.

2.12.5.7 Multichip Modules

A second approach to integrating electronics and chemical sensors is the multichip module (MCM) approach. In an MCM, a small silicon, ceramic, or laminate substrate is used as a host platform onto which other dies are attached via wire bonding, flip chip bonding, or wafer bonding (Wolffenbuttel 1996). In MCMs, the overall device dimensions remain small and the electronics and sensors can be fabricated in separate processes, each tailored to their specific needs. Defective devices can be sorted prior to integration onto the MCM to ensure that only good devices are packaged. Manufacturing the MCM, however, is often a serial process and can be more costly than integration using batch techniques. Sudakov-Boreysha

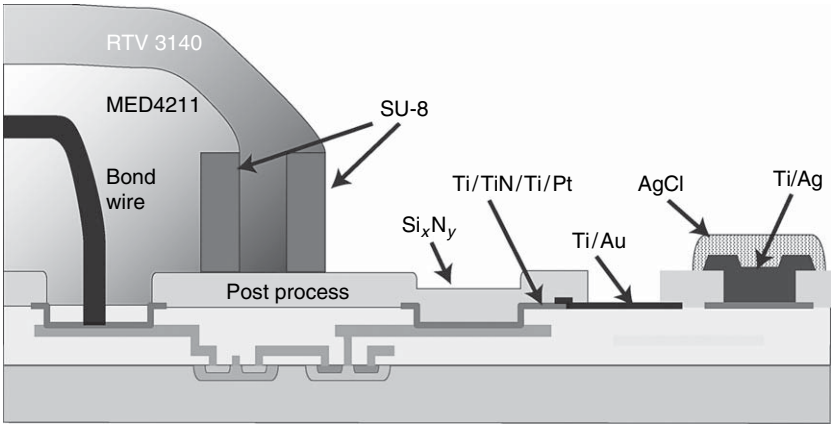

Figure 30 Cross section of a complementary metal oxide semiconductor (CMOS)-integrated active chemical sensor. (Source: Martin S M 2005 CMOS-integrated liquid chemical microdetection systems. Ph.D. thesis, University of Michigan.)

et al. (2004) developed an MCM chemical sensing system with ISFETs using flip chip bonding techniques. Implantable active sensors have also been demonstrated using MCM technology (Meyer *et al.* 2001). The interested reader is directed to Tummala (1992) for a tutorial on MCM devices and technologies. To date, few chemical sensing systems have been fabricated using MCM techniques, but it is expected that more systems will benefit from this approach in the future.

2.12.6 Conclusion

In conclusion, the technology necessary to develop and manufacture microsystems incorporating miniature liquid chemical sensors is rapidly maturing. This chapter has presented some of the theory behind the operation of electrochemical sensors as well as a basic description of the techniques used in fabricating electrochemical sensors. The field of microelectrochemical sensors has already seen great advancements over the last several decades, and it will likely see many more in the coming decades as new products appear on the market incorporating sensors based on these technologies.

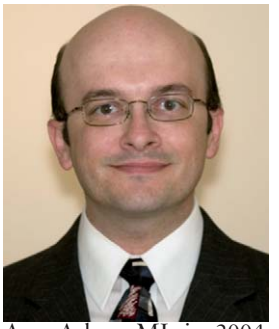
Biographies

Robert K. Franklin received a BS degree in Computer Engineering from Brigham Young University in 2002 and an MS degree in Electrical Engineering from the University of Michigan in 2006. During his undergraduate program, he was the recipient of the ORCA scholarship for excellence in undergraduate research at BYU and developed an automated network intrusion detection system using XILINX FPGA's. He entered the University of Michigan in September 2002 to pursue a Ph.D. in Electrical Engineering. He is currently an NSF fellow working on microelectrode probe arrays for neurochemical detection *in vivo*.

Steven M. Martin received a BS degree from the University of Florida in 1999. He received his MS and Ph.D. from the University of Michigan in 2001 and 2005, respectively. He has conducted research in the areas of high-performance interface circuits for chemical sensors, ultrasound devices, and laser detection systems. He currently works as an analog engineer for Intel Corporation designing multigigahertz I/O circuits. Dr. Martin holds two US patents and has several others pending pertaining to his work on sensors and sensor interfaces.



Timothy D. Strong received a BS degree in Electrical Engineering from Michigan Technological University, Houghton, MI, in 1992, a MS degree in 1997, and a Ph.D. in Electrical Engineering from the University of Michigan, Ann Arbor, MI, in 2004. He is currently employed in research and development at Sensicore, Inc., Ann Arbor, MI, a company developing water quality monitoring systems. His research interests include amperometric and potentiometric chemical sensing, and silicon processing and fabrication.

Richard B. Brown received BS and MS degrees in Electrical Engineering from Brigham Young University, Provo, UT, in 1976 and a Ph.D. degree in Electrical Engineering (solid-state sensors) from the University of Utah, Salt Lake City, UT, in 1985.

From 1976 to 1981, he was VP of Engineering at Holman Industries, Oakdale, CA, and Manager of Computer Development at Cardinal Industries, Webb City, MO. In 1985, he joined the Electrical Engineering and Computer Science Department, University of Michigan, Ann Arbor, MI, where he served as associate chair and interim chair. In June 2004, he was appointed 11th Dean of the College of Engineering, University of Utah. He is Professor in the School of Computing and Department of Electrical and Computer Engineering. He has conducted major research projects in the areas of solid-state sensors, mixed-signal circuits, GaAs and silicon-on-insulator circuits, and high-performance and low-power microprocessors.

Professor Brown is Chairman of the NSF MOSIS Advisory Council for Education. He was Chair of the 1997 Conference on Advanced Research in VLSI and the 2001 Microelectronic System Education Conference. He has served as Guest Editor of the *IEEE Journal of Solid-State Circuits* and *Proceedings of the IEEE* and as Associate Editor of *IEEE Transactions on VLSI Systems*.

2.13.1 Introduction

2.13.1.1 Microfluidics

The history of microfluidics dates back to the early 1950s when efforts to dispense small amounts of liquids in the nano- and subnanoliter range were made for providing the basics of today's ink-jet technology (Le 1998). In terms of fluid propulsion within microchannels of submillimeters cross-section, the year 1979 set a milestone when a miniaturized gas chromatograph (GC) was realized on a silicon wafer (Terry *et al.* 1979). The first high-pressure liquid chromatography (HPLC) column device, fabricated using Si-Pyrex technology, was published by Manz *et al.* (1990b). By the end of the 1980s the first microvalves (Shoji *et al.* 1988) and micropumps (Van Lintel *et al.* 1988) based on silicon micromachining were also presented. All these examples represent microfluidic systems since they enable the precise control of the decreasing fluid volumes on the one hand and the miniaturization of the size of a fluid handling system on the other hand.

Another important aspect of microfluidics is the exploitation of effects and phenomena that can be utilized only in microdimensions. Smaller channel dimensions drastically increase the surface-to-volume ratio and thus surface-related phenomena like laminar flow, capillarity, fast thermal response, and electrokinetics gain influence. This can be used in microfluidic systems to enhance the performance of analytical procedures. Manz *et al.* (1990a) also proposed the concept of miniaturized total chemical analysis systems (TAS) based on the unique conditions in the microdomain. Today this approach is also known as micro total analysis systems (μTAS) or laboratories on a chip (lab-on-a-chip) as proposed by Harrison *et al.* (1992).

Following this μTAS or lab-on-a-chip approach, the first applications that emerged in the field of analytical chemistry were based on the electro-osmotic flow (EOF) to pump liquids into small microcapillaries and on electrophoretic separation (EP) to distinguish sample components (Effenhauser *et al.* 1993, Harrison *et al.* 1992, 1993, Manz *et al.* 1992). These developments in the early 1990s drastically increased the academic and commercial interest in microfluidic technologies. This trend continues to the present day, as described in a recent comment on the proliferation of microfluidics in literature and intellectual property, which claims that 581 of 770 microelectromechanical systems (MEMS)-related papers published in 2003 dealt with microfluidics (Kamholz 2004).

So down to the present day manifold lab-on-a-chip systems have been developed for diverse applications, e.g., for DNA analysis (Burns *et al.* 1998),

DNA amplification (polymerase chain reaction, PCR) (deMello 2003, Kopp *et al.* 1998), proteomics (Lion *et al.* 2003, Marko-Varga *et al.* 2003), sample pretreatment (de Mello and Beard 2003). Recent general reviews on the whole field of lab-on-a-chip systems can be found in Auroux *et al.* (2002), Reyes *et al.* (2002), and Vilkner *et al.* (2004). The enormous impact of microfluidic lab-on-a-chip technologies also becomes obvious by the large number of recently published books. They either cover the whole field of microfluidics (Li 2006, Nguyen and Wereley 2002) or focus on the engineering (Geschke *et al.* 2004) or applications of microfluidic systems (Andersson and van den Berg 2004, Oosterbroek and van den Berg 2003, Tay 2002, Urban 2006). Also journals exclusively dedicated to the field of micro- and nanofluidics (*Microfluidics and Nanofluidics*, Springer) or lab-on-a-chip systems (*Lab on a Chip*, Royal Society of Chemistry) have been published recently.

2.13.1.2 Microfluidics – An Enabling Technology

From a more business-related point of view, it can be stated that nowadays most MEMS-related technology roadmaps and market studies point out the significant technological and scientific impact that microfluidics will have on various industries, especially the life sciences. A dedicated microfluidics roadmap was prepared by Ducrée and Zengerle (2004). In this study the economic development related to microfluidics technologies for the life sciences has been estimated and important market drivers and road blocks have been pinpointed.

Regarding the economic impact of microfluidics, the study anticipates an overall growth rate of more than 30% per annum for microfluidic technologies and products in the life sciences. Drug discovery, medical diagnostics, and therapeutic devices represent the most promising fields. The overall global market of microfluidics in the life sciences has been estimated to be worth approximately 500 million euros in 2002, increasing with an assumed annual growth rate of 19% to 1.4 billion euros in 2008.

Besides the economic impact of microfluidics, technological trends have also been clearly identified in the roadmap. Amongst those the most relevant is the need for microfluidic platforms equipped with a basic set of validated fluidic base operations to arrive rapidly at application-specific microfluidic systems. This system-oriented platform concept contrasts the frequent approaches in which components such as pumps or valves have been optimized at an individual level and assembled afterward.

2.13.1.3 The Need for Microfluidic Platforms

Why are microfluidic platforms needed? As described in Section 2.13.1.1 the impact of microfluidic technologies in the academic world has dramatically increased during the last few years. This is quite amazing since microfluidics is no independent product consumers want to buy. Microfluidics should be merely considered as a toolbox, which is needed to develop innovative new products in such disparate fields as medical, pharmaceutical, and analytical applications. As a consequence, the most important customer for microfluidic know-how and technologies is the research community itself, which develops new products and solutions in the different application areas such as the biotechnology, diagnostics, medical, or pharmaceutical industry.

During the last two decades, thousands of researchers have spent a lot of time developing new microfluidic components or exploring the basic microfluidic operations such as fluid transport, fluid metering, fluid mixing, valving or concentration, and separation of molecules within miniaturized quantities of fluids. Today hundreds of different types of micropumps have been fabricated (Laser and Santiago 2004), hundreds of different types of mixers and hundreds of different types of microvalves are known, and almost no standards are defined in terms of interconnections. It seems to be the right time to raise the question of whether we really need more of those components? On the basis of our experience in the lab-on-a-chip field, a component-based microfluidic approach is much too slow and the R&D effort is much too expensive to explore the huge potential of different applications. In addition, the best performance you can get out of such a component-oriented solution will be far behind what you can get in an integrated system approach, or in other words in a microfluidic platform approach. Therefore we think that the described practice of assembling discrete components such as valves and pumps, at least in the field of lab-on-a-chip applications, belongs to the past and we do not expect it to continue in the future. In our view the research community really needs validated and easy-to-operate microfluidic platforms. They have to offer an adequate number of microfluidic operations that can be easily

combined to build application-specific microfluidic systems. In addition these systems should be fabricated using a standardized cost-efficient technology.

2.13.1.4 Discrete Solutions for Unique Technical Challenges

Before pointing out the advantages of the microfluidic platform concept, we describe the opposite: two examples of application-specific integrated systems, which represent unique engineering solutions for unique technical problems. The electronic fountain pen (Waibel *et al.* 2003) as depicted in **Figure 1** is a good example of such a discrete microfluidic solution. It can be regarded as the first fully functional, highly integrated, miniaturized, and self-sustaining microdosage system of its kind operating under real-world conditions. The main components are a liquid level sensor, a microvalve, and a bubble- and particle-tolerant fluidic system. The pen is optimized with respect to minimum energy consumption. It contains a programmable ASIC and is powered by two standard watch batteries ensuring operation over a period of 2 years under standard conditions.

The oral drug delivery system (**Figure 2**), currently under development at HSG-IMIT, is a similar example (Goettsche and Wolff 2006). It has the size of two buccal teeth and will be integrated into the human denture. It consists of a drug reservoir capable of incorporating a solid pill, an osmotic pump, and a flow sensor. The refillable system is loaded by a solid pill and is designed to deliver liquid drug over a period of 2 weeks at rather harsh ambient conditions

(mechanical loads, wide temperature range, and contact with any kind of food) inside the human mouth.

Both microfluidic systems perfectly fulfill the requirements for their specific applications. However, for any other application in the field of microdosage or more general in the field of microfluidics, the specific know-how from developing such a system is only of very limited value and every development of this kind always starts from the scratch again. This causes significant costs and time at a high economic risk. Although we expect this kind of development to make sense for a few selected applications in diverse fields of applications in the future also, it is quite clear that this approach will not succeed for lab-on-a-chip systems or the diagnostic applications that are dealt with in this chapter.

2.13.1.5 What Is a Microfluidic Platform?

Very similar to the ASIC industry in microelectronics, which provides validated elements and processes to make electronic circuits, a dedicated microfluidic platform comprises a reduced set of validated microfluidic elements. These elements are capable of performing the basic fluidic unit operations required in a given application area. Such basic fluidic unit operations are, for example, fluid transport, fluid metering, fluid mixing, valving, and separation or concentration of molecules or particles. The collection of fluidic unit operations needed for diagnostic applications can have only little overlap with the collection needed for pharmaceutical applications or for applications in microreaction technology. In some cases detection methods also belong to the basic set of microfluidic

Table 1 Common features of microfluidic platforms

Microfluidic operations	*Fabrication technology*
Validated elements for basic microfluidic unit operations such as • Fluid transport • Fluid metering • Fluid valving • Fluid mixing • Separation • Concentration • Detection • ...	Validated manufacturing technology for the whole set of fluidic elements (prototyping and mass fabrication) Seamless integration of different elements • Ideally in a monolithic way • Or by a well-defined easy packaging technique

operations, and in other cases this is not the case (**Table 1**). Nevertheless, in all cases the user of a platform should be capable of readily combining the elements within a given platform in order to implement an assay for diagnostic applications or to screen for new compounds in pharmaceutical applications. Often, an efficient development is intimately linked to the availability of (standard) test setups and simulation tools.

More important than providing a totally complete set of fluidic unit operations in a platform is the fact that all elements have to be amenable to a well-established fabrication technology. Furthermore all elements or modules of a platform have to be connectible, ideally in a monolithically integrated way or at least by a well-defined, ready-to-use interconnection and packaging process. If a platform allows a seamless and simple integration of different fluidic elements in a monolithic way, for example, without sophisticated additional packaging techniques, this provides a significant advantage compared to other platforms. Thus speaking about microfluidic platforms also involves at least one validated fabrication technology to realize complete systems out of the elements. This results in a definition of a platform as follows.

A microfluidic platform allows to perform a set of fluidic unit operations that are enabled by a set of fluidic elements, which are designed for easy combination with a well-defined (and low-cost) fabrication technology. The platform allows to implement and fabricate different application-specific solutions in an easy and flexible way.

2.13.1.6 Overview of the Following Chapters

When comparing microfluidic platforms with the microelectronics industry, the question of whether we really need a diverse set of different microfluidic platforms arises. The coexistence of different platforms and their specific fabrication technologies could be regarded as a drawback since R&D efforts go in many directions and cannot be focused exclusively on one technology (as is complementary metal oxide semiconductor (CMOS) in microelectronics). On the other hand, the diversity of approaches and technologies can be considered as an advantage for their successful adoption in different application fields. Owing to the diversity, specific advantages of certain platforms are likely to succeed in different application areas. It is, however, essential that a specific platform provides all of the characteristic features given in **Table 1**.

This chapter is intended to give an overview of microfluidic platforms that have been developed until today. We will thereby focus only on platforms for lab-on-a-chip application, being aware that there are also other possible fields of applications for microfluidic platforms such as microprocess engineering or microdosage systems. However, in the field of lab-on-a-chip systems also, we cannot cover all microfluidic platforms, which are known from literature. Prominent examples of platforms that will not be discussed here are certainly the electrokinetic platform (EOF, EP), the microarray platform, and the microwell plate technology platform. These platforms, however, are already well described in many scientific papers and books. It is, furthermore, not intended to assess the different platforms by their value to the industry or to the research community.

As is evident in the introduction, the scope of this chapter is not to describe single microfluidic components. For detailed reviews on single components such as micropumps (Gravesen *et al.* 1993, Laser and Santiago 2004, Shoji and Esashi 1994, Woias 2005), valves (Oh and Ahn 2006), mixers (Hessel *et al.* 2005, Nguyen and Wu 2005), microfluidic technologies in general (Squires and Quake 2005, Stone *et al.* 2004), or

simulation techniques for the design of lab-on-a-chip systems (Erickson 2005) we also refer to the published work.

In the following, each microfluidic platform is described in the same way. First, we motivate the platform approach and give a short introduction on the basic setup and functional principle. Then, the main unit operations realized on the platform and an application example based on their selection are presented. Finally, each section closes with a discussion on the strength and the challenges of the platform as we can see them today.

2.13.2 Capillary-driven Test Strips (Lateral Flow Assays)

2.13.2.1 Introduction

The capillary-driven test strip platform is the state of the art in point-of-care diagnostics, with billions of units that are produced in an extremely cheap manner. It is amazing that within the lab-on-a-chip or microfluidics community, not very much is known about this easiest way to perform assays on such an easy to handle widely used platform (e.g., diabetes testing, pregnancy testing).

The first test strip is certainly the indicator paper for pH measurement, which is also a representative for the most simple assay on the capillary-driven test strip platform. It consists only of one single fleece with an integrated colorimetric reagent (**Table 2**). The sample liquid is transported into the fleece of the test strip by capillary forces and a color change, depending on the pH value of the sample liquid, occurs. This color change is initiated by a reaction between the sample and the reactant. Starting from that most simple point of assay format, more complex configurations with multiple reagents or even several fleeces enable the implementation of more complex assays like immunoassays.

The so-called lateral flow assays are well known in the diagnostic field since the 1960s. Although this can be regarded as the most successful microfluidic platform for lab-on-a-chip applications in terms of applications and commercialized products, hardly any publication from a microfluidic point of view exists.

The possibility of performing an automated on-site measurement, using a cheap and small disposable test strip, combined with the simple actuation principle that does not need any energy supply, gives the platform a huge potential for point-of-care and patient self-testing applications. Today, millions of diabetics all over the world use these diagnostic devices to measure their glucose concentration several times per day and therewith adjust their medication.

The basic principle of the platform is the passive liquid transport via capillary forces within the capillaries of a fleece or microstructure layer. The physical background of these actuation principle is described in Section 2.13.2.1.1.

Table 2 Degrees of complexity and application examples on the capillary-driven test strip platform

	Capillary configuration		*Application examples*
Complexity ↓	Single fleece with colorimetric reactant		Indicator paper (pH measurement)
	Single fleece with multiple reactants and colorization		BSE test, TNT test
	Multiple fleeces with different zones of reactants, often cased		Pregnancy test, cardiac markers, drug test
	MEMS-based capillary channels, multiple complex reactions		Detection of up to 100 different proteins (immunoassays)

2.13.2.1.1 About capillary forces

One effect that becomes more and more important when scaling down fluidic channels is the capillary force. A capillary pressure difference

$$\Delta p_\theta = \frac{2\sigma}{r}\cos\theta \qquad [1]$$

appears across the liquid–gas interface with surface tension σ in a capillary of radius r and contact angle θ. For hydrophilic contact angles <90° (partially wetting) the pressure in the liquid phase exceeds the pressure in the gas phase, leading to a further wetting of the capillary. For hydrophobic contact angles >90° (partially nonwetting) the meniscus withdraws respectively.

An important effect when dealing with capillary-driven liquid flows is contact line pinning. It causes the sudden stop of the proceeding meniscus at edges that represent a geometrical singularity. This has to be taken into account when designing microfluidic structures on the capillary test strip platform since no additional pressure is available to overcome this stop. On the other hand, however, this mechanism can be used to control the course of capillary priming on the platform.

2.13.2.2 Unit Operations Controlled by Capillary Forces

2.13.2.2.1 Sample loading

Several methods for sample loading exist. For bigger volumes, the sample is filled into a start reservoir from where it penetrates the underlying capillaries. If the sample volumes are not sufficient, the addition of a dilution buffer is sometimes required to enhance or allow the capillary transport in the first place. The second method, especially used in patient self-testing applications, is the direct capillary filling of the strip from the sampling point. For blood diagnostic assays, for example, the test strip is directly contacted with the blood spilled out of the finger tip that has been locally pricked with a lancet before.

2.13.2.2.2 Separation

Separation steps are required for analyzing human whole blood, for example, since the red blood cells with a volume fraction >40% would interfere with the assay. As the blood passes through a separation fleece, cells are filtered from the blood (Clark *et al.* 2002). Also microfilters or membranes with a more defined pore size can be used. An exemplary immunoassay test strip is depicted in **Figure 3**. The separation fleece is placed directly underneath the start reservoir into which the blood sample is added.

2.13.2.2.3 Transport

Depending on the complexity of the test strip, liquid propulsion is accomplished via capillary forces in fleeces and/or highly precise micromachined structures (**Table 2**). Though the system gains control when using microstructures, its fabrication becomes more expensive on the other hand. Some of the essential features of both types of capillary pumping structures are given in **Table 3**. Due to these considerations, the requirements of the assay decide which propulsion method should be used and certainly the combination of these two can increase the controllability of the assay protocol while still keeping the costs low.

An important issue for liquid transport with merely capillary-driven systems is the transport balance. Since the maximum volume of labeled sample should pass the detection zone in order to have an optimum sensitivity, certain arrangements have to be made. The volume of the transport zones, for example, should be kept small, so that only a small fraction

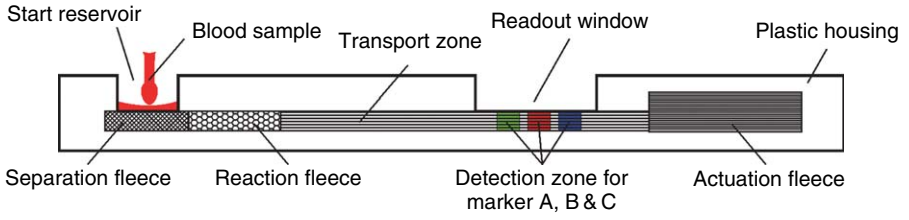

Figure 3 Simplified cross-section of a typical capillary-driven test strip set-up for an immunoassay. The blood sample is applied at the start reservoir and passes through the separation fleece where the red cells are separated from the plasma. The plasma enters a reaction fleece containing labeling reagents comprising fluorescent antibodies that bind to the proteins in the blood plasma. The sample is then transported through the detection zone with immobilized complementary antibodies to the markers under investigation (A, B, and C). The actuation fleece at the end of the strip ensures that the whole liquid volume is sucked through by the capillary liquid propulsion through all fleeces. All fleeces are typically packed into a low-cost plastic housing.

Table 3 Comparison of fleeces and microstructures for capillary propulsion in test strips

Properties	*Fleeces*	*Microstructures*
Cost	Cheap	Expensive
Availability	Good (various types)	Bad (must be created)
Realization of filtering	Easy	Elaborate
Flow guiding	3D structures	2D structures
Control of flow direction	Bad (isotropic, toward unsaturated fleece)	Good (follows structure)
Flow prediction	Not exact	Good

of the initial sample volume remains within that dead volume. Another measure for a good volume balance is to ensure that the capillarity of the input zone (separation and labeling fleece) is lower than the capillarity of the actuation fleece, leading to a complete drainage of the sample into the actuation fleece before the liquid propulsion terminates.

A very fundamental requirement for a successful assay is that the initially added sample volume exceeds a critical minimum. Otherwise, the complete wetting of all the essential test strip zones cannot be assured and the assay fails.

2.13.2.2.4 Incubation

During an assay protocol on the capillary-driven test strip platform, the sample has to get in contact and react with several predeposited reagents. They are integrated into the fleece or microstructure of the strip during fabrication. This is mostly done by fleeces that are saturated with the reagent and dried afterward. If needed, the reactant molecules can also be covalently bound to the surface using standard immobilizing techniques like the carbodiimid (EDC)/*N*-hydroxysuccinimide (NHS) chemistry.

The setting of an appropriate incubation time for reagent dissolution is managed by different zones within the test strip, exhibiting different wetting properties. The basic principle behind this approach is depicted in Figure 4. First, the liquid primes the reaction chamber, where a dry reagent is predeposited in a pillar microstructure. This is achieved very fast due to a low contact angle of 10° only. The propagation of the liquid meniscus is then slowed down within a so-called time gate with an increased contact angle of $\theta = 80°$ and consequently a reduced capillary force. The time for the dissolution of the dry reagent is set by the length of the time gate and ends as soon as the liquid reaches the detection zone with an increased capillary pumping force ($\theta = 10°$) speeding up the flow again.

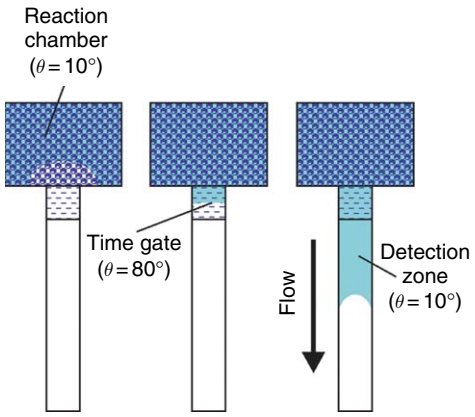

Figure 4 Schematic realization of a certain incubation time in the capillary-driven test strip platform. The liquid flow is throttled in the time gate of reduced wettability ($\theta = 80°$) thus leading to an extended period of time for reaction within the reaction chamber. Consequently, the dried reagents can be dissolved completely before the liquid proceeds along the detection zone.

2.13.2.2.5 Mixing

The dissolution of the preloaded dried reagent situated in the reaction fleece, described as an incubation step before, can also be regarded as a kind of mixing operation. A characteristic feature of the capillary test strip platform is the fact that mixing generally is purely passive and is based only on diffusion. It cannot be accelerated externally and is also one of the major drawbacks of this kind of platform. In order to keep the mixing time short, a high surface-to-volume ratio within the reaction chamber is preferred. However, the dissolution time typically still lies in the range of several minutes and thus the capillary flow through the reaction chamber has to be throttled as described before.

2.13.2.2.6 Metering

The metering of liquids is an important unit operation for quantitative assays. Within a test strip, metering is done by the defined volumes of the fleeces and

microstructures. The liquid flow stops automatically as soon as the actuation fleece (**Figure 3**) is fully wetted with liquid. This way the amount of liquid that has passed the detection zone is well defined. The only thing that has to be ensured is that the start reservoir is filled with enough liquid at the beginning of the assay, i.e., with the volume of the complete test strip (all fleeces and microstructures) and a certain reliability excess to ensure proper functioning.

2.13.2.2.7 Amplification

The results from a test strip assay are mostly read out by optical markers such as fluorescent molecules. Since the concentration of these molecules within the sample liquid is potentially small, they have to be accumulated within the detection zone. The sample volume passes through the detection zone with an adequate flow rate, ensuring the non-diffusion-limited binding of the marked sample molecules to the immobilized capture molecules in the detection zone. A remarkable fluorescent signal is obtained after a multiple of the detection zone volume has passed the immobilized molecules. This can be regarded as a microfluidic amplification unit operation.

2.13.2.2.8 Readout

The fluorescent emission of the detection zone is excited using a laser diode of corresponding wavelength. The phase-shifted (longer wavelength) fluorescent response is detected using a photodiode and an appropriate optical filter within common test strip readers. If regions of different capture molecules are immobilized within the detection zone, the test strip is moved with a stepper motor underneath the detection unit (laser diode and photodiode).

Some assays are also read out using electrochemical mechanisms. The glucose concentration of a blood sample is determined by measuring the electrical charge generated during the enzymatic oxidation of glucose to gluconic acid, for example. The test strip reader applies an external electric potential and measures the current, which is a function of the number of electrons generated.

Besides the above-described device-based readout methods, the reading of assay results with the naked eye is also possible. This is of interest for those applications where a cheap and fast readout is required. A manual readable signal is produced by binding small gold or latex particles to the detection molecule, which accumulate at the detection zone and color it. However, only clear and binary signal-generating assays such as pregnancy tests are capable of manual readout.

2.13.2.3 Application Example: The Cardiac® Reader

Cardiac markers are very important in emergency medicine. They allow a fast decision if a patient with chest pain is suffering from an acute cardiac infarction and has to be treated accordingly. Only the combination of several markers enables a clear diagnostic conclusion on whether the patient had a heart attack or not. Since this diagnostic information and the need for adequate medication should be gained as fast as possible, a lab-on-a-chip system for the point-of-care measurement is demanded.

The Cardiac Reader® from Roche (2006) is a commercial point-of-care system for the detection of four different cardiac markers (myoglobin, troponin T, D-dimer, and NT-probBNP). The test strip reader and the corresponding test strips are depicted in **Figure 5** and allow the determination of these four markers within minutes from a single blood sample. The system is used in doctor's offices or emergency rooms.

The complete test strip consists of different fleeces for liquid transport, blood separation, and readout. First, 150 µl of heparinized venous whole blood is added onto the inlet region above two

Figure 5 The Cardiac® Reader and the four different test strips (Source: Roche 2006 Basel, CH, www.roche.com, accessed 2006.)

reagents containing fleeces. Within these fleeces, two antibodies specifically bind to the antigen (e.g., troponin T protein) of the blood sample. One antibody is labeled with biotin, the other with a gold nanoparticle. After the binding step, the blood sample is transported through a separation fleece, where the cellular constituents are removed.

In the last assay step, the antigen–antibody complex is transported along a detection zone, featuring immobilized strepdavidin proteins, which bind to the biotin of the complex. Thus the protein complex is captured in the detection region, and the assay result is read out optically via a dark line generated by the accumulating gold nanoparticles. To control the assay performance, antigens are immobilized in a control region subsequently passed by the sample liquid. A successful assay run with a negative result, that is, no Troponin T within the blood sample, can be determined by a dark line arising at this control position only (Raschke 2005). The complete assay, starting from the application of the blood sample until the readout of the result, takes 8–12 min.

2.13.2.4 Strengths and Challenges of the Platform

The major strength of the capillary-driven test strip platform is certainly the robust microfluidic flow propulsion principle, relying on capillary forces only. No external energy is required, which opens up a wide field of applications especially for simple color-changing assays such as pH measurement or pregnancy tests. However, complex immunoassay protocols have also been implemented during the last few years. Therefore this special microfluidic platform is setting a benchmark in terms of costs and integrated, automated assay implementation for all microfluidic platforms discussed in this chapter.

Drawbacks of the platform certainly arise from its simplicity. Assay protocols in the capillary-driven systems follow a fixed process scheme, imprinted in the microfluidic channel design. Passive liquid propulsion by capillary forces only cannot be influenced actively once the process is started. As a consequence the exact timing of assay steps depends on variations of viscosity and surface tension of the sample. Therefore the precision of the assay result, for example, is on the order of 10%, which is not always sufficient for several future challenges in the implementation of diagnostic assays. More complex diagnostic assays also cause a larger number of process steps such as reactant dissolution. As previously described, this mixing operation cannot be accelerated in the capillary test strip platform, which leads to long assay times.

Crucial unit operations for the assay precision are metering and incubation steps whose accuracy is limited to the merely capillary-driven system. A further critical point is the long-term stability of the wetting properties inside the fleeces or the microstructures. Usually, the materials are plasma treated or coated by an additional layer to ensure the desired contact angle and thus wetting behaviors. These surface activations or coatings have to be stable at different temperatures and over a long period of time as they define the test strip lifetime.

2.13.3 Pressure-driven Systems

2.13.3.1 One Step Forward in Controllability and Complexity

Assay protocols in capillary-driven systems follow a fixed process scheme, imprinted in the microfluidic channel design. Passive liquid propulsion by capillary forces only cannot be influenced actively once the process is started. In addition the exact timing depends on variations of viscosity and surface tension of the sample, and mixing is rather slow. This certainly offers other platform technologies the chance to show up and get into the market. As an example, pressure-driven platforms enable the control of the running processes. Liquid flows can be stopped, reversed, and their flow rates and ratios can be adjusted online in order to change the course of the assay. A platform-integrated pressure source is required to make this step forward in controllability possible. So the gain of control is accompanied by an increased complexity of the system.

2.13.3.2 Unit Operations in Pressure-driven Microfluidics

2.13.3.2.1 Fluid transport (Laminar flow)

Independent from the liquid propulsion method, the pressure-driven liquid flow within microchannels has some common properties. Strictly laminar flow due to the small Reynolds numbers within the channels of small cross section in combination with the no-slip boundary condition at the channel walls lead to a parabolic velocity profile. Thus, the flow velocity depends on the position within the cross section of

the channel, i.e., long residence time near the walls and short residence time in the center of the channel.

The laminar volumetric flow rate I_v through microchannels

$$I_v = \frac{\pi}{8\eta}\frac{r^4}{l}\Delta p \qquad [2]$$

depends on the applied pressure difference Δp, length l, and radius r of the channel as well as the liquid viscosity η (law of Hagen–Poiseuille).

Different possibilities for pressure generation are described below and are also categorized as shown in **Figure 6**. A constant pressure source can be activated only once and operates autonomously afterward. This is similar to capillary systems, whereas the potential pressures and thus flow rates can be considerably higher compared with merely capillary-driven flows. In addition, liquid propulsion sustains after the whole structure is filled with liquid since no capillary pressure-generating air–liquid interface is required.

The easiest way to accomplish a pressure-driven flow by a constant pressure source is certainly using an external pressure cartridge, connected to the microfluidic chip. However, the macro- to microfluidic interfacing problem has to be solved for these off-chip solutions, which is a common problem when dealing with microfluidics (Fredrickson and Fan 2004). This fluidic interface has to be pressure tight and should not lead to a lot of additional dead volume.

Constant pressure can also be generated on the chip by integrating, e.g., a spring-loaded liquid reservoir. Again, the interfacing problem remains if the reservoir is loaded while already integrated in the chip. More simple techniques for pressure generation on the chip use, for example, thermal phase transition effects and can be switched on via a heater.

If the pressure can be switched on and off, respectively, and if its amplitude can be adjusted within a certain working range, the system gains in controllability. The actuation mechanisms used for pressure generation can be basically divided into hydraulic (liquid) and pneumatic (gas) principles. Liquid propulsion is accomplished by either applying an overpressure at the inlet (pushing of fluid) or applying an underpressure at the outlet (sucking of fluid) of a microchannel structure. Depending on the microfluidic structures as well as the application, both methods can be advantageous in terms of bubble-free priming and leak tightness.

All off-chip macropump solutions require a macro-to-micro interfacing technology, as described in the previous section, leading to a certain dead volume required for interconnection tubing. Although, the dead volume can be decreased by placing a micropump onto the microfluidic chip, a micro-to-micro interface is still needed for interconnection. This is not consistent with the ideal microfluidic platform that allows to realize all fluid unit operations in a monolithically integrated manner using the same fabrication technology. Only this way expensive and error-prone liquid interfaces can be avoided. A large number of micropumps have been presented during the last two decades (Laser and Santiago 2004, Shoji and Esashi 1994, Woias 2005). Many of these pumps are based on the combination of a displacement chamber with two active or passive microvalves. These devices are discussed in more detail in Chapter 2.09 and are not considered here.

More simple and robust pressure-generating principles, like the displacement of a membrane via a finger push or a manually operated syringe, have also been demonstrated as interesting alternatives.

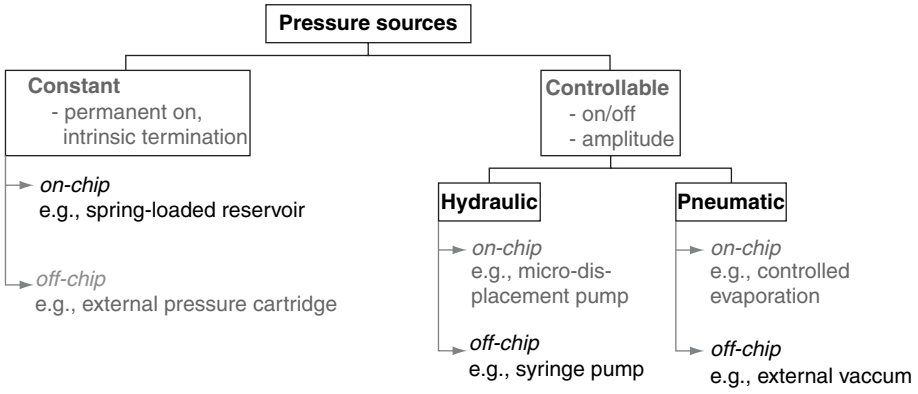

Figure 6 Different pressure sources for microfluidic platforms.

These methods are used in point-of-care testing applications, where a simple and low-energy consuming pumping principle is required. In the following, three examples of novel on-chip pumping mechanisms based on thermal effects are described.

Two nonmechanical implementations of micropumps that allow monolithic integration and that are based on the phase change of a working fluid are depicted in **Figure 7**. Heating elements, integrated into the microfluidic channels, increase the temperature of the fluid locally when actuated. This leads to a phase change of the liquid volume at the position of the heater (evaporation) if the temperature exceeds the boiling point. A virtual movement of the bubble by actuating several discrete and serial aligned heaters subsequently has been proposed by Song and Zhao (2001) (see **Figure 7**, *left*). Using this actuation principle, deionized water has been pumped through a 37.2 cm-long Pyrex glass tube (1.0 mm inner diameter) using 12 serial-aligned heating elements (heating power, 8–12 W). A maximum pressure head of 57 mm H_2O and a maximum volumetric flow rate of 300 µl min^{-1} are reported. Another pumping principle, also based on the thermal phase change is depicted in **Figure 7** (*right*). This device consists of two triangular-shaped heat sources only (Yokoyama *et al.* 2004). The heat flux inside the heater has its maximum at the apex of the triangle, defining the seed position of the bubble during evaporation. A flow rate of 12.5 mm s^{-1} at a driving frequency of 1 Hz has been achieved within a microchannel of 220 mm length and 600 µm × 120 µm cross section using two of the depicted micropumps (overall: four heaters).

Another pumping method that is also based on thermal actuation is depicted in **Figure 8** (Zimmermann *et al.* 2005). The device consists of three independent microchannels, arranged perpendicular to three linear Peltier elements. The channels have an open filling zone, a sealed microchannel in which the assay can be performed, and a likewise open pumping zone. The device is initially primed with liquids by capillary forces via the filling zone. Afterward, the Peltier-1 cools the filling zone to prevent evaporation, i.e., loss of sample or reagent. The ability to keep 90% of 0.6 µL solution in an open filling zone for 60 min is reported.

For liquid propulsion, the Peltier-3 additionally heats the pumping zone leading to a controlled evaporation of liquid at the open interface. The evaporation of liquid sets the flow rate in the microchannel. The functional principle can be considered as a capillary pump maintaining the capillary pressure on both sides of the channel. Flow rates ranging from $\sim 1.2\,nl\,s^{-1}$ to $\sim 30\,pl\,s^{-1}$ have been demonstrated using this principle. The flow rate perfectly matches with the binding kinetics of the molecules inside the liquid to the channel surface, which is diffusion limited, and does exclude faster flow rates.

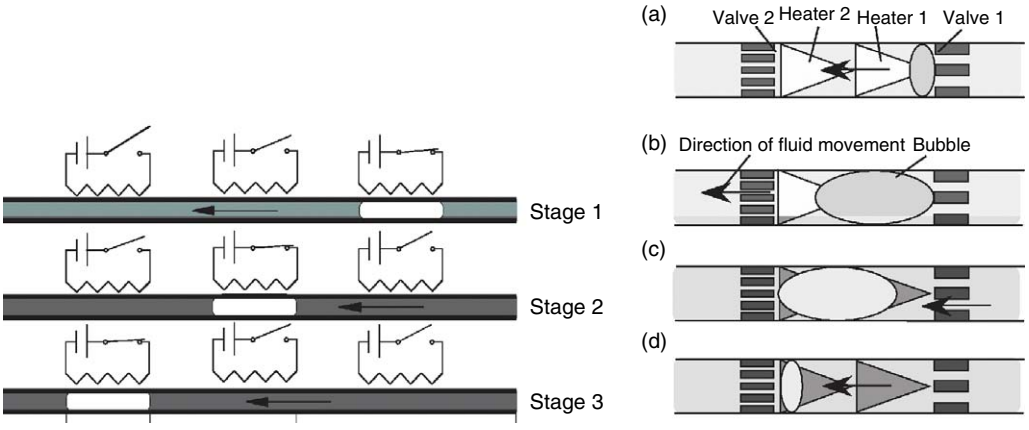

Figure 7 *Left*: Illustration of the phase-change pumping mechanism proposed by Song and Zhao (2001). Three serial-aligned and sequentially actuated heating elements initiate a moving vapor bubble and thus a directed liquid propulsion (stages 1–3). (Source: Song Y J, Zhao T S 2001 Modelling and test of a thermally-driven phase-change nonmechanical micropump. *J. Micromech. Microeng.* **11**, 713–19, IOP Publishing Limited.) *Right*: Basic principle of the thermal micropump described in (a) start of heating (heater 1 on, heater 2 off); (b) bubble growing (heaters 1 and 2 on); (c) start of condensing (heater 1 off, heater 2 on); (d) bubble collapsing (heaters 1 and 2 off). Figure 8 Controlled evaporation method for liquid propulsion. Three microchannels are aligned perpendicular to a set of three Peltier elements allowing the temperature control at the filling, reaction, and pumping zone. Cooling of the filling zone and heating of the pumping zone initiate a controlled evaporation of liquid at the pumping zone. Thus, a liquid flow through the channel is initiated, while preventing evaporation at the inlet zone. 2.13.3.2.2 Valving

A large variety of different active microvalves has been reported during the last two decades (Oh and Ahn 2006) associated to the development of displacement micropumps. However, especially in the field of lab-on-a-chip applications, the required power supply and the high costs of these active valves seem to limit their practical use in pressure-driven systems (**Table 4**).

Therefore, passive microvalves based on capillary stops, which are defined by a change in the channel cross section or the wetting properties of the channel, are more suitable for disposable systems. These valves work similar to passive valving structures in merely capillary-driven systems with the only difference being that the valve can be actively opened at any time by applying an additional pressure load onto the valve.

2.13.3.2.3 Mixing

Since no turbulences can be generated within the laminar flow regime, mixing is related to diffusion processes only in microfluidic channels. Hundreds of micromixing principles and structures have been presented during the last few years to overcome this limitation, see Hessel *et al.* (2005) and Nguyen and Wu (2005) for a detailed and up to date overview.

The basic idea of all micromixers is to increase the interfacial area between the fluids that should be mixed. Well-established methods for continuous mixing are multilamination (Ehrfeld *et al.* 1999, Hessel *et al.* 2003) and split-and-recombine (Chen and Meiners 2004, Cheng *et al.* 2001, Schonfeld *et al.* 2004) flow schemes. A large number of alternating thin lamellae of the liquids A and B are generated within these mixers (A–B–A–B–A···). This increases the interfacial area between the two liquids, which fastens up the homogenization of the two liquid phases via diffusion.

In a multilamination mixer, the initial liquid flows (phases A and B) are split into several substreams, guided to a junction area and then merged into an alternating phase pattern (A–B–A–B–A–B···). The split-and-recombine principle depends on the repetitive splitting of a phase pattern and combining the substreams again. This way the number of phase interfaces is doubled by each split-and-recombine stage (e.g., A–B leads to A–B+A–B).

Another method to increase the interface between two liquid flows is transversal advection. Centrifugal

Table 4 Comparison of active and passive microvalves

Properties	*Active valves*	*Passive valves*
Power supply	Required	Not required
Moving parts	Yes	No
Capable of complex fluid processing	Yes	Limited
Cost-efficient	No	Yes
Works well with fluids containing higher solvent or surfactant concentration	Yes	No
Design	Multilayer structures	Simple
Structure size	Large	Small

forces within bended channels, for example, are utilized to generate an additional flow component perpendicular to the initial direction of flow (Jiang *et al.* 2004, Sudarsan and Ugaz 2006). Due to this transversal advection, the contact interface increases along the channel and thus mixing is supported. Advection can also be induced in simple straight channels at low Reynolds numbers (<100) by manufacturing a (staggered herring bone-shaped) surface texture on one channel wall (Johnson *et al.* 2002, Stroock *et al.* 2002).

All the principles described so far are intended to mix different liquid flows and therefore called continuous micromixers. However, the mixing of liquids, located within a microchamber, can also be of interest. Active micromixers are mainly used for this purpose, e.g., by moving magnetic particles through the chamber.

2.13.3.2.4 Metering

Metering on pressure-driven platforms is typically realized by controlling liquid flows into or through reaction chambers possibly supported by flow rate sensors. With these methods, however, metering, isolation, and further processing of a discrete liquid volume are not possible. Therefore additional active or passive valving structures are required that can release the liquid out of a metering chamber after it has been metered to a defined volume via an overflow channel. Such a structure utilizing a passive, hydrophobic valve for stopping the liquid and metering it to a defined volume has been presented by Yamada and Seki (2004). Metered liquid volumes of 3.5 and 20 nl have been demonstrated in these structures.

2.13.3.2.5 Switching

Flow switching can be realized in a straightforward approach by integrating several (at least two) active microvalves, e.g., on the two continuative channels of a T-shaped structure. Depending on the desired flow path, one of both valves is opened while the other remains closed. However, for complex liquid processing, which is required for the implementation of assay protocols on the platform, a large number of active valves have to be integrated.

Another possibility to switch continuous liquid flows between several outlet channels is based on hydrodynamic focusing (Lee *et al.* 2001a, b). Generally, a sample flow that is symmetrically enframed by two sheath flows at the junction of a Y-shaped channel is focused to a thin stream line under laminar conditions (**Figure 9**) due to the so-called hydrodynamic focusing effect (Knight *et al.* 1998). Depending on the ratio of the flow velocities $\overline{v}_1$, $\overline{v}_2$, and $\overline{v}_3$, the sample liquid stream ($\overline{v}_2$) is directed toward one of the seven outlet ports (A–G). This switching method, however, is based on continuous flows and consequently a certain sample volume is required for liquid routing. This limits the applicability of the method to applications with large sample volumes only.

2.13.3.2.6 Separation

Separation processes are basic techniques to decrease the complexity of material mixtures and are often required in analytical chemistry. Many different physical and chemical separation methods are used in classic analytical assays, e.g., sieving, centrifugation, chromatography, crystallization, adsorption, distillation. Several of these methods have been used in microfluidic systems during the past few

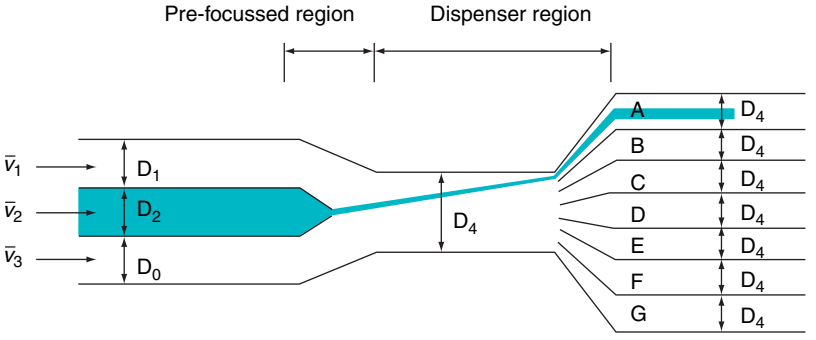

Figure 9 Principle of the continuous flow switch based on hydrodynamic focusing. The liquid stream $\overline{v}_2$ is focused by two lateral flows $\overline{v}_1$ and $\overline{v}_3$ within the prefocused region and then deflected into one of seven outlets (A–G) within the dispenser region. (Source: Lee G B, Hung C I, Ke B J, Huang G R, Hwei B H 2001a Micromachined pre-focused 1×*N* flow switches for continuous sample injection. *J. Micromech. Microeng.* **11**, 567–73, IOP Publishing Limited.)

years, and novel separation principles utilizing the fundamental different hydrodynamics in microchannels have also been proposed.

A separation method that depends on the different diffusion constants of particles of different sizes is the so-called H-Filter, developed and distributed by the company Micronics Inc. (2006). The functional principle of the structure is depicted in **Figure 10**. A sample liquid containing particles of different sizes (Inlet 2) and an extraction liquid without particles (Inlet 1) are combined at one side of a H-shaped channel network. Subsequently, they are guided through the horizontal connecting channel and are completely split into two fractions of equal flow rate at the outlet of the channel.

The flow within the connecting channels stays undisturbed due to the laminar flow conditions. Therefore, the particles present in the sample liquid leave the structure via outlet 2 as far as they do not enter the upper flow portion in the horizontal channel by diffusion. By setting the flow rate, the residence time within the connecting channel and thus the timeframe for the diffusion of the particles can be adjusted. Smaller particles can diffuse a larger distance within a certain timeframe compared with bigger ones. Thus, a fraction of small particles are found within the extraction liquid at outlet 1 and the bigger particles stay within the sample liquid at outlet 2 (Weigl *et al.* 2003). Using this method, the extraction of the antibiotic cephradine from human blood with a recovery of ~32% has been demonstrated (Jandik *et al.* 2002).

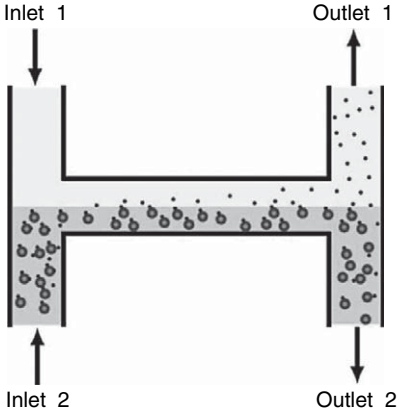

Figure 10 Functional principle of the H-filter. Depending on their diffusion coefficient, the particles start to diffuse across the fluid interface within the horizontal channel. Under optimized conditions, 50% of the population of small particles can be removed from a sample containing large particles also. (Reprinted with permission from Weigl B H, Bardell R L, Cabrera C R 2003 Lab-on-a-chip for drug development. *Adv. Drug Deliv. Rev.* **55**, 349–77. Copyright 2003 Elsevier.)

Another method that is based on particle diffusion utilizes the asymmetric bifurcation of laminar flow around obstacles. The particles follow different migration paths, depending on their size. Microspheres of 0.8, 0.9, and 1.0 µm size were successfully sorted within 40 s in such a device (Huang *et al.* 2004).

A hydrodynamic particle separation method, the so-called pinched flow fractionation (Yamada *et al.* 2004), is based on the parabolic flow profile and on the fact that the center of the particle cannot get close to the channel wall than the radius. The particles of different sizes within the sample flow are aligned to the channel wall by a second pinching liquid flow after a Y-shaped junction. The channel then expands and the flow spreads while retaining laminar conditions. Thus, each particle follows the streamline of its center. This leads to a separation of the particles perpendicularly to the flow direction according to their size. Using the pinched flow fractionation principle, the successful separation of 15- and 30-µm-diameter particles has been demonstrated. Even a mixture of 1- to 5-µm particles can be separated using an improved structure based on this principle (Takagi *et al.* 2005).

Another hydrodynamic method, called hydrodynamic filtration (Yamada and Seki 2005), is based on the topology of the particles and the laminar flow profile (**Figure 11**). Here, no additional liquid flow is needed for the alignment of the particles along the channel wall as is the case for the pinched flow fractionation. In the first part of the structure (concentration and alignment), only a small fraction of the liquid is withdrawn through the side channels (**Figure 11(a)**). Thus, neither of the particles enter the side channel since their center still lies beyond the flow fraction directed to the side channel (dashed line). Due to the permanent volume extraction on both sides of the channel, however, the particles are aligned onto both channel walls after some concentration steps.

In a subsequent side channel (first selection), the relative flow rates are adjusted to extract small particles from the suspension within the main channel (**Figure 11(b)**). At the second selection branch, the flow rate into the side channel is increased once again to extract the bigger particles. The concentration of polymer microspheres with diameters of 1–3 µm was increased 20- to 50-fold, and they were collected independently according to the size using such a

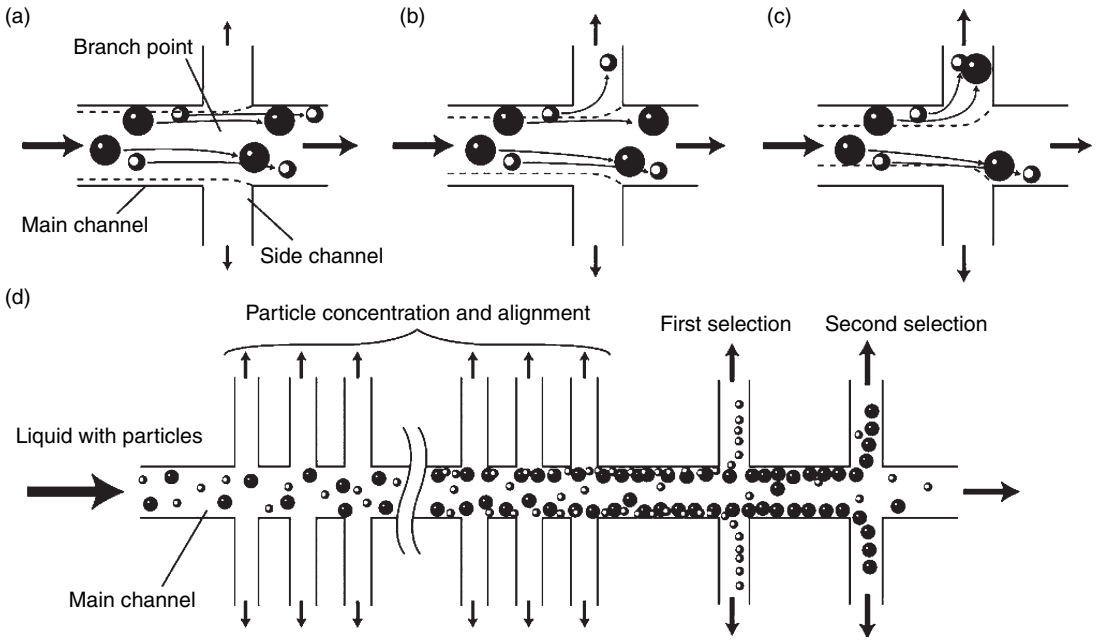

Figure 11 The hydrodynamic filtration method. The situation at a branch point for different flow ratios is depicted in (a)–(c). The relative flow rate into the side channel is (a) low, (b) medium, or (c) high; (d) The complete structure consists of a concentration and alignment as well as a selection part. (Source: Yamada M, Seki M 2005 Hydrodynamic filtration for on-chip particle concentration and classification utilizing microfluidics. *Lab Chip* **5**, 1233–9, Reproduced by permission of The Royal Society of Chemistry.)

structure. In addition, selective enrichment of leukocytes from blood was successfully demonstrated (Yamada and Seki 2005). Using an improved device for continuous particle concentration and size-dependent separation based on the same principle but featuring an additional splitting and recombining of the fluid flow, the concentration of 2.1- to 3.0-µm particles can be increased 60- to 80-fold (Yamada and Seki 2006).

2.13.3.3 Application Examples

2.13.3.3.1 Portable handheld analyzer: i-STAT®

The i-STAT® analyzer from Abbott Point of Care (2006) is a portable diagnostic platform. Several disposable cartridges for the determination of a multitude of blood parameters (blood gases, electrolytes, coagulation, cardiac markers, and hematology) can be read out using the same handheld analyzer (**Figure 12**, *left*). Only the low-cost polymer cartridge is contaminated with the blood sample and can be disposed after the diagnostic assays while the readout and assay processing analyzer is reused. The system

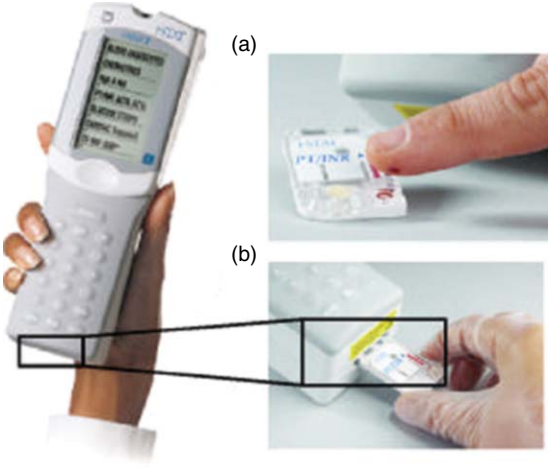

Figure 12 *Left*: The portable i-STAT® analyzer for clinical blood tests. *Right*: Depending on the blood parameters to be measured, (a) a certain disposable cartridge is filled with blood by capillary forces from the fingertip and (b) later loaded into the analyzer for assay processing and readout. (Source: Abbott P-C 2006 East Windsor, NJ, USA, www.abbottpointofcare.com, accessed 2006.)

reduces the time-to-result for the determination of important blood parameters down to several minutes, enabling faster diagnostic decisions.

The reagent solution for sensor calibration is contained in the cartridge within a foil pouch. As depicted in **Figure 12**, the blood sample is filled into the cartridge by capillary forces (**Figure 12(a)**) and placed into the analyzer (**Figure 12(b)**). During the subsequent assay cycle, the analyzer presses the front of the cartridge, causing a barb to puncture the pouch. This releases the calibrant solution and additionally generates a pressure-driven flow over the silicon sensor array for measurement. Subsequently, the analyzer presses an air bladder on the cartridge, which pushes the calibrant into the waste reservoir and the blood sample over the sensor array. Thereby, the blood parameters are determined depending on the type of cartridge and presented at the display of the handheld analyzer.

2.13.3.3.2 Diffusion-based assays: T-Sensor®

Micronics Inc. (2006) has developed the microFlow™ platform for the implementation of automated diffusion-based assays. The system consists of a disposable plastic card containing the microfluidic structures and a microfluidic work station for external pressure generation (syringe pumps) and detection. Microfluidic unit operations such as separation in the ActiveH™ card with an integrated H-filter or controlled mixing via diffusion through the ActiveT™ card, can be combined to conduct diffusion-based assays.

The microFlow platform as well as the ActiveT card containing the microfluidic T-Sensor® is depicted in **Figure 13**. A stable sheath flow is generated under laminar conditions at the junction of three inlet channels. No chaotic mixing occurs in the subsequent detection stream due to the strictly laminar flow conditions in the microchannel. The only transport of material from one stream to another is by diffusion. Consequently two diffusion zones on both sides of the central stream evolve. The left zone between the reference solution and the detection liquid represents a system-integrated real-time calibration. The other zone evolves at the right side of the detection stream being in contact with the sample liquid. The faster diffusion of smaller molecules also enables the detection of smaller components of interest present in a complex sample without previous separation. The reaction between the reference and the detection as well as between the sample and the detection stream is measured via a single fluorescent readout across the complete channel.

2.13.3.4 Strength and Challenges of the Platform

Pressure-driven platforms are certainly the most investigated ones in terms of the number of developed microfluidic components like micropumps, micromixers, microvalves, etc. However, only a small number of platform applications have been commercialized so far. The main reason for this is that many of the proposed components are based on different fabrication technologies. Thus, their combination on a pressure-driven platform causes liquid interfacing problems. However, the advantages of the pressure-driven approach are obvious: an increased level of controllability as compared with pure capillary-based test strips, easy integration of almost all

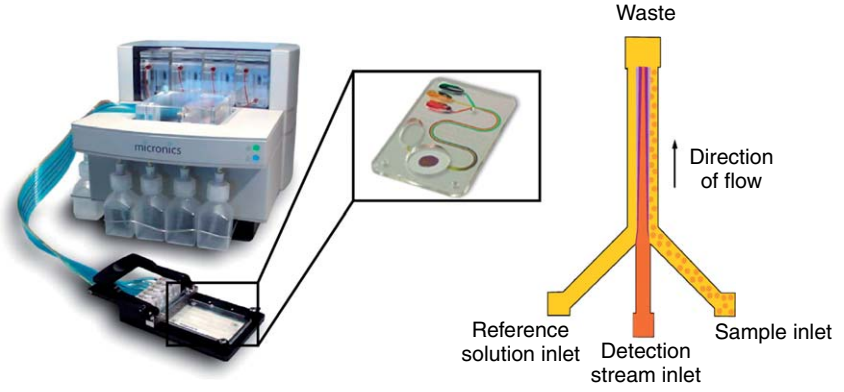

Figure 13 *Left*: The microFlow™ platform with an ActiveT™ card in the insert. *Right*: The functional principle of the T-Sensor® structure. The detection stream meets at the junction part with a reference liquid on the left and the sample liquid on the right side, respectively. (Source: Micronics Inc. 2006 Redmond, WA, USA, www.micronics.net, accessed 2006.)

biochemical sensor principles, and the compatibility to standard lab equipment.

The real potential of a pressure-driven platform becomes evident in Section 2.13.4, where the microfluidic large-scale integration (LSI) platform – a special type of pressure-driven platform – is described, which is probably the most sophisticated platform concept presented in the field so far.

2.13.4 Microfluidic Large-scale Integration

2.13.4.1 Introduction

Before the beginning of the 1990s, the screening for novel active agents in the pharmaceutical industry was done by laboratory staff in manually pipetted assays. A biological target molecule is exposed to many compounds in order to find a positive, i.e., matching compound (hit). The assay result is mainly read out optically (change in color or fluorescent signal) after the reaction. Since the texture of the biological target molecule is unknown, all possible combinations out of a compound library are tested. This merely statistical approach is called combinatorial chemistry.

Over the years, the number of screening experiments rapidly grew just as the compound libraries increased, making manual processing impossible. With the advent of highly automated liquid handling instrumentations such as pipetting robots, the number of experiments per day can be increased enormously. Over 100 000 experiments can be performed within a single day using these so-called high throughput screening (HTS) technologies. A current trend is the further reduction of the liquid volumes per screening experiment, e.g., by novel dispensing systems for liquid volumes in the nanoliter and picoliter range (see Section 2.13.7). Besides cost issues the finite amount of (biological) target molecules is the main driving force for this progression.

However, when shrinking reaction volumes why not also miniaturize the liquid handling devices to do thousands of chemical experiments on the footprint of a stamp? In the early 1990s, the realization of such an integrated microfluidic platform seemed unrealistic in terms of simply shrinking microvalves, micropumps, and mixers developed so far. Comparable to the invention of the transistor in 1947, a pivotal innovation in microfluidics was needed to overcome the existing barrier. This innovation arose with a novel fabrication technology for microfluidic channels, called soft lithography. Using this technology, the monolithic fabrication of all necessary fluidic components from one single elastomer material (polydimethylsiloxane, PDMS) became possible, similar to the silicon-based technology in microelectronics.

2.13.4.1.1 PDMS – Soft lithography

PDMS is an inexpensive but still powerful material offering several advantages compared to silicon or glass. It is a cheap, rubber-like elastomer with good optical transparency and biocompatibility. It can be structured using the soft lithography technique based on the replication molding on micromachined molds. It has first been used by George Whitesides's group for the fabrication of optical devices (Xia *et al.* 1996) and stamps for chemical patterning (Xia and Whitesides 1998a, b). A general and detailed up-to-date view of the use of PDMS in different fields of applications can be found in Sia and Whitesides (2003).

Thereafter, microfluidic devices have also been manufactured using PDMS technology (Delamarche *et al.* 1997, Duffy *et al.* 1998, Effenhauser *et al.* 1997, Fu *et al.* 1999, Hosokawa *et al.* 1999). So far, however, PDMS has been used merely as a passive material for the realization of microfluidic channels. The strength of the technology, however, really became obvious, when Stephen Quake's group expended the technology toward the multilayer soft lithography (MSL) process (Quake and Scherer 2000, Unger *et al.* 2000). With this technology, several layers of PDMS can be hermetically bonded on top of each other resulting in a monolithic, multilayer PDMS structure. The single layers are formed from a master structure either by casting or by using spin coating (**Figure 14**). One of the two layers contains a sparse cross-linking agent, while the other has an excess concentration. Both layers are separately prehardened, removed from the masters, and aligned to each other. Afterward, the PDMS stack is again baked, initiating the reaction of the cross-linking agent on the layer interface. A monolithic, multilayer elastomer structure results, which is finally bonded to a glass substrate for easier handling. Today, this technology is pushed forward by the company Fluidigm Corporation in the United States (Fluidigm Corporation 2006).

2.13.4.2 Microfluidic Large-scale Integration: Unit Operations

2.13.4.2.1 Valving

The resulting microfluidic platform mainly depends on the elastomer properties of PDMS with a low Young's modulus value of ~750 kPa (Lotters *et al.*

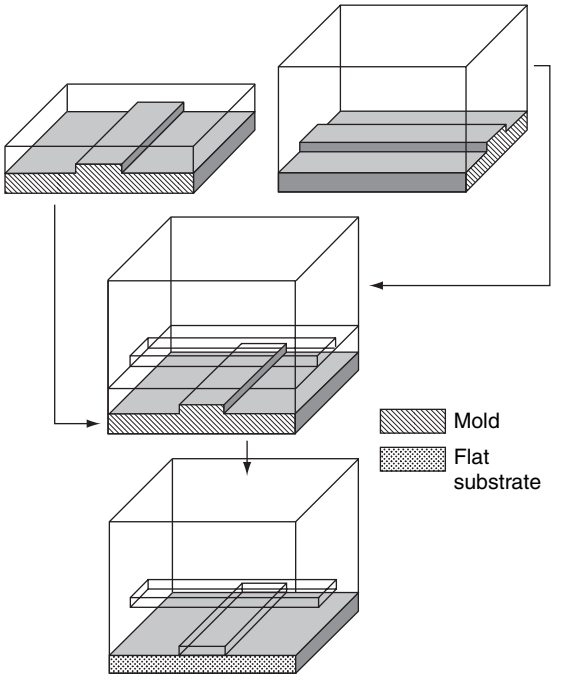

Figure 14 The multilayer soft lithography (MSL) fabrication principle. Two fluidic channel layers are casted from microfabricated molds. In a second step both layers are combined and compounded chemically. At last the compound is placed on a glass substrate for robust handling. (Reprinted with permission from Unger M A, Chou H P, Thorsen T, Scherer A, Quake S R 2000 Monolithic microfabricated valves and pumps by multilayer soft lithography. *Science* **288**, 113–16. Copyright 2000 AAAS.)

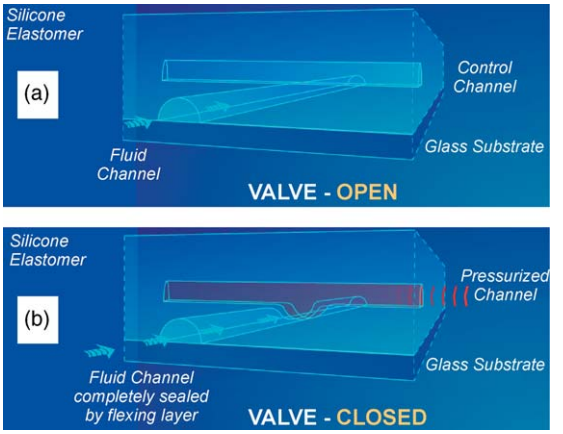

Figure 15 Schematic sketch of the microfluidic NanoFlex™ valve realized in the multilayer soft lithography (MSL) technology. (a) Liquid can pass through the fluid channel as long as no pressure is applied to the control channel. (b) An increased pressure within the control channel causes the thin elastic polydimethylsiloxane (PDMS) membrane between the two channel layers to deflect into the fluid channel and blocks the liquid flow therein, i.e., the valve is closed. (Source: Fluidigm Corporation 2006 San Francisco, USA, www.fluidigm.com, accessed 2006.)

1997). Based on this elasticity, the basic microfluidic unit operation is a valve, which is made of a planar glass substrate and two layers of PDMS on top of each other. The lower elastomer layer contains the fluidic ducts and the upper elastomer layer features pneumatic control channels. To realize a microfluidic valve, a pneumatic control channel crosses a fluidic duct as depicted in **Figure 15**. A pressure applied to the control channel squeezes the elastomer into the lower layer, where it blocks the liquid flow. Because of the small size of this valve on the order of $100 \times 100\,\mu m$, a single integrated fluidic circuit can accommodate thousands of valves. Compared to the development in microelectronics, this approach is called microfluidic large-scale integration (LSI) (Thorsen *et al.* 2002).

The valve technology called NanoFlex™ is the core technology of the complete platform. Placing two of such valves at the two arms of a T-shaped channel, for example, realizes a fluidic switch for the routing of liquid flows between several adjacent channels. Other unit operations based on the MSL technology are described in the following sections.

2.13.4.2.2 Pumps and mixers

The platform offers two possibilities to transport liquids. On the one hand, external pumps can be used to generate liquid flows within the fluid channel layer. With that approach, the PDMS multilayer device works merely passively, controlling the externally driven liquid flows with the integrated valves. On the other hand, an integrated pumping mechanism can be achieved by combining several microvalves and actuating them in a peristaltic sequence (**Figure 16(b)**).

Also a micromixer for the accelerated homogenization of liquids can be realized using the above-described pumping mechanism (**Figure 16(c)**). The liquids to be mixed are segmentally introduced into the fluidic loop through the left inlet, while the right outlet valve is still closed. Afterward, the inlet and the outlet valve are closed and the three control channels on the orbit of the mixing loop are displaced with a peristaltic actuation scheme leading to the circulation of the mixture within the loop (Quake and Scherer 2000). Thereby the liquids are mixed and afterward flushed out of the mixer by a washing

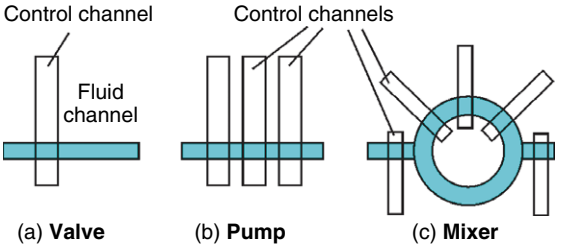

Figure 16 Realization of the main unit operations on the multilayer polydimethylsiloxane (PDMS)-based platform. Based on the NanoFlex™ (a) a valve, (b) an integrated peristaltic micropump, (c) and a micromixer can be designed.

liquid (inlet and outlet valves are opened again). Using this mixing scheme, an increase in the reaction kinetics of surface binding assays by nearly two orders of magnitude has been demonstrated (Chou *et al.* 2001).

Another mixing concept in the microfluidic LSI platform involves simply opening the valve between two different chambers containing different liquids. In this mixing scheme, the liquids mix only by diffusion. Although a merely diffusional mixing is very slow, it is also very controllable in return. A controllable and slow mixing process in particular is required for protein crystallization, which is described in more detail in Section 2.13.3.3.1.

2.13.4.2.3 Multiplexing

The key principle to tap the full potential of the LSI approach is the multiplexing technology, which allows the control of N fluid channels with $2 \log_2 N$ control channels as depicted in **Figure 17** (Thorsen *et al.* 2002). This, for instance, means that 256 fluid channels can be controlled individually by 33 pneumatic control channels.

Thorsen *et al.* demonstrated a microfluidic storage device with 1000 independent compartments of approximately 250 pl volume and 3574 microvalves. Therefore, two multiplexers, one for the row decoding and the other for the column decoding, have been used. The complete microfluidic chip has a surface area of 25 mm × 25 mm.

2.13.4.2.4 Metering

Liquid volumes can also be metered using crossed fluid channels and a set of microvalves. Addressed by a multiplexer, the liquid is loaded into a certain fluid channel in the first step of the metering protocol (**Figure 18**). Afterward the valves between the different chambers are closed and thus the continuous

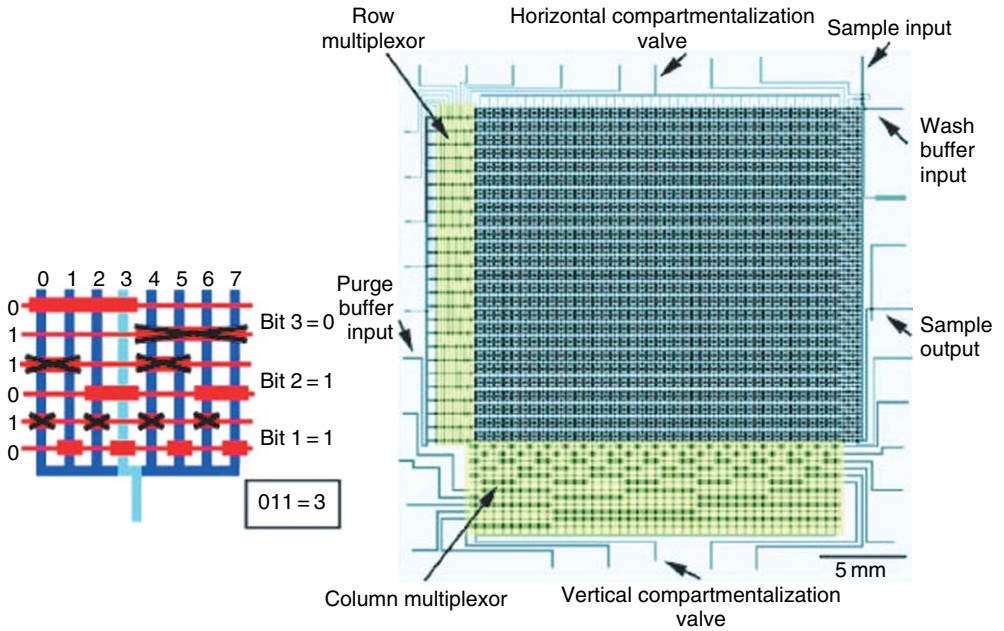

Figure 17 *Left*: Operational diagram of the microfluidic multiplexer: eight vertical fluid channels can be individually controlled by six horizontal control channels. The pressurized control channels block the fluid channels only at positions where the width of the control channel is widened. *Right*: Mask design for the microfluidic memory storage device. (Reprinted with permission from Thorsen T, Maerkl S J, Quake S R 2002 Microfluidic large-scale integration. *Science* **298**, 580–4. Copyright 2002 AAAS.)

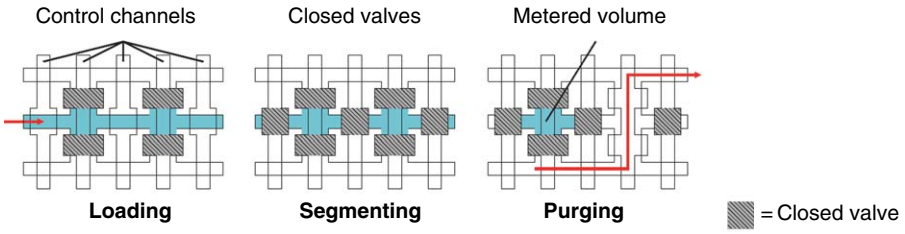

Figure 18 Using crossed fluid channels, liquid metering is also possible on the microfluidic large-scale integration (LSI) platform. In the first loading step, a certain fluid channel is addressed using the multiplexer structure and filled with liquid. In the second step, the liquid within that channel is segmented by closing the valves between the chambers. In the last step, fluid that should not be kept is purged via two additional fluid channels on both sides of the metering channel.

liquid plug within the fluid channel is segmented into several equal-sized (if the chambers all have the same dimensions) liquid compartments. During the last step, a washing liquid is pumped through the system, addressed to the fluid channel right next to the metering fluid line. All chambers that should not contain a metered volume of the initial liquid after the metering process are now purged vertically since the vertical valves to the two neighboring channels are now open. As a result a metered liquid volume is retained in designated metering chambers only.

The described unit operations should demonstrate the enormous possibilities of the platform. Depending on the design of the fluid channel and the control channel layer, many different processes for the conduction of certain assay protocols can be realized. To give an impression on these possibilities, two application examples, protein crystallization and nucleic acid processing, are described in Section 2.13.4.3, both realized on the microfluidic LSI platform.

2.13.4.3 Application Examples

2.13.4.3.1 Protein crystallization

How does this protein that causes a certain disease look like? Answering this question in an acceptable period of time would cause a revolution in the merely statistically driven pharmaceutical research based on the HTS of large compound libraries. The trail-and-error approach would be replaced with a more rational procedure; the systematic tailoring of a complementary active compound to the known structure of the target protein would then be feasible (structural biology).

In order to investigate the structure of a protein, first of all it has to be transferred into a crystalline state suitable for X-ray crystallography. As there is currently no way to predict crystallization conditions *a priori*, a large number of experiments are required to uncover successful crystallization conditions. It is obvious that a microfluidic-based solution would have many advantages, since it requires only a small amount of protein, and precise volume definition as well as controllable mixing processes by diffusion can be implemented.

The crystallization method that is used in the microfluidic LSI platform is called free interface diffusion (FID) (Salemme 1972). It is based on the counterdiffusion of the protein and the precipitant solution through the liquid–liquid interface between these two phases. During the diffusion process, the concentration profile changes and crystal growth is initiated as soon as the appropriate conditions are met. In conventional FID setups a stable and undisturbed liquid–liquid interface between the protein and the precipitant solution has to be assured by proper liquid handling to avoid unwanted mixing. Because of buoyancy-driven convection caused by density differences this can hardly be achieved in macroscopic capillaries.

Within a microfluidic crystallization structure, however, a stable interface with diffusion-based mixing only can be implemented very easily (negligible gravitational effects due to high surface-to-volume ratio). The successful growth of protein crystal has been demonstrated in a microfluidic chip based on the LSI technology (Hansen and Quake 2003, Hansen *et al.* 2002). Overall, 144 crystallization experiments can be performed in parallel on the presented microfluidic chip. One such microfluidic unit cell is depicted in **Figure 19(a)** and comprises microchambers of 5, 12.5, and 20 nl. They are arranged and coupled to define mixing ratios of 1:4, 1:1, and 4:1 with a fixed total volume of 25 nl.

The crystallization assay starts with the filling of the chambers while the valve between the chambers (horizontal yellow bar in the middle) is still closed (**Figure 19(b)**). The air is vented via diffusion

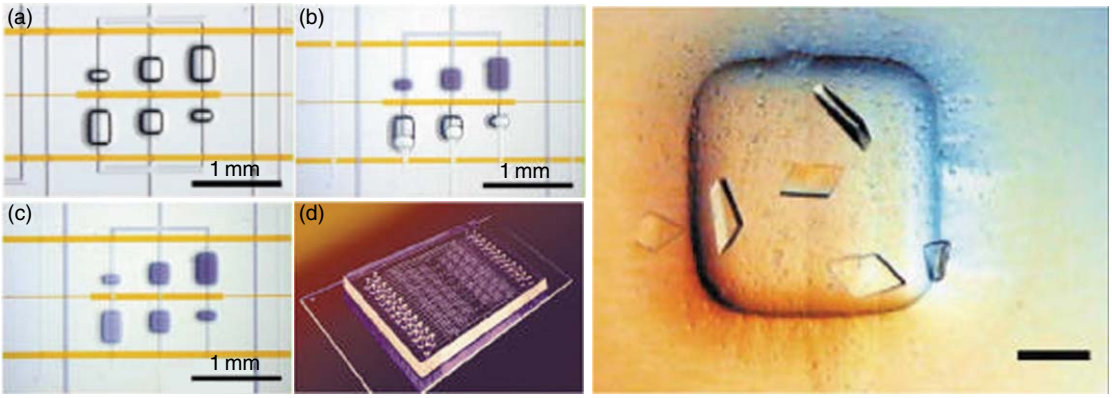

Figure 19 *Left*: Microfluidic crystallization structures. (a) Three crystallization assays with different mixing ratios (1:4, 1:1, 4:1) and a fixed total volume of 25 nl. (b) The central interface valve is closed and the chamber is filled with solution while the air diffuses through the bulk elastomer. (c) The intermediate valve is opened, initiating the diffusional mixing process. (d) The complete chip features 48 unit cells performing 144 simultaneous crystallization experiments while using 3 μl of protein sample only. *Right*: Example of protein crystals grown in the described microfluidic structure (scale bar, 100 μm). They have been grown within 12 h only, while the conventional process takes over a week. (Reprinted with permission from Hansen C, Quake S R 2003 Microfluidics in structural biology: Smaller, faster··· better. *Curr. Opin. Struct. Biol.* **13**, 538–44. Copyright 2003 Eksevier.)

through the gas-permeable bulk elastomer during the filling of the dead-end chambers. The filling valves are closed in the next step and the counterdiffusion is initiated as soon as the middle valve is opened (**Figure 19(c)**). The concentration within both chambers now changes with time due to the diffusion of species through the connecting channel. A crystal growth initiates in chambers with proper transient concentrations distributions only.

The channel between the two chambers has a small cross-section (10 μm × 100 μm) compared to that of the two chambers (300 μm × 100 μm). Thus, it acts like a diffusion impedance, slowing down the diffusion process and implying almost homogeneous concentrations within the chambers. As a concentration gradient is apparent only along the length of the channel, the rate of equilibrium can be influenced by the geometry of the structure (namely the length of the channel and the ratio of the chamber volume to the channel cross-sectional area). The end point itself, however, is predefined by the volume of the two precisely fabricated chambers. The accurate control over the kinetics of equilibration without changing the chemical evolution has important implications for crystal optimization where it is often desirable to approach crystallization conditions slowly while conserving the successful thermodynamic variables (Hansen and Quake 2003).

The parallel implementation of 48 unit cells in a single crystallization chip facilitates 144 different simultaneous protein crystallization reactions while consuming only 3.0 μl of protein solution – only 20 nl per assay (**Figure 19(d)**). **Figure 19** (*right*) shows a crystal that has been grown within 12 h using the microfluidic LSI chip. In a conventional system, this process lasts over 1 week. The protein crystallization technology on the LSI platform has been commercialized by the company Fluidigm (Topaz® technology).

2.13.4.3.2 Nucleic acid isolation

A second application example of the microfluidic LSI platform is the purification of nucleic acids from a small amount of cells. The isolation of DNA or mRNA from microbial or mammalian cells, including their lysis on-chip, has been showed by Stephen Quake's group at Stanford (Hong and Quake 2003, Hong *et al.* 2004). For the extraction of DNA from a cell suspension, the cell membrane has to be destroyed first (lysis of the cell). Then, the DNA has to be specifically separated from the residual cell constituents within the solution. This extraction protocol is completely implemented on the microfluidic platform using the basic unit operation structures for valving, metering, mixing, and switching of fluids.

The channel network for performing the DNA isolation assay is depicted in **Figure 20(f)**. Three extractions can be performed in parallel with three rotary reactors aligned vertically (the different fluid channel lines are colored with food dye for visualization). The chip is operated in two different modes, loading and processing. In the loading mode, the

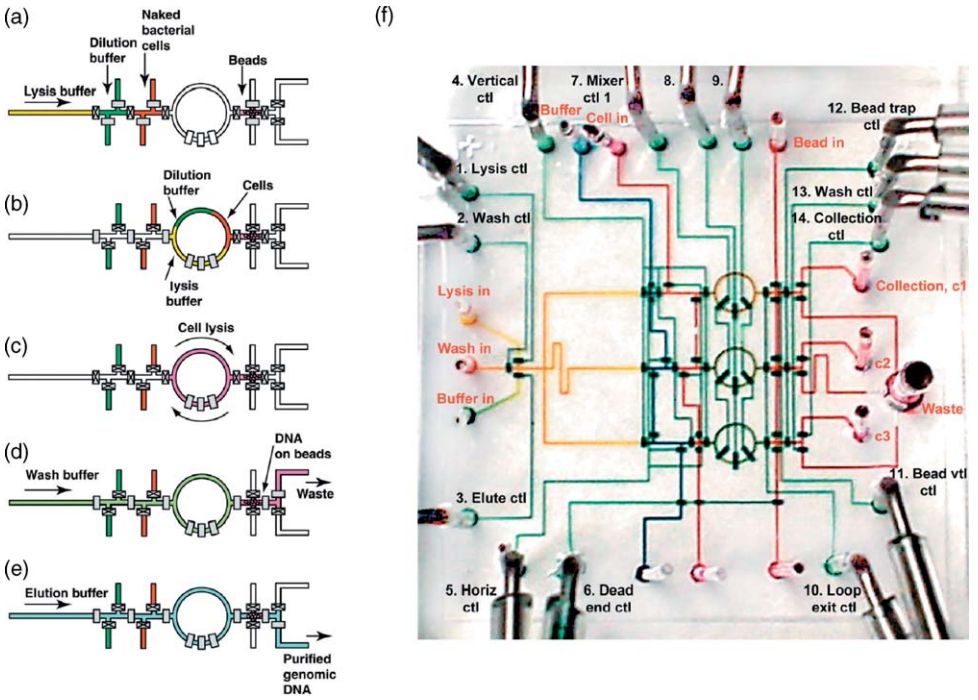

Figure 20 Microfluidic large-scale integration (LSI) DNA purification chip (f) and the course of an isolation protocol. (a) The bacterial cell culture, the dilution, and the lysis buffer are introduced into the chip via fluid channels (open valve, rectangle; closed valve, x in rectangle). (b) The vertical valves are opened, and the three liquids are externally pumped into the circular mixing channel. (c) Mixing is initiated by circular peristaltic pumping. (d) The mixture containing the lysed cells is flushed by a washing buffer over a column of microbeads. The DNA molecules bind to the bead surface and the buffers and the residual cell constituents are directed toward the waste outlet. (e) The elution buffer is flushed over beads, the DNA molecules are transferred into the liquid phase again and leave the structure through the lower outlet. (Reprinted with permission from Macmillan Publisher Ltd: Hong J W, Studer V, Hang G, Anderson W F, Quake S R 2004 A nanoliter-scale nucleic acid processor with parallel architecture. *Nat. Biotechnol.* **22**, 435–9. Copyright 2004.)

valves of the control layer are activated, so that the liquids flow in the north/south direction. During this step, the horizontal metering chambers are loaded with the diluent buffer (green), the bacterial cell solution (red), and the bead suspension (white) as depicted in **Figure 20(a)**. Then, the control valves on the north/south channels are closed leading to segments of the respective liquids. Also a certain volume of bead suspension is metered within the microchannel to define the number of beads that lead to a defined binding capacity for the later solid-phase extraction (100 pg of DNA on the beads of diameter 2.8 µm).

To exploit the high integration possibilities of the platform, the three isolation structures differ with regard to the volume of the bacterial cell solution. The volumes used in the top, middle, and bottom structure are 1.6, 1.0, and 0.4 nl, respectively. Since the total volume of each rotary reactor is the same (5 nl), 0.4-, 1.0-, and 1.6-nl dilution buffer are metered on the platform and added to the cell solution. Subsequently, the chip is switched to the processing mode: valves are actuated such that flow is allowed only in an east/west direction and all the three batch reactors are operated in parallel. Lysis buffer (3.0 nl) is injected from the left to flush the cell solution and the dilution buffer into the rotary reactor (**Figure 20(b)**).

Within the rotary reactor, the three different valves are actuated sequentially to generate a circulating flow. This reduces the mixing time from several hours for merely diffusional mixing to several minutes in the micromixing scheme (**Figure 20(c)**). As a result, the bacterial cells within the reactor are completely lysed after some minutes and can be forwarded to the next process step.

Now, the valve at the outlet of the rotary reactor is opened, and the solution containing the lysed cells is flushed out of the ring over the aggregated beads and leaves the structure via the upper waste outlet (**Figure 20(d)**). The beads are retained within the channel by a partially closed valve, where the beads larger than the valve opening cannot pass through. The DNA molecules within the lysed solution bind

to the bead surface. In a subsequent washing step, all unbound components are washed away from the bead column and likewise drained through the waste outlet.

Purified DNA is recovered from the chip in the last process step, by introducing elution buffer from the left side of the chip, which passes over the aggregated beads. The DNA is transferred back into the liquid phase and leaves the system through the lower DNA outlet. Two valves at the end of the structure act as a fluidic switch, guiding the liquid flow either toward the waste or toward the purified DNA outlet. The DNA gained from the on-chip isolation is now readily available for further analysis or manipulation. **Figure 20(f)** shows the complete microfluidic chip for four parallel DNA isolation assays; it has 26 access holes, 1 waste hole, and 54 integrated valves within the overall 20 mm× 20mm chip.

Purified genomic DNA from less than 28 bacterial cells (*Escherichia coli* culture) could be successfully isolated on the platform. Additionally, seven chips were used as negative controls in which pure water was introduced instead of bacteria, and no signal was detected within the off-chip detection (PCR amplification). Thus, it could be shown that it is possible to reduce the required amount of bacterial cells for the isolation of the needed DNA using the microfluidic LSI platform. This corresponds to an increase in the sensitivity of this process by three to four orders of magnitude compared with that of conventional methods (Hong *et al.* 2004).

Based on this technology, a complete nucleic acid processor is currently being developed in Stephen Quake's group at Stanford University. Starting from single cells, the isolation of nucleic acid, with a subsequent synthesis of cDNA (Marcus *et al.* 2006a), PCR (Liu *et al.* 2003), or real-time polymerase chain reaction (RT-PCR) (Marcus *et al.* 2006b) completes the platform for complete single-cell gene expression analysis.

2.13.4.4 Strength and Challenges of the Platform

The microfluidic LSI platform has certainly the potential to become one of the foremost microfluidic platforms for highly integrated applications. It is a flexible and configurable technology, which stands out owing to its suitability for LSI. The PDMS fabrication technology is comparably cheap and robust, and it can be used to fabricate disposables. Reconfigured layouts can be assembled from a small set of validated elements, and design iteration periods for new chips are on the order of days. Some of the system functions are hardware defined by the fluidic circuitry but others, such as process sequences, can be programmed from outside easily. The approach of building up an entire processor from a very limited set of elementary units resembles the microelectronics industry in which functional steps are configured by a circuit of transistors and capacitors.

Limitations of the platform are related to the material properties of PDMS: for example, chemicals that are not inert to the elastomer cannot be processed, or elevated temperatures, such as in microreaction technology, are not feasible. Also the implementation of applications in the field of point-of-care diagnostics, where often a handheld device is required, does not seem to be beneficial using the LSI platform. The external pressure sources and valves have to be shrunk to a smaller footprint, which is technically feasible of course, but the costs would be higher in comparison to other platform concepts.

2.13.5 Centrifugal Microfluidics

The approach of using centrifugal forces to process samples and reagents dates back to the end of the 1960s (Anderson 1969, Burtis *et al.* 1972). At that time, centrifugal analyzers were used to transfer and mix a series of samples and reagents in the volume range from 1 up to 110 µl into several cuvettes followed by spectrometric monitoring of reactions and real-time data processing. In the beginning of the 1990s, the company Abaxis Inc. (2006) developed the portable clinical chemistry analyzer (Schembri *et al.* 1992, 1995). The system consists of a plastic disposable rotor for processing the specimen, dried reagents preloaded to the cartridge, and an analyzer instrument for actuation and readout (**Figure 21**).

The next generation of centrifugal devices emerged from the technical capabilities offered by microfabrication and microfluidic technologies (Duffy *et al.* 1999, Ekstrand *et al.* 2000, Madou and Kellogg 1998, Madou *et al.* 2001). Length scales of the fluidic structures in the range of a few hundred micrometers allow parallel processing of up to a hundred units assembled on the disk. This enables a high throughput of many tests by highly parallel and automated liquid handling. In addition, the new opportunities arising from the miniaturization of the centrifugal fluidics cut down the assay volumes to <1 µl. In particular, fields such as drug screening, where precious samples are analyzed, benefit from the low assay volumes.

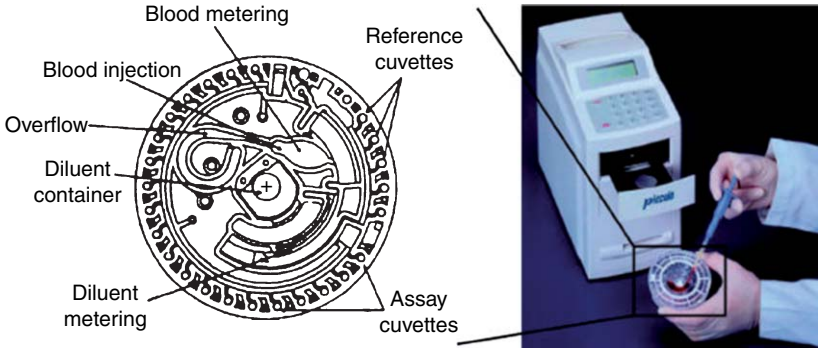

Figure 21 *Left*: Schematic of the rotor comprising the fluidic channels, reservoirs, and the cuvettes for optical detection. (Source: Schembri C T, Ostoich V, Lingane P J, Burd T L, Buhl S N 1992 Portable simultaneous multiple analyte whole-blood analyzer for point-of-care testing. *Clin. Chem*. **38**, 1665–70. Reproduced by permission of American Association for Clinical chemistry.) *Right*: Image of the portable analyzer. (Source: Abaxis Inc. 2006 Union City, CA, USA, www.abaxis.com, accessed 2006.)

Furthermore, the miniaturized assays can also offer shorter time-to-result and thus either higher throughput or shorter therapeutic turnaround times for critical care applications. The centrifugal microfluidic approach is also referred to as 'lab-on-a-disk'.

2.13.5.1 Introduction to the Lab-on-a-Disk Approach

The basic concept of centrifugal microfludics is the transport of fluids within a rotating channel by means of the centrifugal force. For a module rotating with an angular frequency $\omega = 2\pi v$, the centrifugal force density

$$f_\omega = \rho\omega(\omega \times \mathrm{r}) \qquad [3]$$

acts on a fluid of mass density ρ at a radial position r. This pumping force is directed in a radial outward direction, thus driving liquid plugs toward outer diameters as long as they possess a net radial plug length. Besides the liquid properties, only the radial position and the rotational speed define the pumping force and thus the liquid handling actuation. This eases the parallelization of several identical microfluidic structures being placed on one rotating substrate at different angular, but the same radial position. Although these structures experience the same centrifugal force, they still operate independently of each other, thus making this scheme of parallelization very robust.

The substitution of pressure-generating pumping devices by the pulse-free centrifugally initiated fluid flow enables complex liquid handling processes within a completely passive microstructure. Without any moving part, the rotating modules called disks or CDs can be fabricated using cost-efficient microfabrication technologies for plastics like injection molding. The processes are readily available from the audio compact disk industry, where microstructure polymer discs have been injection molded for several decades. Low-cost disposable disks combined with a nondisposable rotary drive and detecting unit build the modular centrifugal microfluidic platform.

Besides the centrifugal force, the Coriolis force can also be used to manipulate liquid flows on the centrifugal platform as depicted in **Figure 22**. It acts on every moving liquid portion within the rotating frame of reference and scales with the flow velocity as well as the frequency of rotation. The Coriolis pseudo force is always directed perpendicular to the direction of flow and even prevails over the centrifugal force over a critical frequency of rotation (Ducrée *et al.* 2005).

2.13.5.2 Microfluidic Unit Operations on the Centrifugal Platform

2.13.5.2.1 Fluid transport

On the centrifugal platform, two pressure-generating mechanisms are employed to accomplish complex liquid processing protocols. The centrifugal force f_ω (see eqn [3]) enables the liquid transport in radial outward direction. This actuation principle can be scaled over a wide range by the frequency of rotation. Small flow rates in the order of nanoliter per second can be accomplished to extract molecules from a continuous flow while passing immobilized capture molecules. For this purpose the residence time for the streaming molecules have to be larger than the time for diffusion of the immobilized molecules. In return also high throughput up to $1\,\mathrm{ml\,s^{-1}}$ has been reported in a 3 cm-long microchannel of $260\,\mu\mathrm{m} \times 195\,\mu\mathrm{m}$ cross section for microprocess engineering applications (Haeberle *et al.* 2005). So scaling of flow rates over six orders of magnitude has been demonstrated. Many different (bio-) fluids can be processed on the platform, independent of their chemical composition, ionic strength, conductivity, or pH value opening a wide field of possible applications.

The second microfluidic effect that plays an important role for liquid propulsion is capillarity. As soon as the disk is at rest or rotates with a small frequency of rotation, the always coexistent capillary pressure gains impact. If there is at least one liquid–gas transition, a pressure drop appears at the interface. Liquid plugs can be transported in any direction, especially toward the center of the disk also in a hydrophilic channel using the capillary pumping mechanism. This is due to the fact that the capillary pressure is independent of the angular and radial position of the channel. It, for example, allows the complete initial priming of microchannels if the proceeding meniscus experiences a higher capillarity than the capillary pressure at the other end of the liquid plug. Most of the microfluidic structures for the different unit operations described in this section are based upon the interplay of centrifugal and capillary transport mechanisms.

2.13.5.2.2 Valving

Stopping of liquid flows, that is, the realization of a liquid valve, can be realized with different microfluidic structures on the centrifugal platform. A very simple valve arises at the sudden expansion of a microfluidic channel, e.g., into a bigger reservoir. The valving mechanism of this capillary valve is based on the surface tension that develops at this expansion and prevents further proceeding to the liquid–gas interface (**Figure 22(a)**). Under rotation, however, a certain pressure load

$$p_\omega = \rho\omega^2\overline{r}\Delta r \qquad [4]$$

due to the artificial gravity is applied on the liquid–gas interface. It depends on the liquid density ρ, the frequency of rotation ω, the mean radius $\overline{r}$, and the radial length Δr of the liquid plug (Duffy *et al.* 1999). As soon as this pressure exceeds the surface tensional counter pressure, the valve breaks. For a given liquid plug position and length, i.e., for a given set of geometric parameters, the valve can be influenced by the frequency of rotation only and a critical burst frequency ω_c can be attributed to every valve structure.

Another possibility to stop the liquid flow within a channel is the local hydrophobic coating of the channel walls. The hydrophobic patch defines the stop position for the liquid–gas interface within a hydrophilic channel of constant channel cross section (**Figure 22(b)**). Also this valve is opened as soon as the rotational frequency exceeds the critical burst frequency ω_c and the pressure load due to the liquid plug above the hydrophobic valve overcomes capillarity. The net capillary pressure

$$\Delta p_\theta \propto 2\sigma\left(\frac{\cos(\theta_1)}{r_1} - \frac{\cos(\theta_2)}{r_2}\right) \qquad [5]$$

of a liquid plug with surface tension σ, located in a channel of radius r_1 at the first and r_2 at the second liquid–gas interface can be used besides the radial plug length and position of the plug to engineer the critical burst frequency ω_c.

A third method utilizes the interplay of inertial and capillary forces in a different way. At high frequencies of rotation, the centrifugal force tends to leverage of the two liquid–gas interfaces within a U-shaped hydrophilic siphon channel of different cross sections (**Figure 22(c)**). Only a small difference in the radial position caused by the unequal channel cross sections and thus capillary pressures can be observed, which is negligible for high frequencies of rotation. Below a critical frequency ω_c, however, the meniscus proceeds toward the smaller duct due to the higher capillary force therein. As soon as the meniscus has passed the bend and proceeds in a radial outward direction again there comes a moment when a net radial length $\Delta r > 0$ exists. From that moment on, the centrifugal force supports the moving meniscus and the whole liquid plug escapes the siphon.

All the valves described are passive structures that do not need any movable parts within the chip. They are opened or closed by the frequency of rotation only. Therefore they can be considered as preprogrammed microfluidic networks with imprinted geometric parameters once fabricated. An alternative approach for the control of liquid flows on the centrifugal platform is followed by the company Spin-X Technologies (2006), Switzerland. A laser beam individually opens fluidic interconnects between different channel layers on a plastic substrate (virtual laser valve, VLV). This enables an online control of the liquid handling process on the rotating module almost independently of the geometry of the structures. Consequently, metered volumes and incubation times can be manipulated within a wide range. Hence, the Spin-X platform works with a standardized fluidic cartridge that is not custom-made for each specific application, but can be programmed right before the measurement or even online during a running process.

2.13.5.2.3 Metering and aliquotting

The valving principles, described in Section 2.13.5.2.2, present the basic fluidic function for many unit operations on the centrifugal platform. Using hydrophobic valves, for example, the exact metering of liquid volumes can be accomplished, which is one of the most important unit operations needed for all quantitative assay protocols. Especially in point-of-care applications, only an undefined sample volume, for example, a droplet of blood derived from the fingertip, is available. However, for quantitative analysis a defined sample volume is required, which has to be defined within a designated metering structure. The high precision of microfabrication technologies facilitates small coefficients of variations (CVs = standard deviation/mean value) down to metered volumes in the lower nanoliter range (Steinert *et al.* 2007).

Typical metering structures exhibit a hydrophobic valve at the outlet and an overflow channel connected to a metering chamber of designated volume (Steigert *et al.* 2005). During the metering process, the liquid initially fills the metering chamber at a frequency below the burst frequency ω_c. The liquid stops at the hydrophobic valve (**Figure 23**). Venting of the chamber is done via the outlet or a separate venting channel. After the metering chamber is completely filled with liquid, the excessive fluid volume is removed via an overflow channel and is cut off at a defined position at the inlet of the structure. Thereby, the volume is defined to the geometrically imprinted volume of the metering chamber while the valve still holds back the liquid since the centrifugal pressure falls short of the critical pressure of the valve.

In the last step, the frequency is increased and the hydrophobic valve breaks to release the metered liquid portion through an outlet channel toward further downstream processes. Using this technology, metered liquid volumes from the microliter to the nanoliter range with an extremely high reproducibility, e.g., a CV < 5% for a volume of 300 nl, have been demonstrated (Steigert *et al.* 2006).

By arranging several metering structures of, for example, different volumes interconnected via an appropriate distribution channel, simple aliquotting structures can be realized (Zoval and Madou 2004).

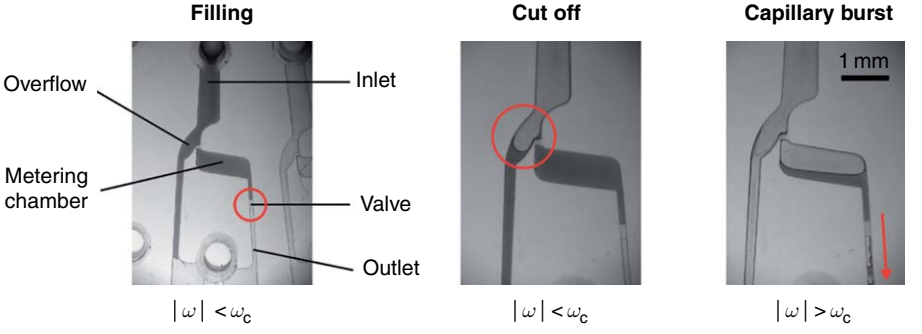

Figure 23 Metering structure based on a hydrophobic valve. In the initial filling stage, the fluid network is primed with an undefined sample volume. After the metering chamber is filled, the residual fluid is cut off at a frequency still beyond the critical burst frequency of the valve ω_c. In the last step the frequency is increased over the burst frequency of the valve leading to a radial drainage of the metered volume through the structures outlet. (Source: Steigert J, Grumann M, Brenner T, Riegger L, Harter J, Zengerle R, Ducrée J 2006 Fully integrated whole blood testing by real-time absorption measurement on a centrifugal platform. *Lab Chip* **6**, 1040–4. Reproduced by permission of The Royal Society of Chemistry.)

These structures split a sample into several defined volumes enabling the parallel conduction of several assays from the same sample. Multiparameter diagnostics and pharmaceutical screening are possible applications where such an aliquotting structure is required.

2.13.5.2.4 Mixing

Mixing of miscible fluids within the laminar regime on the centrifugal platform can be in the simplest case accomplished by joining two microfluidic channels to a single meander-shaped channel. By maintaining the feeding flows, a stoichiometric correct mixing ratio can be achieved. The required length of the mixing channel depends on the flow rate, i.e., the retention time within the channel, as well as the diffusional velocity in the transversal direction. In general, mixing processes can be speeded up by increasing the interfacial area between the phases to be mixed. However, if two liquid streams are simply contacted within the laminar regime, the contact interface equals the channel height and does not increase in the downstream direction. An increasing interfacial area along the direction of flow is possible if the liquid moves not only along the channel but also perpendicular to it (transversal advection).

Considering mixing of continuous liquid flows within a radial-directed rotating channel, the transversal-directed Coriolis force f_C automatically generates a transversal liquid flow $u(f_C)$ as depicted in **Figure 24** (Ducrée *et al.* 2005, 2006, Haeberle *et al.* 2005). The Coriolis force scales with the radial flow velocity $u(f_\omega)$, which has its maximum in the center of the channel due to the parabolic radial velocity profile (no slip boundary condition at the channel walls). Therefore, at the center of the channel, the flow experiences the highest Coriolis force f_C directed laterally. This leads to a transversal liquid movement $u(f_C)$ from the center to the left and backward on the upper and lower channel parts where the smallest Coriolis counter force is present. This transversal advection, also called Coriolis stirring, constantly increases the interfacial area between the two concurrent liquid flows and thus accelerates mixing.

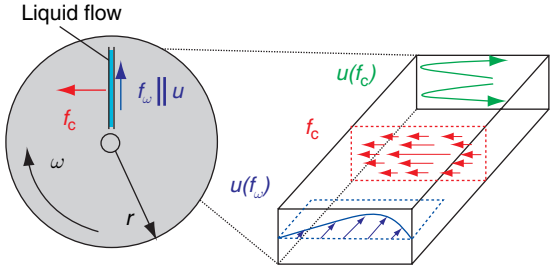

Figure 24 The Coriolis stirring effect within a radial, rotating microchannel. The inhomogeneous transversal Coriolis force field f_C initiates a transversal advection $u(f_C)$ thus increasing the interface between two liquid streams. (Source: Haeberle S, Brenner T, Schlosser H P, Zengerle R, Ducrée J 2005 Centrifugal micromixer. *Chem. Eng. Tech.* **28**, 613–16. Reproduced by permission of Wiley VCH.)

A continuous centrifugal micromixer, utilizing the Coriolis stirring effect, showed an increasing mixing quality toward very high volume throughputs of up to 1 ml s^{-1} per channel. This is enabled by the increasing impact of the transversal Coriolis force toward higher flow rates (Haeberle *et al.* 2005). It opens an interesting and so far barely explored microprocess engineering field for centrifugal microfluidic technologies, which however is not discussed in detail here.

Besides the mixing of continuous liquid flows, the homogenization of discrete and small liquid volumes inside small chambers is also of importance especially when analyzing small sample volumes (batch-mode mixing). One possibility to enhance the mixing of two small liquid portions is to guide them into a common chamber. The streams violently splash against a common chamber wall causing their efficient mixing (Zoval and Madou 2004).

Another possibility is the active agitation of the liquid within a mixing chamber either by using periodically actuated magnetic microparticles under rotation (Grumann *et al.* 2005) or by means of an inertial effect induced by a fast change of the sense of rotation (shake-mode mixing). The course of mixing within a microchamber under the impact of the shake mode is depicted in **Figure 25** (*left*). The course of mixing strongly depends on the applied mixing scheme as depicted in **Figure 25** (*right*). The shake-mode mixing under an alternate spinning protocol drastically enhances the mixing efficiency. Characteristic mixing times on the order of several seconds compared to several minutes for pure diffusion-based mixing can be achieved. The shake-mode mixing has been integrated into a complete colorimetric assay protocol as described in Section 2.13.5.3.4.

2.13.5.2.5 Switching

Switching liquid flow from one common channel to one of at least two continuative channels is very important, e.g., for extraction protocols. A promising switching method on the centrifugal platform should

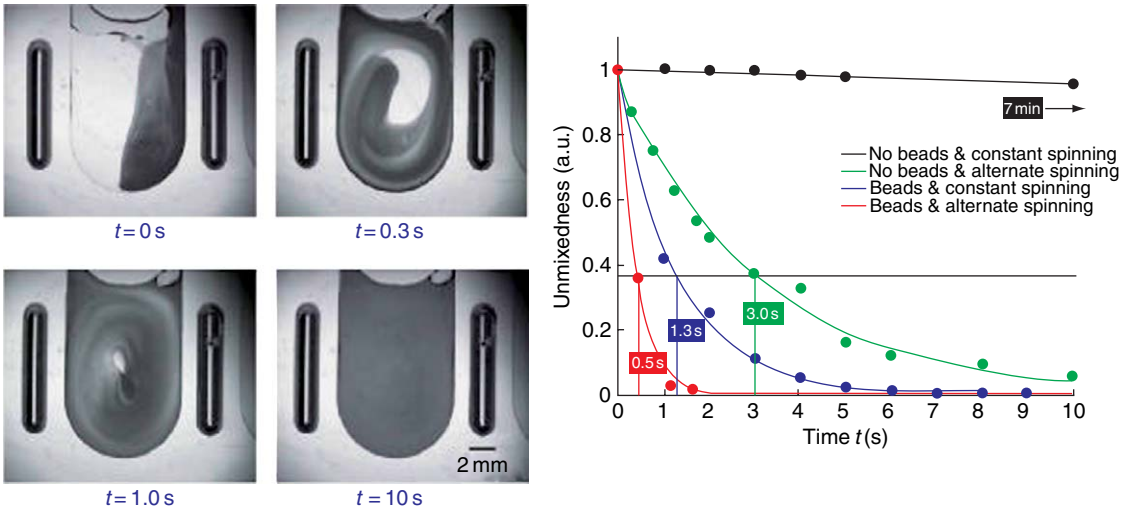

Figure 25 *Left*: Two initially separated liquids (pure water on the left and ink on the right) are mixed under the impact of the shake-mode mixing within 10 s. *Right*: Typical mixing times for different mixing schemes: no beads and constant spinning represent mixing via diffusion only. Alternate spinning describes the shake-mode mixing scheme. Additional magnetic beads within the chamber can be used to further decrease mixing times. (Reprinted with permission from Steigert J, Grumann M, Brenner T, Mittenbühler K, Nann T, Rühe J, Moser I, Haeberle S, Riegger L, Riegler J, Bessler W, Zengerle R, Ducrée J 2005 Integrated sample preparation, reaction, and detection on a high-frequency centrifugal microfluidic platform. *J. Assoc. Lab. Autom.* **10**, 331–41. Copyright 2005 Elsevier.)

be possible without the integration of any active or moving part. Following this philosophy, a liquid switch availing the transversal Coriolis force to guide liquid flows between two outlets at the branching of an inverse Y-shaped channel has been presented (Brenner *et al.* 2005).

The functional principle is depicted in **Figure 26**. Depending on the sense of rotation, the Coriolis force is either directed to the left (counterclockwise rotation) or to the right (clockwise rotation). One common radial channel is split toward a left and a right reservoir at the branching. The liquid stream is directed into one of these reservoirs depending on the direction of the Coriolis force, i.e., the sense of rotation. A fully reliable switching behavior has been reported for frequencies above ~55 Hz for a continuous flow. An improved version of Coriolis-based switching operates on individual droplets and enables switching of small flow rates of 160 nl s^{-1} only at low frequencies down to a few Hz (Haeberle *et al.* 2006b).

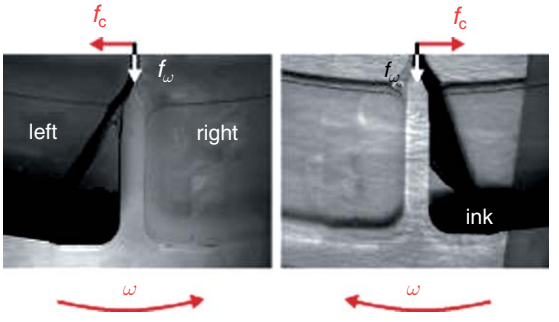

Figure 26 Liquid streams are switched between two possible outlet channels at the Coriolis flow switch, an inverse Y-shaped channel. (Source: Brenner T, Glatzel T, Zengerle R, Ducrée J 2005 Frequency-dependent transversal flow control in centrifugal microfluidics. *Lab Chip* **5**, 146–50. Reproduced by permission of The Royal Society of Chemistry.)

Another method for liquid routing based on different wetting properties of the continuative channels has been reported by Gyros AB (2006), Sweden. The liquid stream is initially guided toward a radial channel, exhibiting a hydrophobic patch at the beginning. Therefore, the liquid is deflected into another channel, not the hydrophobic channel next to the radial one. For high frequencies of rotation, the approaching liquid possesses sufficient energy to overcome the hydrophobic patch and is therefore routed into the radial channel. This enables the frequency-dependent routing of liquid flows between two consecutive channels (Ekstrand and Thorsen 2005).

2.13.5.2.6 Droplet formation

Monodisperse droplet emulsions can be generated in an adopted flow focusing structure under the centrifugal gravity field. Trains of water droplets dispersed into a continuous oil stream with droplet volumes

between 5 and 22 nl with a CV of the droplet diameter below 2% are reported (Haeberle *et al.* 2006c). The flow focusing structure contacts a central water-guiding channel to two symmetric oil flows at a junction. During the droplet formation process, a water plug is expelled out of the central channel into the junction area and is subsequently forced through a geometrical constriction. This leads to the controlled break-off of small water droplets into the continuous oil flow and thus a monodisperse droplet emulsion. Additional droplet-based unit operations like splitting of droplets or droplet sedimentation have also been realized on the centrifugal multiphase platform.

2.13.5.2.7 Separation

Within the artificial gravity field under rotation, different phases can be separated if they possess different mass densities. This process is called sedimentation and is used as a standard routine in laboratory centrifuges. Since lab-on-a-chip systems, especially within the field of point-of-care testing, deal with raw biological samples, which have to be pretreated before the analytical assay can be conducted, a system-immanent separation method is of great importance.

The extraction of plasma from a blood sample is the prevalent first step in a complete analytical protocol starting from an untreated whole blood sample. Since blood plasma is less dense than the white and red blood cells it is found in the upper phase, the so-called supernatant after sedimentation. The separation of the cellular and plasma phase in a sedimentation chamber, however, is just one part of a complete plasma extraction process. The second step is the spatial extraction of the gained plasma from the cellular pellet, located at the bottom of the chamber. This extraction is done by manual or automated pipetting in classic macroscopic plasma extraction protocols. However, to arrive at an extraction method capable of the seamless integration into automated centrifugal platform protocols, the plasma phase has to be extracted automatically within the microfluidic channel network.

Two methods have been proposed to achieve an integrated plasma extraction on the centrifugal platform. In the first method, plasma and cells are separated in a sedimentation chamber. A capillary extraction channel branches from the sedimentation chamber at radial position where only plasma is expected. It is used to extract the supernatant plasma phase at lower frequencies via capillary action (Schembri *et al.* 1995). The whole blood sample has to be metered prior the sedimentation process in order to guarantee proper function and also to result in a metered extracted plasma volume. A complete analyzing system using this extraction method is described in more detail in Section 2.13.4.3.

Another method uses a preseparation of the cellular and plasma phase during the sample flow through an azimuthal-aligned channel of just 300 µm radial width (Haeberle *et al.* 2006a). The obtained plasma fraction is thereafter split from the cellular components by a decanting process (**Figure 27**, *left*).

The whole extraction proceeds as follows: Initially, a raw blood sample is metered to a fixed volume defined by an overflow channel next to the outlet of the metering chamber. Subsequently, the metered sample is forwarded via the drain channel to the decanting structure. Within the drain channel the blood is preseparated with the plasma phase flowing on top of the cellular phase. The two joint streams separate when they enter the decant chamber. The more dense cellular phase sinks outward while the less dense plasma phase stays on top. When the decant chamber is entirely filled, pure plasma in the supernatant overflows into a plasma chamber (**Figure 27**, *right*). The course of separation concludes when the entire blood sample has been transported from the metering chamber into the

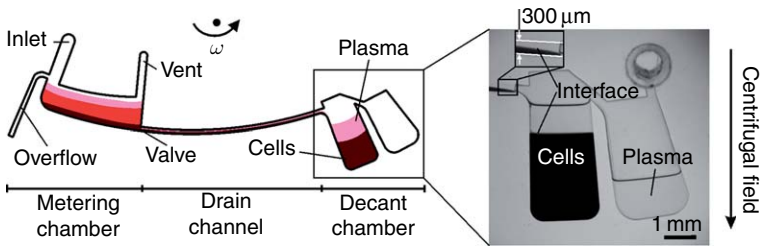

Figure 27 *Left*: Flow scheme of the decanting structure for plasma extraction from a raw blood sample. *Right*: Purified plasma is decanted into a separate reservoir while the cellular pellet is retained at the bottom of the decant chamber. (Source: Haeberle S, Brenner T, Zengerle R, Ducree J 2006a Centrifugal extraction of plasma from whole blood on a rotating disk. *Lab Chip* **6**, 776–81. Reproduced by permission of The Royal Society of Chemistry.)

decant and the plasma chamber. The extracted plasma volume is defined by the chamber geometries and can therefore be directly forwarded to further downstream processes, e.g., by a capillary duct.

This centrifugal flow separation technique extracts 2 µl of plasma from a raw blood sample that is initially metered to 5 µl. Typical separation times of 20 s can be achieved for moderate spinning frequencies of 40 Hz. The residual cell concentration in the bulk plasma is <1‰.

2.13.5.3 Application Examples

2.13.5.3.1 Blood test (Abaxis Picolo®)

The Abaxis Picolo® system (Abaxis Inc., 2006) is a centrifugal analyzer for near-patient testing (Schembri *et al.* 1992, 1995). The rotor, with a diameter of approximately 8 cm, is made of molded 2 cm-thick polymethylmethacrylate (PMMA) plastic (see **Figure 21**). It consists of a series of many interlinked chambers and passages. The movement of fluid is controlled by a series of stop junctions, capillaries, and siphons managed by the use of centrifugal force. The center of the rotor hosts a diluent container while dried reagent beads are placed in cuvettes in the periphery of the rotor. Fifteen cuvettes are reserved to analyze the patients' sample and further ten are used as internal quality control. The loading port for blood injection is coated with heparin to prevent blood coagulation.

The operator adds an unmetered blood sample between 90 and 120 µl. The sample preparation steps such as metering, blood separation, and mixing are performed in the rotor in an automatic fashion. Once the rotation starts, the centrifugal force propels the diluent outward into a chamber that contains a ball coated with dye. Simultaneously, the blood sample is metered to 75 µl and moves into the separation chamber, where 20 µl of plasma is obtained within 30 s. The blood plasma is afterwards diluted and distributed to the cuvettes for detection. The chemical reactions in the cuvettes are optically monitored and checked with an enzymatic control in the reference cuvettes before the results from the analysis are reported. The centrifugal platform enables point-of-care measurements of multiple analytes, e.g., glucose of whole blood samples in about 10 min. At present, Abaxis supplies the Piccolo platform for medical and veterinary diagnostics.

2.13.5.3.2 Enzyme-linked immunosorbent assay (LabCD)

Madou *et al.* from University of California, Irvine, CA, showed a series of capillary valves to perform enzyme-linked immunosorbent assays (ELISAs) on the centrifugal platform (Lai *et al.* 2004). An antibody is immobilized in the detection reservoir 2 in an off-chip protocol (**Figure 28**). Different reagents are then loaded into their corresponding reservoirs, numbered 3–7 on the CD, which is then mounted on a motor plate.

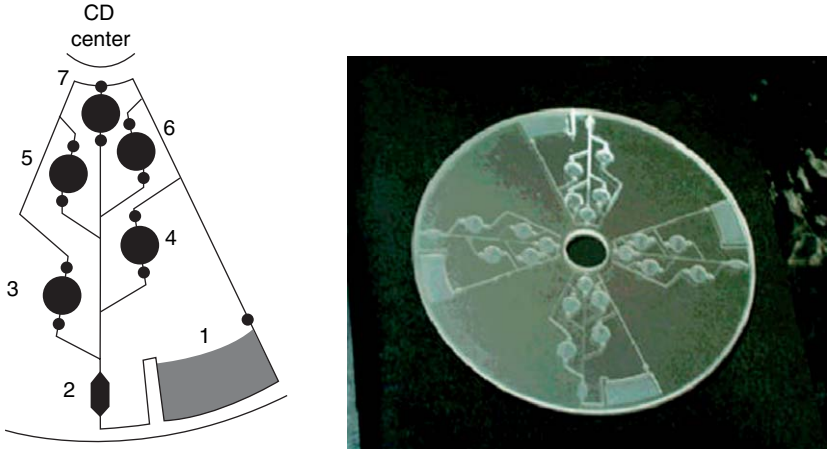

Figure 28 *Left*: Channel design for the enzyme-linked immunosorbent assay (ELISA) assay. Several reservoirs containing different sample and washing solutions can be opened serially depending on the frequency of rotation. *Right*: Picture of the compact disk fabricated by computer numerical control (CNC) milling with four identical assay structures. (Reprinted with permission from Lai S, Wang S, Luo J, Lee L J, Yang S T, Madou M J 2004 Design of a compact disk-like microfluidic platform for enzyme-linked immunosorbent assay. *Anal. Chem.* **76**, 1832–7. Copyright 2004 American Chemical Society.)

Under rotation (360 rpm), first the sample solution is released from reservoir 3 into reservoir 2 for the antigen–antibody binding process. The capillary valve at the outer radius of reservoir 3 is designed with the lowest burst frequency to accomplish an automated assay procedure. After an incubation step, reservoir 2 is washed with washing solution from reservoir 4 at a higher frequency of rotation (560 rpm, greater than burst frequency of reservoir 4). Following this serial flow-through assay scheme, the conjugate solution (reservoir 5) is released at 790 rpm, the detection chamber is washed (reservoir 6) at 1190 rpm, and finally the substrate solution (reservoir 7) is flushed through reservoir 2 at 1280 rpm. Immediately after the release of the substrate, the disk is stopped and the assay result is detected using an inverted fluorescent microscope.

It can be shown that the centrifugally conducted assay has the same performance in terms of detection range as the conventional method on the 96-well microtiter plate, while having advantages over the conventional method such as less reagent consumption and shorter assay time.

2.13.5.3.3 Protein quantification (Gyrolab Bioaffy®)

Gyros AB (2006), Sweden uses a flow-through sandwich immunoassay at the nanoliter scale to quantify proteins within the Gyrolab™ Workstation. Therefore, a column of prepacked and streptavidin-coated microparticles is integrated in each of the total 112 identical assay units on the microfluidic CD. Each unit has an individual sample inlet and a volume definition chamber that leads to an overflow channel. Defined volumes (200 nl) of samples and reagents can be added to the prepacked particle column (**Figure 29**). Samples and reagents can be added to a specific unit via an individual inlet port or via a common inlet feeding defined clusters. Capillary action draws samples and reagents into the microstructures where volumes are precisely defined. This enhances reproducibility and reliability as well as eliminates concerns about pipetting precision. After the sandwich assay protocol is completed, the assay result is read out using a detection reagent bound to the target protein and laser-induced fluorescence. The laser-induced fluorescent (LIF) detector is incorporated into the Gyrolab Workstation.

Using this technology, multiple immunoassays with 200 nl of sample have been carried out to determine the imprecision of the assay result. The day-to-day (total) imprecision (CV) of the immunoassays on the microfluidic CD is <20% (Honda *et al.* 2005). The assays were carried out within 50 min, while in comparison the traditional ELISA in a 96-well plate typically takes a few hours, with sample volumes of a few hundred microliters.

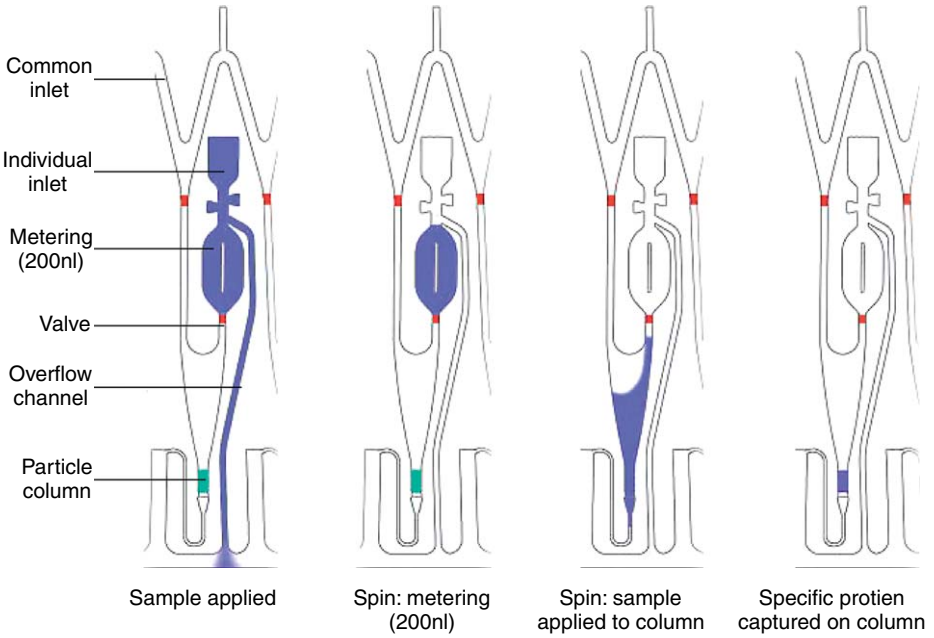

Figure 29 Metering step of the sandwich immunoassay protocol shown for one microstructure unit in Gyrolab Bioaffy® system. The sample is applied to the individual inlet port and metered to a volume of 200 nl. Subsequently, it flows through a column of functionalized particles. A certain protein specifically binds to a surface-immobilized capture protein and is read out in a subsequent assay step. (Source: GYROS AB 2006 Uppsala, Sweden, www.gyros.com, accessed 2006.)

2.13.5.3.4 Alcohol test (Bio-Disk)

A fully integrated colorimetric assay for the determination of the alcohol concentration in human whole blood has been shown on the centrifugal Bio-Disk platform (Steigert *et al.* 2006). After loading the reagents into the reagents reservoir, a droplet of untreated human blood derived from fingertip is loaded into the inlet port of the microstructure. All process steps of the assay are implemented by a fully automated frequency protocol.

First, a small 500 nl blood volume is metered from the sample and purged into the detection chamber at a frequency exceeding the burst frequency of the hydrophobic valves. At this frequency, the assay reagents also enter the reaction chamber. To enforce rapid mixing the sense of rotation is frequently reversed for 10 s, leading to a homogeneous mixture (shake-mode mixing). Thereby an enzymatic reaction is initiated by changing the color of the mixture depending on the alcohol concentration. During the subsequent sedimentation step, the disk is spun at a frequency of 30 Hz for 30 s so that all the cells contained within the blood sample settle at the radial outer end of the detection chamber. After sedimentation, the absorbance is monitored in real time during constant spinning for about 100 s to obtain the optical density of the mixture.

According to the Beer–Lambert law, the absorbance (or optical density) linearly depends on the molar extinction coefficient of the solution, which is governed by the products of the colorimetric reaction and thus the alcohol concentration. Since the absorbance scales with the optical path length l_{abs}, the sensitivity of this readout method can be enhanced by elongating the path of the laser beam through the analyte solution. A flat polymer substrate, however, enables only small optical lengths in readout schemes perpendicular to the disk surface. Therefore micromachined V-grooves placed on both sides of the detection chamber to deflect the laser beam by total internal reflection into the disk plane have been applied on one side of the disk (total internal reflection (TIR) set-up, **Figure 30**).

Using this automated assay and readout protocol the concentration of alcohol in human whole blood can be determined within 150 s only. The results are comparable to common point-of-care tests and require a minute blood volume of just 500 nl.

2.13.5.4 Strengths and Challenges of the Platform

The modular set-up of the system with cheap, disposable, and easy exchangeable plastic cartridges is certainly one major advantage of the centrifugal microfluidic platform, especially in the field of diagnostics. The cost-efficient fabrication predominantly originates in the simple and passive microfluidic elements that can be easily combined in a monolithic way within the same fabrication process. Those elements allow to implement all unit operations needed to perform complex assay protocols in an automated way. Due to the rotational symmetry of the disks optionally a high degree of parallelization can be achieved. All processes are controlled by the frequency of rotation

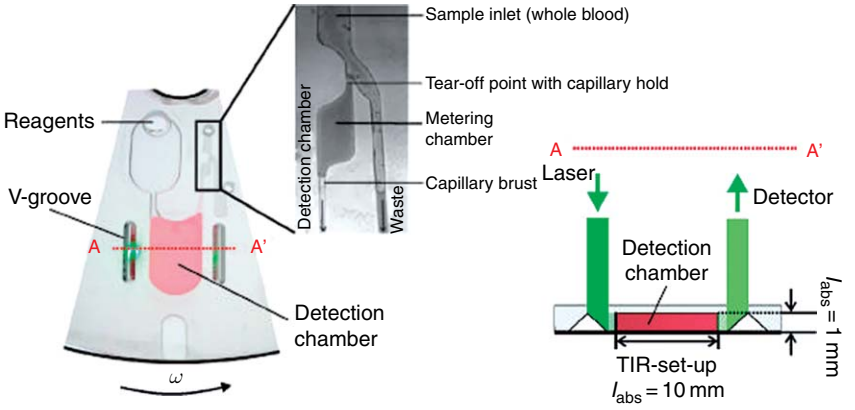

Figure 30 *Left*: Microfluidic structure for the fully integrated alcohol determination starting from a raw sample of human blood. First, the sample is metered and then mixed with the reagent within the detection chamber. *Right*: Readout is accomplished by the total inner reflection of a laser beam into the disk plane to elongate the optical path length l_{abs} from approximately 1 to 10 mm (TIR set-up). (Source: Steigert J, Grumann M, Brenner T, Riegger L, Harter J, Zengerle R, Ducrée J 2006 Fully integrated whole blood testing by real-time absorption measurement on a centrifugal platform. *Lab Chip* **6**, 1040–4. Reproduced by permission of The Royal Society of Chemistry.)

of one single macroscopic rotary engine only. In addition the centrifugal microfluidic platform can be easily applied to a wide range of different applications due to the fact that it allows scaling of the pulse-free flow rates by six orders of magnitude.

As soon as any additional actuation or sensing function is required on the module while rotating, things however become tricky from a technical point of view if a contact-free interfacing is not applicable. The platform also lacks flexibility compared to other that allow online programming of fluidic networks within one piece of hardware that fits all needs (see Sections 2.13.6.3 and 2.13.6.4). Most of the logic functions as well as their critical frequencies are imprinted into the channel network.

2.13.6 Droplet-based Microfluidic Platforms

2.13.6.1 Introduction

The principal idea behind droplet-based microfluidic systems is the use of single droplets as reaction confinements for biological assays or chemical reactions. Dominant interfacial and surface tensional forces in the microdimension enable the precise generation and spatial stabilization of these droplets. Since the droplets are kept isolated within an immiscible surrounding fluid like air or oil, lateral dispersion (Taylor dispersion) can be avoided while moving the droplets to different locations.

Droplets as reaction confinements can be regarded as nanoliter-sized batch reactors for mixing and reacting in contrast to the merely flow-through concept of the other platforms described so far. Many parallel screening reactions, each consuming only a minute amount of reagents, are enabled inside the small-sized droplets. The reproducibility of the reaction conditions is very high, since the droplet volume as well as the reaction conditions within the droplet, i.e., temperature and mixing conditions, can be controlled precisely. This is of paramount interest, especially for HTS applications in the pharmaceutical industry.

The droplet-based microfluidic systems can be fundamentally divided into two basic setups, the channel-based and the planar surface-based approach described in **Table 5**. The channel-based systems are mostly pressure-driven with the droplet generation and manipulation depending on the actuation via liquid flows within closed microchannels. On the planar surface-based platforms, droplets can be arbitrarily moved in two dimensions representing planar programmable laboratories on-chip. They are actuated by electrowetting-on-dielectric (EWOD) or surface acoustic waves (SAW).

The different mechanisms to transport and manipulate droplets on the three different droplet-based microfluidic platforms, namely the pressure-driven, electrowetting-driven, and SAW-driven platform, are discussed in the following sections.

2.13.6.2 Pressure-driven Unit Operations

2.13.6.2.1 Basic set-up

The pressure-driven, droplet-based platform depends on the two-phase liquid flow through microchannels. The two immiscible phases are dispersed into each other so that a sample liquid (e.g., aqueous

Table 5 Description of the two basic set-ups for droplet-based microfluidic platforms

Approach	*Schematic sketch*	*Description*
Channel-based		Liquid flow-driven actuation (pressure-driven) Simultaneous motion in one dimension, droplet movement defined by geometry, closed microchannels, fixed droplet arrangement in channel under stable conditions possible, e.g., for droplet storage
Surface-based		Actuation by SAW or EWOD, individual motion in two dimensions, arbitrary droplet movement on surface, planar (open) surface, online control of assay protocol

solution) forms plugs of a certain length, separated by the carrier liquid (e.g., oil) along the channel. The flow scheme is called segmented flow, since the size of the inner phase droplet exceeds the cross-sectional dimensions of the channel leading to squeezed liquid plugs. The two-phase flow is pumped throughout the channels by an externally applied pressure.

2.13.6.2.2 Droplet generation and metering

The most elementary unit operation on the pressure-driven, droplet-based platform is the initial generation of the droplets. This step can also be considered as metering, since the liquid volumes involved in the latter reaction within the droplet are defined during the droplet formation process. Generally, two different microfluidic structures have been reported for a controlled droplet generation, the flow focusing structure (Anna *et al.* 2003, Joanicot and Ajdari 2005), and the T-junction (Nisisako *et al.* 2002) (**Figure 31**).

Besides these two most prominent methods, other microfluidic structures for droplet formation, mainly for emulsification in the field of microprocess engineering, have also been proposed. Vertical microchannels leading into a steady continuous phase (Kobayashi *et al.* 2005) or liquid plugs sliding down from a microterrace (Sugiura *et al.* 2001), for example, are used to generate droplets with a higher throughput. Also the production of double emulsions, e.g., water-in-oil-in-water (W/O/W), has been shown in a serial arrangement of T-junctions (Okushima *et al.* 2004) or within more complex interleaved microcapillaries arrangements (Utada *et al.* 2005).

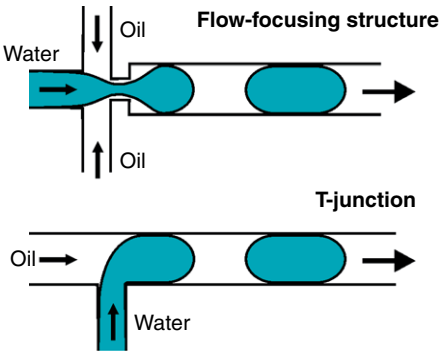

Figure 31 Both microfluidic channel arrangements, the flow-focusing structure depicted on the top and the T-junction depicted on the bottom, can be used to reproducibly initiate a droplet break-off. The sketches describe the arrangement of water as the sample and oil as the carrier phase.

The flow-focusing device and the T-junction, however, are more adequate for the injection of droplets into small microchannels inducing a segmented flow scheme. For both structures, the size of the droplet is influenced by the strength of the shear forces at the channel junction (higher shear forces lead to smaller droplets). Thus, the droplet diameter can be controlled via the flow rates and flow rate ratios of the two phases. In order to ensure a complete isolation of the single droplets, the wetting properties of the channel walls have to be assumed to be non-wetting for the sample phase. Thus, the sample phase droplets are not in contact with the walls and no leakage out of them can cause changing concentrations during a reaction.

Also the injection of gaseous bubbles into a continuous liquid stream at a flow focusing structure has been demonstrated (Garstecki *et al.* 2004, 2005b). Using these mechanisms, gas–liquid segmented flows can be generated within microchannels, which are, for example, used for the enhanced mixing of two liquid phases as described in Section 2.13.6.2.6.

2.13.6.2.3 Sample load

In order to use the droplets inside a channel as reaction confinements, the different liquid educts have to be loaded into the droplets first. A method to combine three different sample liquid streams by a sheath flow arrangement with subsequent injection as a common droplet into the carrier fluid has been shown by the group of Rustem F. Ismagilov at the University of Chicago, USA (Song *et al.* 2003b) (**Figure 32**). Different concentrations and ratios of two reagent substreams and a dilution buffer merge into one droplet and perform a so-called on-chip dilution (Song and Ismagilov 2003). The mixing ratios can be adjusted by the volume flow ratio of the three streams as depicted in the two exemplary photographs in **Figure 32**. Food dye has been used to color the reagents green and red and to visualize their portion within the generated droplet depending on the corresponding flow rates.

Using a combination of two opposing T-junctions connected to the same channel, the formation of droplets of alternating composition has been demonstrated (Zheng *et al.* 2004b). This method can be used for protein crystallization (see Section 2.13.6.2.9) or indexing within continuous flow screening experiments on the droplet-based platform. There, the first droplet of each droplet pair is used to conduct

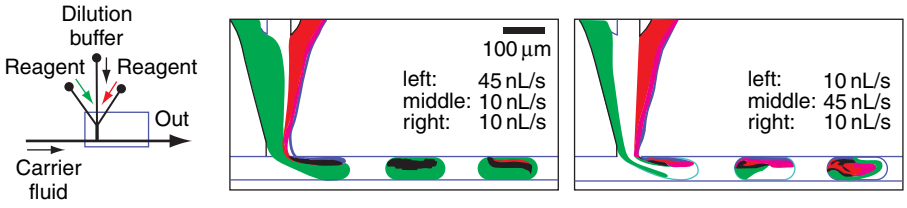

Figure 32 On-chip dilution depicted with two exemplary situations at the droplet formation T-junction. Different flow rates of the reagent streams (food dye colored green and red), separated by the transparent dilution buffer stream in the middle, are injected into the droplet. Different concentrations of the two reagents are then loaded into the droplet for reaction. (Reprinted with permission from Song H, Ismagilov R F 2003 Millisecond kinetics on a microfluidic chip using nanoliters of reagents. *J. Am. Chem. Soc.* **125**, 14613–19. Copyright 2003 American Chemical Society.)

the reaction, and the second droplet is used to index the composition of the first droplet. Using a similar technique, the injection of an additional reactant into a liquid plug moving through the channel at an additional downstream T-junction has also been demonstrated (Shestopalov *et al.* 2004).

However, not only liquid chemical reagents but also other components like cells have been loaded into droplets as reported in He *et al.* (2005). Therefore, a flow focusing device has been used with an aqueous cell suspension as the sample phase flowing through the central channel. The selective encapsulation of single cells into droplets of femtoliter volume has been demonstrated.

2.13.6.2.4 Merging and splitting of droplets

Merging of the droplets of different sizes and possessing different velocities to form single droplets has been demonstrated by Ismagilov *et al.* (Song *et al.* 2003b). In the same work, they also show the controlled splitting of droplets at a channel branching point. A constriction of the channels at the branching leads to longer and narrower droplets that could be split into two subdroplets. The size of the two split droplets was proportional to the relative flow rates in the two outlet channels. Using a similar method, the formation of droplet emulsions with controlled volume fractions and drop sizes has been demonstrated (Link *et al.* 2004).

2.13.6.2.5 Transport

The droplets are transported via a pressure-driven flow through the microchannels. Since the droplets typically are bigger in size than the channel cross section, they form a plug within the channel, segmenting the continuous phase (segmented flow). This keeps the phase configuration along the channel stable since no liquid is exchanged between the plug interspaces. This way, plugs can be moved spatially separated through a channel network.

This has been used, e.g., for a polymerization process. Liquid monomer droplets have been hardened by exposing UV light to the droplets- carrying microchannel. Using this method, nonspherical particles can also be generated by polymerizing within a microchannel of small cross section wherein the droplets are squeezed and thus become disk shaped (Dendukuri *et al.* 2005).

2.13.6.2.6 Mixing

The starting point of the mixing process is set to the time when the droplet is generated and released into the pressure-driven segmented flow (**Figure 32**) or when two droplets are merged. In the first case a buffer liquid separates the two reagent flows prior to the injection into a droplet. The two reagents are then mixed by a recirculating flow inside the droplets due to shear forces induced by the motion along the stationary channel wall (Tice *et al.* 2003). This effect is even more pronounced if two liquids of differing viscosities (2.0 and 18 mPa s) are mixed within the droplet as reported in Tice *et al.* (2004).

Based on the recirculation flow, a mixing scheme for the pressure-driven, droplet-based platform has been proposed using winding microchannels as depicted in **Figure 33** (Song *et al.* 2003a). Within each 90° channel curvature the orientation between the phase pattern in the droplet and the direction of motion is changed so that the inner recirculation leads to stretching and folding of the phases. Therewith, the number of phase lamellae within the droplet continuously increases by every bend along the channel. Under favorable conditions, submillisecond mixing can be achieved and has been employed for the multistep synthesis of

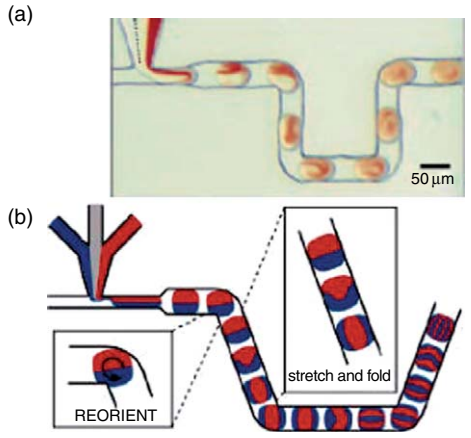

Figure 33 Mixing within liquid droplets moving through bending microfluidic channels shown (a) experimentally and (b) schematically. (Source: Song H, Bringer M R, Tice J D, Gerdts C J, Ismagilov R F 2003a Experimental test of scaling of mixing by chaotic advection in droplets moving through microfluidic channels. *Appl. Phys. Lett.* **83**, 4664–6. Reproduced by permission of American Institute of Physics.)

nanoparticles, for example (Shestopalov *et al.* 2004). A detailed and theoretical description of this mixing effect is given in Bringer *et al.* (2004).

Besides the mixing within liquid droplets, dispersed into another liquid carrier phase, mixing within the carrier phase can also be accelerated by a segmented flow. The injection of gas bubbles into a continuous liquid stream forming a segmented gas–liquid flow has been described by Klavs Jensen and his group at the MIT (Gunther *et al.* 2004, 2005). The gas bubbles are introduced into the liquid flow and initiate recirculation flows within the liquid segments in between due to the motion along the channel wall. The gas bubbles can be completely separated from the liquid stream using a planar capillary separator after the reaction is completed. Using this technology, the synthesis of colloidal silica particles has been demonstrated (Khan *et al.* 2004). Compared to a pressure-driven flow without segmentation, the axial dispersion is eliminated in the proposed gas–liquid flow scheme. Therefore, the residence time distribution of the reactants is also narrowed leading to less polydisperse particles.

Another microfluidic mixing scheme based on a gas–liquid segmented flow uses an additional repeated separation and recombining of the channel (Garstecki *et al.* 2005a). Homogenization of two aqueous streams has been demonstrated after 10 branching units for various flow rates (Reynolds numbers between 0.01 and 100) using this mixing scheme.

2.13.6.2.7 Incubation

The incubation time of the reagents combined inside a droplet at the injection position can easily be calculated at a certain point of observation from the traveling distance of the droplet divided by the droplet velocity. A unique feature of the platform is that a time-resolved monitoring of the incubation can easily be done by scanning along the channel from the injection point to more downstream positions. Thereby the kinetics of chemical reactions in the order of some milliseconds can easily be investigated and have been reported. On the other hand, incubation times on the order of a week for storing applications have been demonstrated. This is enabled by the droplet compartments that are separated by the carrier fluid, which prevents evaporation and diffusion. Using this approach, several 60 nl liquid droplets containing one or a few cells were generated within a microfluidic chip and were then flushed into a Teflon® capillary tube for cultivation. The cell densities were still as high as in conventional systems after 144 h of growth within the droplets (Martin *et al.* 2003).

2.13.6.2.8 Switching

Switching on the droplet-based and pressure-driven platform means the controlled routing of single droplets. All liquid routing technologies, available on the pressure-driven platform described in Section 2.13.3.2.5, can be used to switch droplets in the channel-type droplet-based microfluidic platform. If certain droplets out of a train of droplets should be separated, for example, an X-shaped channel crossing can be used. As soon as the droplet of interest passes the junction within the main flow, a short pressure pulse is applied at a side channel to direct the droplet into one of the two remaining outflow channels.

2.13.6.2.9 Application example: protein crystallization

Protein crystallization (see Section 2.13.4.3.1 for description) has been implemented on the pressure-driven, droplet-based platform by Ismagilov and coworkers (Zheng *et al.* 2003, 2004c). The basic principle is depicted in **Figure 34(a)**: droplets of three liquids namely the protein solution, the buffer, and the precipitant are dispersed into the oil carrier phase. The precipitant concentration inside the

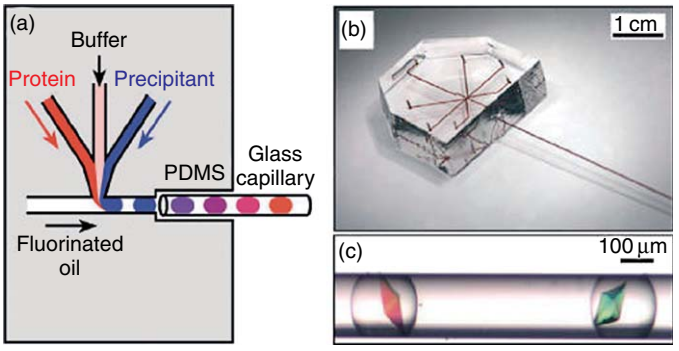

Figure 34 (a) Schematic illustration of the protein crystallization device and (b) the complete set-up consisting of a polydimethylsiloxane (PDMS) chip and a glass capillary. (c) Examples of thaumatin crystals that were grown inside droplets in a capillary. (Source: Zheng B, Tice J D, Roach L S, Ismagilov R F 2004c A droplet-based, composite PDMS/glass capillary microfluidic system for evaluating protein crystallization conditions by microbatch and vapor-diffusion methods with on-chip X-ray diffraction. *Angew. Chem. Int. Ed.* **43**, 2508–11. Reproduced by permission of Wiley VCH.)

droplet is adjusted via the buffer and precipitant flow rate. Therewith, different concentrations are generated and transferred into a glass capillary for later detection. Nonspecific protein adsorption onto the liquid–liquid interface can be suppressed by adding certain surfactants to the carrier phase (Roach *et al.* 2005). As depicted in **Figure 34(b)**, the droplets containing the protein crystals can be directly forwarded into a glass capillary ready for the X-ray analysis (Yadav *et al.* 2005).

As described earlier in this chapter, successful protein crystallization is initiated for a certain precipitation concentration only. Therefore, the conduction of many crystallization experiments within a short time and with a reduced amount of protein sample is favorable and is enabled by the described sample loading technique. Examples of crystallized thaumatin proteins are depicted in **Figure 34(c)**. The effect of mixing on the nucleation of protein crystallization has been investigated by combining the described crystallization structure with a winding mixing channel as described in Section 2.13.6.2.6 (Chen *et al.* 2005). Fast chaotic mixing has been found to be favorable for the formation of well-formed proteins within the droplets (Zheng *et al.* 2005).

Besides the described method for crystallization, an alternative process in which the concentration within one droplet is changed over time has also been developed by the group of Ismagilov, based on water diffusion between droplets (Zheng *et al.* 2004a, c). In this case, a carrier liquid that enables diffusion between the droplets, that is, a water-permeable liquid, is selected. Alternating droplets of protein and precipitant on the one hand and a high-concentration salt solution on the other hand are generated using two opposing droplet generation structures (Zheng *et al.* 2004b). Water diffuses through the oil carrier phase from the low salt concentration, i.e., from the protein-containing droplet to the high-concentration droplet. This steadily increases the concentration within the protein-containing droplet until the suitable crystallization condition is achieved.

Recent developments on the pressure-driven, droplet-based platform aim at HTS applications. Therefore a large number of droplets, each containing a different reagent, are separated and surrounded by a fluorinated carrier fluid within a microcapillary. In order to prevent coalescence during possibly long storage times, a gas bubble is injected between the droplets as an additional separation phase (Zheng and Ismagilov 2005). Based on this three-phase liquid–liquid–gas system, reliable and HTS assays can be performed, which could be an alternative for well plates in the future (Chen and Ismagilov 2006).

2.13.6.3 Electrowetting-driven Unit Operations

2.13.6.3.1 Basic set-up

The electrowetting effect was first described by Gabriel Lippmann in 1875 while the recent developments were initiated in the early 1990s by introducing the idea of using thin insulating layers to separate the conductive liquids from the metallic electrodes in order to eliminate the problem of electrolysis (taken from Mugele and Baret (2005) on electrowetting). This paved the way for the

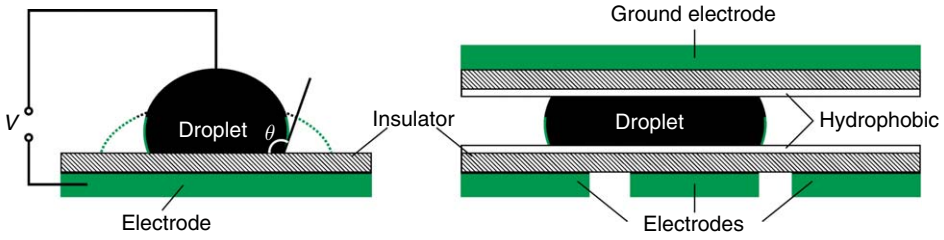

Figure 35 *Left*: The electrowetting principle. If a voltage V is applied between a conductive liquid and an electrode separated by an insulating layer, the contact angle θ of the liquid–solid interface can be decreased. *Right*: Schematic diagram of the electrowetting actuation of liquid droplets. Several individual addressable control electrodes (bottom) are used to locally change the contact angle and thereby initiate a droplet movement.

application of the electrowetting effect as a liquid propulsion principle for lab-on-a-chip systems.

The principal setup of an EWOD (Lee *et al.* 2002) setup is depicted in **Figure 35** (*left*) with a liquid droplet on top of an insulating dielectric layer. A voltage V can be applied between the conductive liquid droplet and the electrode leading to a change in the contact angle, θ

$$\gamma_{lg}\cos\theta = \gamma_{sg} - \gamma_{sl} + \frac{1}{2}\frac{\varepsilon_0\varepsilon_r}{d}V^2 \qquad [6]$$

depending on the interfacial tension at the liquid–gas interface γ_{lg}, solid–gas interface γ_{sg}, and solid–liquid interface γ_{sl}. The thickness of the insulator d and the dielectric parameters ε_0 and ε_r define the impact of a voltage change on the contact angle. So EWOD can be simply described as a tool to control the contact angle of conductive liquids (Mugele *et al.* 2005).

Using the EWOD set-up, a microfluidic actuation method for moving droplets between two parallel electrodes has been published by Pollack *et al.* (2000) from the Duke University in Durham and by Chang-Jin (CJ) Kim from the University of California, Los Angeles, CA (UCLA) (Lee and Kim 2000). A schematic cross-section of an EWOD actuator is depicted in **Figure 35** (*right*). Several individual addressable control electrodes are located on the bottom of the device to control the droplet path. They are typically arranged in 2D arrays. An additional hydrophobic layer (mostly Teflon) is added to the insulator surface to enhance the droplet movement. A common ground electrode in contact with the liquid droplet replaces the extended electrode.

The droplet, which is enclosed between the two electrode plates, features a certain volume so that it covers parts of two addressable electrodes at all times. If a voltage is applied on one of the control electrodes covered by the droplet, the contact angle is reduced at this part of the droplet. This initiates droplet movement along the paths given by the activated pads. Because the path of the droplets is determined by the pattern of electric potentials, the EWOD-driven, droplet-based platform is easily programmable. This allows different assays to be run by different programs on the same piece of hardware.

Besides the transport of aqueous solutions, several other liquids like organic solvents, ionic liquids, aqueous surfactants solutions (Chatterjee *et al.* 2006), and also biological fluids like whole blood, serum, plasma, urine, saliva, sweat, and tears (Srinivasan *et al.* 2004) have also been successfully transported on the EWOD droplet-based platform.

An alternative actuation principle for surface-based droplet manipulation that does not require a second electrode in contact with the droplet is dielectrophoresis. The basic unit operations, like droplet generation, movement, metering, and merging, using this alternative actuation have been demonstrated recently (Gascoyne *et al.* 2004, Schwartz *et al.* 2004). However, they are not discussed in detail in the following sections that focus on EWOD-based unit operations only.

2.13.6.3.2 Metering

The dispensing, i.e., initial metering unit operation, is probably the most critical step on the EWOD-driven, droplet-based platform. Although droplets may be formed by simply pulling liquid out of a reservoir, the location of the tear-off can hardly be predicted. In the method depicted in **Figure 36**, metered droplets are formed from an on-chip reservoir in three steps (Srinivasan *et al.* 2004). First, a liquid column is extruded from the reservoir by activating a series of electrodes adjacent to it. Second, once the column overlaps the electrode on which the droplet is to be formed, all the remaining electrodes are turned off to

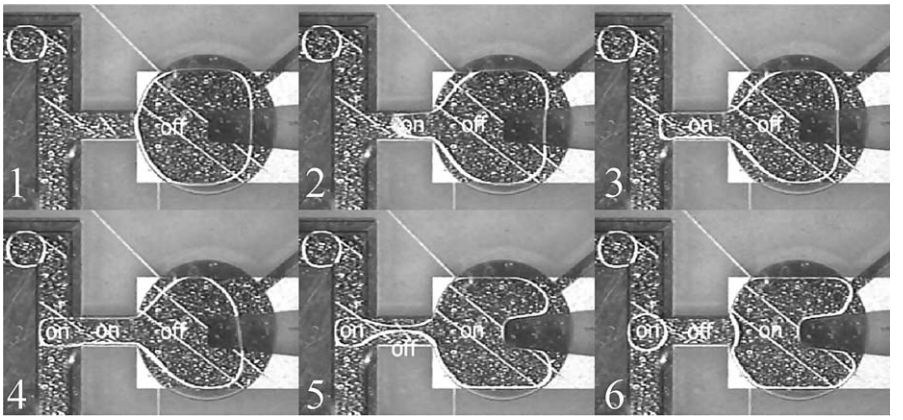

Figure 36 Droplet formation from an on-chip reservoir using electrowetting forces only. First, a liquid column is extruded from the reservoir and tears off after the connecting electrode is turned off. (Source: Srinivasan V, Pamula V K, Fair R B 2004 An integrated digital microfluidic lab-on-a-chip for clinical diagnostics on human physiological fluids. *Lab Chip* **4**, 310–15. Reproduced by permission of The Royal society of Chemistry.)

form a neck in the column. The reservoir electrode is then activated in the third and last step to pull back the liquid and break the neck completely to form a droplet. Using this droplet metering structure, droplets of 20 nl volume can be generated with a standard variation below 2% (Srinivasan *et al.* 2004).

Since the droplet dispensing is a crucial step for the performance and the accuracy of all assays on the EWOD platform, additional measures for a controlled liquid metering such as on-chip capacitance metering for volume control (Ren *et al.* 2004) or the use of numerical methods for the design of EWOD structures (Berthier *et al.* 2006) have been proposed.

2.13.6.3.3 Mixing

The most basic of miscible liquids within droplets on the EWOD platform is by oscillating the droplet between two electrodes. Before this active mixing scheme is used, the two droplets containing the liquids to be mixed have to be merged into a single droplet. This coalesced droplet is then moved along the electrodes in an oscillating fashion to induce advectional effects inside the droplet. An increasing frequency of droplet movement leads to reduced mixing times. The mixing process can be further accelerated by oscillating over a longer linear electrode array. The shortest mixing time for two 1.3-µl droplets in linear oscillation on four electrodes was about 4.6 s (Paik *et al.* 2003b). In another work, the mixing time was further reduced to less than 3 s using 2D arrays (Paik *et al.* 2003a).

2.13.6.3.4 Merging and splitting of droplets

Together with droplet generation from a reservoir and the droplet transport along electrode arrays, the controlled merging and splitting of droplets complete the four fundamental fluidic operations considered essential to build digital microfluidic circuits for lab-on-a-chip applications (Cho *et al.* 2003).

The realization of droplet splitting and merging on three linearly aligned EWOD electrodes is depicted in **Figure 37** (Pollack *et al.* 2002). The initial droplet volume is first elongated toward the middle electrode by applying a voltage on it (**Figure 37(b)**). After a certain time delay, required for the stabilization of the droplet, the voltage is switched from the middle to the right electrode, initiating a division of the droplet into two subdroplets placed on the left and the right electrode, as depicted in **Figure 37(c)** and **37(d)**. For a subsequent merging of the droplets, the voltage is again switched from the right to the middle electrode, moving the right subdroplet back again to the middle position and bringing it in contact with the left subdroplet (**Figure 37(e)**–**(f)**).

2.13.6.3.5 Readout

Different readout schemes for biochemical assays have been applied to the EWOD-driven, droplet-based platform. Colorimetric, enzymatic assays that are important for diagnostic applications have been successfully implemented and glucose concentration measurements on several biological fluids (serum, plasma, urine, and saliva) with good comparable results have been demonstrated (Srinivasan *et al.* 2004).

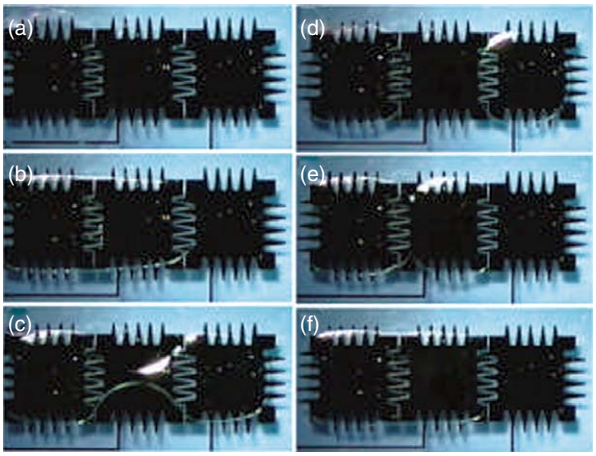

Figure 37 A sequence of photographs showing the droplet splitting and merging. (a) Initially, only the left electrode is activated. (b) The middle electrode is then activated and, (c) and (d) after a delay, the voltage is switched from the middle to the right electrode resulting in division of the droplet. (e) and (f) The original droplet is reassembled by switching the voltage on the right electrode back to the middle electrode. (Source: Pollack M G, Shenderov A D, Fair R B 2002 Electrowetting-based actuation of droplets for integrated microfluidics. *Lab Chip* **2**, 96–101. Reproduced by permission of The Royal Society of Chemistry.)

Another example with regard to the use of an EOWD system for the automated sample preparation of peptides and proteins for matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) is reported (Wheeler *et al.* 2004). In this work, standard MALDI-MS reagents, analytes, concentrations, and recipes have been demonstrated to be compatible with this technique, and mass spectra comparable to those collected by conventional methods were obtained.

2.13.6.4 SAW-driven Unit Operations

2.13.6.4.1 Basic set-up

An alternative to the electrowetting-based actuation of droplets on a plane surface has been proposed by Achim Wixforth and his group at the University of Augsburg, Germany (Wixforth 2003). The approach is based on SAW, which are mechanical waves with amplitudes of typically only a few nanometers. In contrast to ordinary sound waves, which are of longitudinal type, SAW are transversal waves. Their amplitude can be either parallel to the surface (Love waves) or perpendicular to the surface (Rayleigh waves) or of mixed type. For the manipulation of droplets on the SAW-based platform, typically Rayleigh waves are used.

The SAW are generated by a piezoelectric transducer chip (e.g., quartz), which can be fabricated by placing interdigital electrodes (interdigital transducer, IDT) on top of a piezoelectric layer, for example. Liquid droplets are placed on the hydrophobic surface of the chip and can be moved by the SAW on the surface. Appropriate AC signals are applied to the electrodes only at a certain region of the piezoelectric layer. Thus the SAW are exclusively generated at the desired location and can be focused on the droplet. If the acoustic pressure exerted on the liquid droplet is high enough, the droplet can be deformed or even be moved as depicted in **Figure 38** (Wixforth *et al.* 2004).

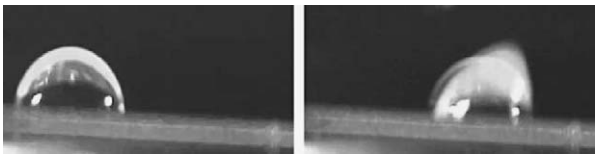

Figure 38 Side view of an approximately 50-nl droplet on the hydrophobic surface (contact angle of about 90°) of a piezoelectric substrate. *Left*: Resting droplet. *Right*: The droplet is hit by SAW impinging from the left resulting in a momentary asymmetry of the wetting angles of the droplet. (Source: Wixforth A, Strobl C, Gauer C, Toegl A, Scriba J, von Guttenberg Z 2004 Acoustic manipulation of small droplets. *Anal. Bioanal. Chem.* **379**, 982–91. With kind permission of Springer Science and Business Media.)

This approach is also sometimes referred to as flat fluidics, because no cover or slit is required as in the EOWD approach but only a flat surface where the SAW are generated is needed. Today, this technology is being pushed forward by the company Advalytix AG (2006), Germany.

2.13.6.4.2 Metering

Metering is accomplished by a combination of locally changed wetting properties of the surface and the actuation via SAW. One possible metering process is depicted in **Figure 39**. An initial water plug of approximately 100 nl is placed on an oval hydrophilic zone on the chip surface (**Figure 39(a)**). After the first actuator (IDT) is activated, SAW propagate horizontally toward the liquid plug, pushing it to the right across another small hydrophilic metering spot (**Figure 39(b)**). After the actuation, the liquid volume withdraws to the hydrophilic regions on the chip, leaving behind a small metered liquid portion (**Figure 39(c)**). This droplet is subsequently moved upward by another IDT for

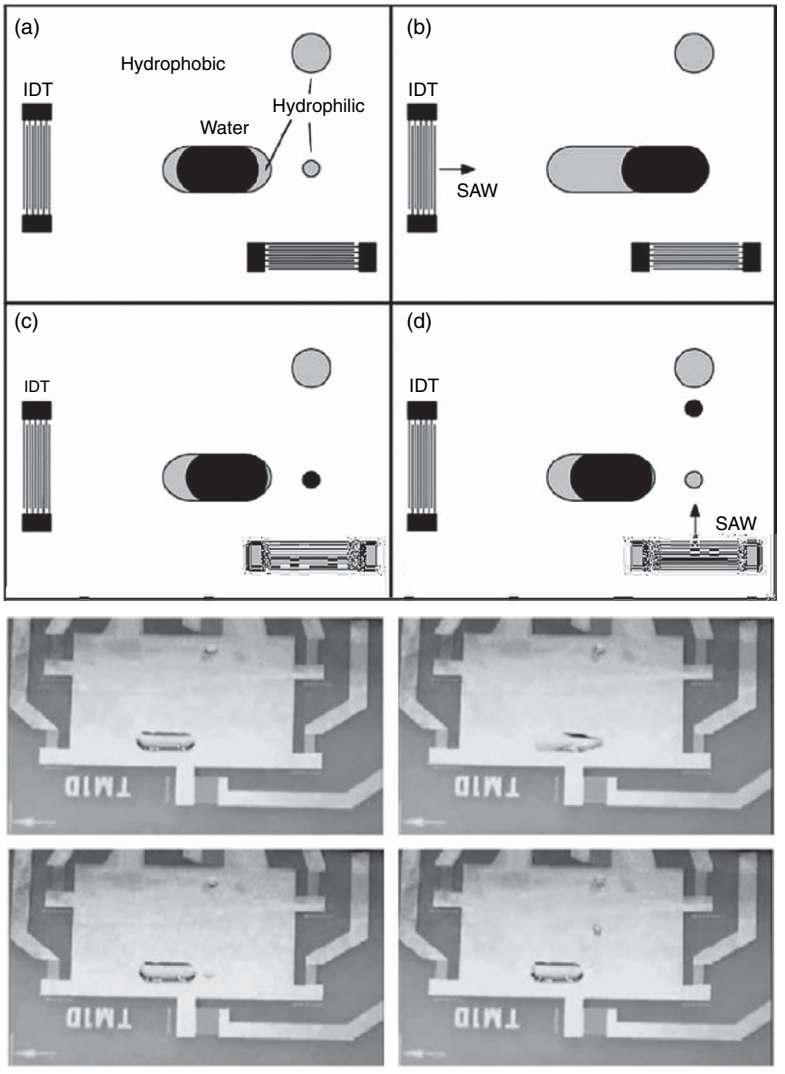

Figure 39 Acoustically driven metering process on the SAW platform. (a)–(d) Hydrophobic and hydrophilic areas are indicated in the schematic sketch on the top. First, the horizontally acting interdigital transducer (IDT) pushes the water droplet to the right across the hydrophobic substrate. After the actuation, the droplet withdraws meanwhile separating a small liquid volume, which remains at the small hydrophilic spot, as depicted in (c). In the last step, this metered liquid portion is pushed upward toward another hydrophilic zone. Corresponding photographs of the actual experiment are also depicted. (Source: Wixforth A, Strobl C, Gauer C, Toegl A, Scriba J, von Guttenberg Z 2004 Acoustic manipulation of small droplets. *Anal. Bioanal. Chem.* **379**, 982–91. With kind permission of Springer Science and Business Media.)

further processing (**Figure 39(d)**). At the bottom of **Figure 39**, a sequence of experimental photographs shows the metering process on the open chip surface.

2.13.6.4.3 Mixing

Mixing presents a system-immanent unit operation on the SAW-driven, droplet-based platform. A droplet, which is placed on the substrate and is hit by SAW, experiences an internal streaming due to the vibrating forces of the wave. If the amplitude is not large enough for a droplet movement, the liquid inside the droplet is efficiently stirred while its position on the substrate is retained. The internal streaming is depicted in **Figure 40** where a fluorescent dye is dissolved into a 50-nl droplet under SAW agitation.

2.13.6.4.4 Merging and splitting of droplets

Using the SAW-based mechanism for droplet movement in combination with a certain pattern of different wetting areas on the chip surface, droplet splitting as described in Section 2.13.6.4.2 as well as droplet merging can be accomplished.

The splitting of one droplet into several smaller volumes of the same size, i.e., aliquotting, is realized by moving the initial droplet over a hydrophobic/hydrophilic chessboard zone. Since the transport of a droplet depends nonlinearly on the droplet size, the initial droplet of bigger volume is constantly moved forward, while small, picoliter-sized droplets remain on the hydrophilic parts of the wetting pattern (Wixforth 2003).

2.13.6.4.5 Incubation and entrapment

For some assay protocols, longer incubation steps at elevated temperatures are also required, e.g., for a PCR amplification. The liquid plug is placed above a microheating element on the substrate surface for these incubation steps. However, since the nanoliter-sized droplet possesses a high surface-to-volume ratio, the liquid volume decreases rapidly due to evaporation. Hence to avoid evaporation, the aqueous liquid plug is covered with an oil plug having a smaller contact angle. This droplet in droplet configuration still can be moved via SAW on the substrate surface. Using this technology, a PCR assay within a 200-nl droplet enclosed in mineral oil was performed with an online monitoring of the DNA concentrations and provided a sensitivity of 0.1 ng (Guttenberg *et al.* 2005).

2.13.6.4.6 Readout

The fabrication of the electrodes for the actuators (IDT) as well as the fabrication of the wetting patterns on the substrate is done by high-precision lithographic processes. Therefore, heaters, electrodes, or different types of sensors based on surface micromachining can easily be integrated in a straightforward way. Also, optical readout schemes have been realized for the online fluorescent monitoring of the RT-PCR progress, for example (Guttenberg *et al.* 2005).

2.13.6.5 Strengths and Challenges of the Platform

General advantages of droplet-based microfluidics are the small liquid volumes of the droplets reducing reagent and sample consumption and thus paving the way for HTS applications. Additionally, the batch-mode operation scheme used in the nanoliter- to microliter-sized droplets represents a consistent further development of the classic assay protocols in, for example, well plates.

The pressure-driven approach combines these advantages with the high-throughput capabilities in a quasi-continuous operational scheme. The completely enclosed liquid droplets furthermore allow the incubation and storage of liquid assay

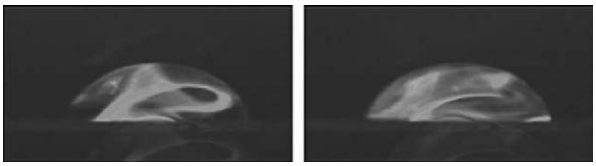

Figure 40 Internal streaming is induced within an approximately 50-nl droplet, hit by SAW. The internal mixing process is visualized by a fluorescent dye placed on the surface of the chip, which is dissolved by the SAW agitation. (Source: Wixforth A, Strobl C, Gauer C, Toegl A, Scriba J, von Guttenberg Z 2004 Acoustic manipulation of small droplets. *Anal. Bioanal. Chem.* **379**, 982–91. With kind permission of Springer Science and Business Media.)

results over a long period of time without evaporation. However, the microfluidic functionality is engraved by the channel design and cannot be adopted during an assay, for example.

In contrast, the surface-based actuation schemes (EWOD and SAW) come up with a high flexibility since liquid processing paths can be freely programmed. In addition, the simple setup without any moving parts can be fabricated very cost-efficiently using standard lithographic processes.

When comparing the EWOD and SAW principle for droplet actuation on the planar surface, the electrical change of the contact angle depends on the liquid properties and can cause electrolysis while the SAW principle allows easier adoption of the liquid properties. Evaporation of liquid and the long-term stability of the hydrophobic and hydrophilic surface coatings are the major drawbacks of the surface-based techniques. Last but not least, all planar droplet-based platforms do not really work properly in nonplanar positions and therefore, for example, a handheld operation is not recommendable.

2.13.7 Free Scalable Noncontact Dispensing

2.13.7.1 Introduction and Motivation

The free scalable noncontact dispensing platform allows to deliver liquids as free-flying droplets onto planar substrates (e.g., microarrays), conventional containers such as well plates, or any other target. This approach is closest to the traditional lab routine, which is based on conducting assays via successive pipetting steps, manually or by automated lab equipment like robots. In these fields, the dispensing of droplets of different volumes (picoliter to milliliter range), from a single channel or up to thousands of channels in parallel, with different pitch sizes and individual controllability is required. An overview of the different fields of operation regarding the droplet volume on the one hand and the number of different liquids to be dispensed at once on the other hand is depicted in **Figure 41**. Here we focus on the simultaneous dispensing of a large number of different reagents in parallel and will not focus on noncontact printing technology in general (for an overview of ink-jet printing technologies, see Le (1998)). All the three highlighted operating principles are based on one microfluidic platform as described in Section 2.13.7.2.

2.13.7.2 Unit Operations

2.13.7.2.1 Metered dispensing

One functional unit of the free scalable noncontact liquid dispensing platform is based on the combination of a reservoir for holding the liquid, a nozzle chamber with a nozzle from which the liquid is dispensed, and a capillary channel connecting reservoir and nozzle chamber. Depending on the arrangement of these components as well as the actuation principle, liquid volumes from several tens of picoliters to several microliters can be dispensed. Arranging several units on a so-called dosage chip enables the handling of up to thousands of different liquids in

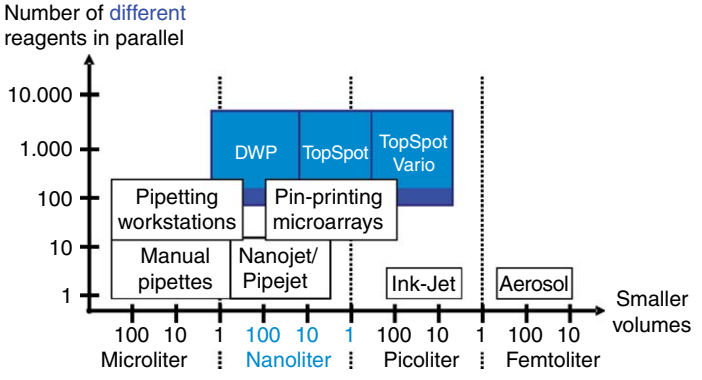

Figure 41 Overview of low volume dispensing. The presented platform for noncontact dispensing depends on three different techniques to dispense well-defined liquid volumes. These techniques are named according to the pilot application they are used for (dispensing well plate (DWP), TopSpot®, TopSpot® Vario). The platform covers the volume range from several tens of picoliters (pl) to several microliters (μl). Several thousands of dispensing units can principally be arranged in parallel to handle the same number of different liquids, e.g., different biological reagents in parallel.

parallel and has been demonstrated at a pitch ranging from several hundreds of micrometers to several millimeters. Three different actuation schemes based on the same geometrical arrangement, namely the dispensing well plate (DWP) (Koltay *et al.* 2004a, b), the TopSpot® (de Heij *et al.* 2003, 2004), and the TopSpot® Vario (Steinert *et al.* 2004) technology are depicted in **Figure 42**.

The noncontact dispensing process, strictly speaking, represents two unit operations, liquid metering on the one hand and liquid transfer on the other hand. The metered liquid volume is delivered as a free-flying droplet or a jet in a noncontact manner to any substrate, receiving vessel, or the reservoir of another dispensing unit. The volume of that liquid portion is determined by the nozzle geometry and the external actuation mechanism.

The DWP principle is based on the complete drainage of the liquid volume within the nozzle chamber. The micromachined nozzle chamber can be considered as a metering structure, which is filled with liquid from the reservoir by capillary forces via the capillary channel between two dispensing events. The total liquid present in the nozzle chamber is dispensed by applying a pneumatic pressure of 30–80 kPa for 3–10 ms. Since this pressure pulse is applied on the liquid–air interface of the nozzle chamber and the reservoir, no pressure gradient evolves along the capillary channel and thus no backflow of liquid from the nozzle chamber to the reservoir is observed. The dosed volume is hardly affected by the liquid properties like viscosity, density, and surface tension, but is affected only by the geometry of the nozzle chamber, making this dispensing method very robust.

The TopSpot principle also depends on a pneumatic pressure pulse, which in this case is on the submillisecond timescale. Such a short pneumatic pressure pulse can be generated only by compression of an enclosed gas volume. Therefore an assembly of a piezo stack actuator driving a piston into a closed actuation cavity above the nozzle chambers is used. The pressure pulse acts equally on all nozzle chambers within the pressurized actuation cavity and causes the simultaneous ejection of single droplets out of each nozzle. The droplet volume is typically on the order of 1 nl for a 50-µm nozzle, which is in contrast to the DWP principle just a small fraction of the nozzle chamber volume. The exact droplet volume depends on the liquid properties, the actuation parameters, and the nozzle dimensions (Gutmann *et al.* 2004b).

In contrast to the pneumatic technologies described so far, the TopSpot Vario principle uses the direct displacement of an incompressible but easily deformable elastomer for actuation. The elastomer inlay replaces the air volume in the set-up (see **Figure 42**, *right*) and is displaced into the nozzle chambers by the piston movement if the piezo stack is actuated. A well-defined volume of liquid in the nozzle chamber is displaced by the elastomer and a droplet of the corresponding volume is ejected out of the nozzle. This direct displacement principle allows the independent control over the droplet volume and the droplet speed by adjusting the stroke and the speed of the piezo actuator. The tunable volume range of the droplets is from 100 pl up to 1400 pl (1.4 nl) for a 50-µm nozzle and can easily be adopted by varying the control voltage of the piezo actuator.

The basic structures like reservoirs, capillary channel, nozzle chamber, and nozzles can be fabricated by different technologies using different materials. Dry etching of silicon (deep reactive ion etching, DRIE) (Steinert *et al.* 2004), lithographic fabrication in SU-8 (Bohl *et al.* 2005), and

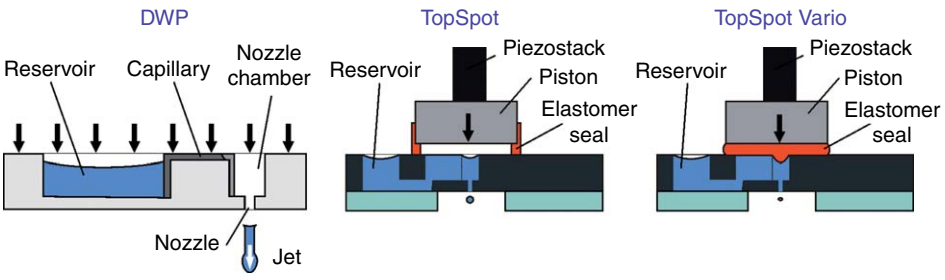

Figure 42 Dispensing well plate (DWP): Pressure-based actuation for dispensing from 10 nl up to several microliters; TopSpot®: pressure-based actuation for dispensing volumes in the lower nanoliter range; TopSpot® Vario: direct displacement principle via an elastomer for dispensing volumes from 50 to 1.000 pl.

micromilling of plastics (Steger *et al.* 2004) have been demonstrated. A high precision in the geometry of the dispensing units is needed for a high precision of the dispensed liquid volumes, and this results in the need for a high precision of the fabrication processes.

One unique feature of all the three dispensing principles described is the possibility to arrange many of them in parallel with a free scalable pitch of the nozzle chambers and the reservoirs. The capillary channel that connects these two substructures accomplishes the format conversion from a reservoir pitch of a few millimeters (enabling the filling of the dispensing chip using standard pipetting robots) to the pitch of the nozzle of a few hundred micrometers. This is important for the fabrication of microarrays, which is one application example for the platform, described in more detail in Section 2.13.7.3.1.

2.13.7.2.2 Incubation

Besides the noncontact dispensing of a metered liquid volume, incubation steps at defined temperatures are also important for conducting biological assays. This can be realized on the free scalable noncontact dispensing platform by a reversible sealing of the structure openings, namely the nozzle, nozzle chamber, and the reservoirs preventing any liquid flow through the capillaries. The reservoirs and the nozzle chambers act as standard reaction cavities, then enabling incubation steps as long as the sealing is not removed (**Figure 43**, *left*).

2.13.7.2.3 Amplification

Similar to the incubation described in Section 2.13.7.2.2, also temperature-initiated amplification using the polymerase chain reaction (PCR) method can be conducted within the cavities of the platform (**Figure 43**). Therefore, the sealed dispensing chip is mounted between an upper and a lower heating plate, which perform a certain temperature cycle between three temperatures (94°C, 53°C, and 72°C). This process is similar to the common PCR cycling within standard well plates. However, for the microcavities within the PCR slides the upper heating plate also has to change the temperature according to the cycling sequence in order to avoid temperature gradients within the PCR solution. Within the microwell plate, the upper heat plate can be fixed at a high temperature (to prevent condensation) since the air volume between the liquid and the heat plate acts as a thermal insulator. When the cycling is finished the PCR product (amplified DNA) can be dispensed in nanoliter portions into a microliter plate for further processing, onto a microarray for detection, or into another dispensing chip.

2.13.7.3 Application Examples

2.13.7.3.1 TopSpot for microarray spotting

A DNA microarray is an ensemble of microscopic DNA spots attached to a flat solid surface forming an array of different well-known capture molecules (probes) at well-defined positions. It can therefore be considered as a highly parallel biosensor, based on the lock and key principle. The probes on the surface react with a complex mixture of molecules (sample) during the hybridization phase of a microarray experiment. The sample molecules are equipped with fluorescent markers for later detection in a fluorescent readout device. The position of a positive fluorescent signal provides information about the identity of the sample (**Figure 44**).

The engineering challenge in the microarray fabrication is to immobilize up to 1000 different analytes as spots of approximately 1 nl volume, with a pitch of typically 500 µm and below, at high quality, high throughput, and low costs onto a substrate. One of the technical solutions to this problem is based on the TopSpot technology, a first application of the free scalable noncontact dispensing platform (Gutmann

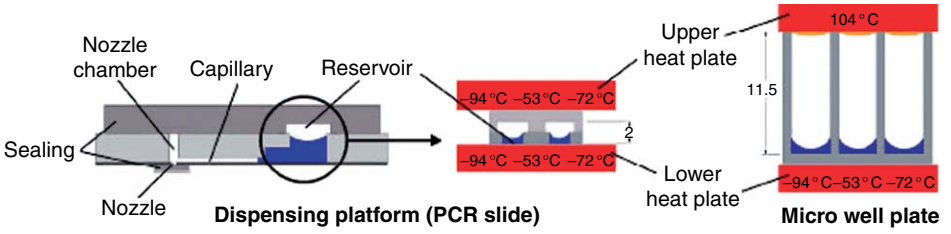

Figure 43 The nozzle and the reservoir opening are sealed for incubation and amplification. Thermal cycling within the thin substrate (polymerase chain reaction (PCR) slide) requires an equal temperature for the upper and the lower plate at any time. Otherwise, inhomogeneous liquid temperatures can influence the assay performance.

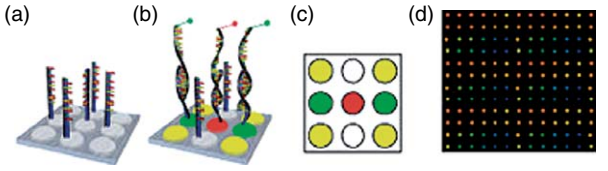

Figure 44 Illustration of the working principle of a DNA microarray. (a) Probe molecules are immobilized as different spots with a certain pitch on the solid surface; (b) a binding reaction takes place between the probe and the sample molecule if the chemical structures are complementary; (c) the fluorescent readout after the microarray experiment indicates positive binding events; and (d) fluorescent image from a real microarray experiment.

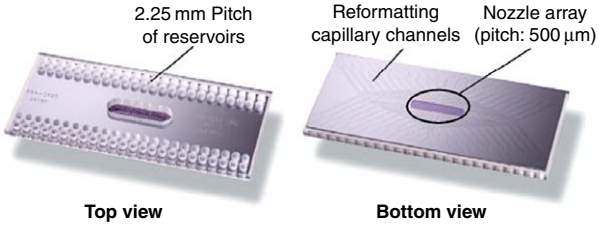

Figure 45 Picture of a 96 TopSpot® printhead. The top view shows the reservoirs that are filled via manual pipetting or lab robots. The capillary channels that connect each reservoir with a certain nozzle chamber ending up in an array of nozzles of pitch 500 μm, a feature called reformatting, can be seen on the underside of the printhead (*right*).

et al. 2004a, c). A dispensing chip or so-called printhead featuring 96 parallel dispensing channels is depicted in **Figure 45**.

The key advantage of the noncontact dispensing platform for microarray fabrication is the ease to perform passive format conversion in the system. The reservoirs on top of the printhead are arranged at a pitch of 2.25 mm corresponding to the pitch of 384 well plates enabling the filling with standard lab equipment, e.g., pipetting robots. Several microliters of liquids can be loaded into each of the 96 reservoirs, which is enough for several thousand dispensing events without the need for refilling. Each reservoir is connected to a certain nozzle chamber in the middle of the printhead via a capillary channel. The liquids are simply transported to the nozzle chamber by capillary forces and stop at the nozzle until a pressure pulse is applied. The nozzles are arranged in an array of 500-μm pitch on the underside of the printhead defining the later spot positions on the microarray.

The typical CV of spot diameters on the microarray is found to be <1% for a single dispensing unit and <1.5% between all nozzles of a printhead for all relevant printing buffers used (Gutmann *et al.* 2004a). Using the TopSpot technology, protein microarrays as well as living cell microarrays have also been fabricated (Gutmann *et al.* 2005).

2.13.7.3.2 Dispensing well plate

Well plates are the standard assay format in the life science industry, especially in HTS instrumentations for drug discovery. The assays are conducted by transferring different reagents between different containments called wells using pipetting robots. Different well plate standards such as the 96, 384, and 1536 format exist, differing in the pitch of the reservoirs (9.0, 4.5, and 2.25 mm, respectively) but all having the same outer dimensions (8 cm × 12 cm) according to the SBS standard. The trend toward smaller wells and consequently assay volumes also provokes the need for liquid handling systems being able to transfer small liquid volumes in the submicroliter range.

A method for the simultaneous and contact-free dispensing of typically 50-nl liquid jets into microwell plates or onto flat substrates has been realized on the dispensing platform. The so-called DWP principle (**Figure 42**) uses a set of dispensing units, arranged according to the well plate format, each featuring a liquid reservoir, a capillary channel, and a nozzle chamber (**Figure 46**).

The nozzle chamber is filled with the liquid from the reservoir by capillary forces only. Afterward, all dispensing units are actuated in parallel by applying a pressure pulse on top of the dispensing chip initiating the simultaneous and complete drainage of all nozzle chambers through the nozzle. As a result, an array of

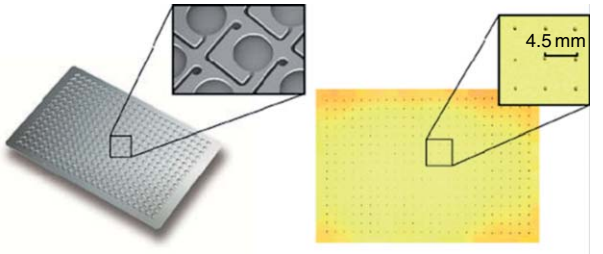

Figure 46 Picture of a 384 dispensing well plate (DWP) dispensing a chip micromachined in silicon. The 384 reservoirs are connected to 384 nozzle chambers next to the reservoirs via capillary channels. No format transformation (reformatting) but the metering and allocation of a defined liquid volume is accomplished within each of the 384 units. All these liquid portions are then transferred to another platform within the pneumatically driven noncontact dispensing process (**Figure 42**) or to a flat surface as depicted on the right.

individual spots is delivered on another well plate or a plane substrate (**Figure 46**, *right*). After switching off the driving pressure, the nozzle chambers refill again from the reservoirs via the capillary channels. Since the reservoir contains a multiple of the nozzle chamber volume, many dispensing events can be performed before the chip has to be refilled. This, for example, enables the fast replication of a certain well plate loading into other plates (compound reformatting) or the addition of nanoliter volumes to plate-based assays. The reproducibility (CV) of the mean dosage volume has been reported to be better than 3% (Steger *et al.* 2004).

2.13.7.4 Strengths and Challenges of the Platform

The wide range of dispensing volumes from 0.05 nl up to 1000 nl of the TopSpot Vario and the DWP, respectively, using the same basic geometric building blocks is certainly the main advantage of the free scalable noncontact dispensing platform. The three dispensing principles can easily be combined on one flat substrate with or without the reformatting by capillary channels and can be actuated in a highly parallel mode of operation.

However, the fabrication costs of the dispensing chips have to be reduced in the future making disposable printheads possible to avoid laborious washing procedures. Since cost reduction is not possible in silicon micromachining (no potential in downscaling of the footprint of the dispensing chips or printheads) microfabrication technologies for polymers like injection molding or hot embossing are likely the most promising alternatives. Today, this technology is pushed forward by the company Biofluidix GmbH (2006) in Germany.

2.13.8 Conclusion

The collection of examples of microfluidic platforms given in the previous sections shows that the platform idea has already been taken up by many groups within the microfluidics community. They not only work on individual components fabricated using diverse technologies, and above all focus on the combination of validated fluidic elements by simple proved technologies. This approach allows to design and fabricate application-specific systems easily and will lead to a paradigm shift from a component and technology-based research to a system-oriented approach. The platforms will allow the microfluidics community to leave today's device-oriented research in order to face the next challenge: the flexible and cost-efficient design of thousands of different applications that might be accessible by using the full potential of microfluidic platforms without starting always from scratch.

A good indicator for the growing interest in microfluidic platform technologies can be also seen in the remarkable number of spin-off companies that arose during the last years trying to commercialize lab-on-a-chip products based on microfluidic platform concepts. Some of them have been mentioned in the previous sections, but there are many more in business already or to emerge in the near future.

Stefan Haeberle is a Ph.D. student in the laboratory for MEMS applications at the Department of Microsystems Engineering (IMTEK) at the University of Freiburg, Germany. He received his diploma degree in Microsystem Engineering in 2004 from the University of Freiburg. His research concentrates on the development of lab-on-a-chip systems based on the centrifugal microfluidics platform. Freiburg, 02.11.2006 Stefan Haeberle.

Prof. Dr. Roland Zengerle is the head of the laboratory for MEMS applications at the Department of Microsystems Engineering (IMTEK) at the University of Freiburg, Germany. In addition, he is a director at the Institute for Micro- and Information Technology of the Hahn-Schickard-Gesellschaft (HSG-IMIT). HSG-IMIT is a nonprofit organization supporting industries in the development of new products based on MEMS technologies.

The research of Dr. Zengerle and his team of 50 engineers is focused on microfluidics and covers topics like miniaturized and autonomous dosage systems, implantable drug delivery systems, nanoliter and picoliter dispensing, lab-on-a-chip systems, thermal sensors, miniaturized fuel cells as well as micro- and nanofluidics simulation. Dr. Zengerle coauthored more than 200 technical publications and 25 patents. He is the European editor of the *Springer Journal of Microfluidics and Nanofluidics*. Dr. Zengerle serves on the international steering committee of the IEEE-MEMS conference as well as on the technical program committees of several other international conferences.

2.14 Ultrasonic Transduction

B. T. Khuri-Yakub, A. S. Ergun, O. Oralkan, and G. G. Yaralioglu, E. L. Ginzton Laboratory, Stanford University, Stanford, CA, USA

2.14.1 Introduction

Ultrasonic transducers can be classified based on the physical mechanism involved in the conversion of electrical energy into ultrasonic energy or *vice versa*. Magnetostriction, piezoelectricity, and electrostatics are some of the physical mechanisms used to generate and detect ultrasound.

Throughout the history of ultrasound imaging, piezoelectric crystals, ceramics, polymers, and recently piezocomposite materials have been used to generate and detect ultrasound. Although the idea of electrostatic transducers is as old as the early piezoelectric transducers, piezoelectric materials have dominated ultrasonic transducer technology. Electrostatic transduction can best be explained by means of a parallel plate capacitor, where one plate is kept stationary and the other is displaced either due to an electric field (transmit) or by the reflection of a wave at its surface (receive). The reason why electrostatic or capacitive transducers had not been popular is the need for high electric fields to be maintained to achieve acceptable efficiencies. Recent advances in microfabrication technology have made it possible to build capacitive ultrasound transducers that can compete with piezoelectric transducers.

Micromachined electrostatic transducers were first reported in the late 1980s (Hohm and Hess 1989, Suzuki *et al.* 1989) and the early 1990s (Rafiq and Wykes 1991). These devices were not well characterized, nor easily fabricated. The performance was also not at a level to compete with the piezoelectric transducers. A capacitive micromachined ultrasonic transducer (cMUT) with more advanced fabrication technology and improved performance was introduced in 1993 (Haller and Khuri-Yakub 1994). Advanced microfabrication processes enable realization of the submicron gaps between the electrodes, which makes it possible to achieve high electric fields. These processes also provide a precise control over device dimensions in the vertical and lateral directions. The wide bandwidth and the potential for integration with electronic circuits are other advantages associated with cMUTs. Since the first demonstration of cMUTs in the early 1990s, extensive research has been conducted on fabrication and modeling of this new transducer technology (Eccardt *et al.* 1996, Khuri-Yakub *et al.* 2000, Schindel and Hutchins 1995).

This chapter reviews the theory and modeling of this modern type of electrostatic transducers, explains fabrication methods, and gives examples of imaging systems based on this new technology.

2.14.2 Theory and Modeling of Capacitive Ultrasonic Transduction

Both analytical and numerical methods have been used to analyze cMUTs. A cMUT membrane can be modeled by a parallel plate capacitor with a moving top electrode as shown in **Figure 1**.

Under DC bias, the top electrode is attracted toward the bottom electrode. At equilibrium, the deflection due to the electrostatic force is counterbalanced by the mechanical spring force of the membrane. Assuming that the top electrode is displaced by x, the capacitance of the parallel plate capacitor is given by

$$C(x) = \frac{S\varepsilon_0}{\frac{t_i + t_m}{\varepsilon_r} + g_0 - x} \quad [1]$$

or

$$C(x) = \frac{S\varepsilon_0}{g_{eff} - x} \quad [2]$$

where S is the area of the top electrode, ε_0 the permittivity of vacuum, ε_r the relative permittivity of the insulator and the membrane material (assumed to be the same here), g_0 the initial gap distance under zero bias voltage, t_i the insulator thickness, t_m the membrane thickness, and g_{eff} the effective gap height.

For a parallel plate capacitor, the electrostatic attractive force applied on the top plate is given by

$$F_E = \frac{1}{2}QE \quad [3]$$

where $(1/2)E$ is the electric field due to the charge on the bottom plate. We also assume that $+Q$ and $-Q$ are the charges on the top and bottom plates, respectively. Since Q is given by the product of the capacitance and the applied voltage, the electrostatic force is

$$F_E = \frac{1}{2}\frac{C(x)}{g_{eff} - x}V^2 \quad [4]$$

at the applied bias voltage V. The total net force on the top plate is given by

$$F_N = \frac{1}{2}\frac{C(x)}{g_{eff} - x}V^2 + k_s x \quad [5]$$

where the second term in the right-hand side of the equation is the mechanical force of a membrane whose spring constant is k_s. At equilibrium, the electrical attraction and mechanical restoring forces are equal, and the resulting F_N is zero. Therefore, the relation between the applied voltage and the displacement is given by

$$V = \sqrt{\frac{2k_s x}{S\varepsilon_0}}(g_{eff} - x) \quad [6]$$

As expected, the top electrode displacement increases as the bias voltage increases according to eqn [6]. Also, as the top electrode moves closer to the bottom electrode due to the applied voltage, the electric field increases and the top electrode displaces further, acting as if the spring constant of the top electrode decreases under the influence of the applied voltage. This is called spring softening, which we will evaluate quantitatively later.

The capacitor in **Figure 1** exhibits an important phenomenon. If the bias voltage is increased beyond a certain value, the top electrode collapses on the bottom electrode. This means that a small displacement of the top electrode results in an increase in the electric field and an increase in the attractive force that cannot be balanced by the spring force, with the end result being the collapse of the top electrode onto the bottom electrode. Mathematically, this occurs when the electrostatic force gradient is larger than the mechanical force gradient. One can calculate collapse voltage from eqn [5] by equating the force gradient to zero.

$$\frac{d}{dx}F_N = -\frac{1}{2}\frac{d}{dx}\left(\frac{C(x)}{g_{eff} - x}\right)V^2 + k_s = -\frac{S\varepsilon_0 V^2}{(g_{eff} - x)^3} + k_s \quad [7]$$

The force gradient can also be viewed as the spring constant of the membrane in an electric field.

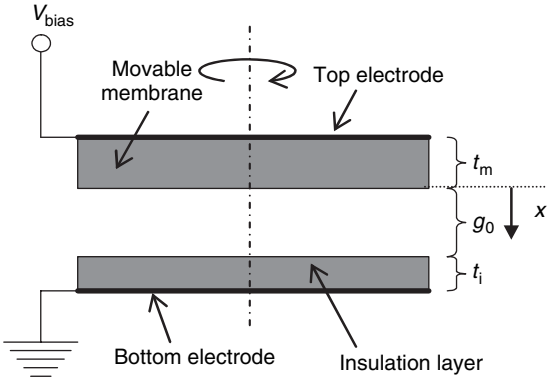

Figure 1 Parallel plate capacitor with moving top electrode.

By substituting the voltage from eqn [6] into eqn [7], the softened spring constant of the membrane can be found in terms of x:

$$k_s' = k_s\left(1 - \frac{2x}{g_{\text{eff}} - x}\right) \qquad [8]$$

The collapse occurs when the gradient of the total force F_N is negative. At that point, incremental increase in electrostatic force overcomes the incremental increase in the mechanical force. On equating eqn [8] to zero, it is found that the displacement is one-third of the effective gap at the collapse voltage:

$$x = \frac{g_{\text{eff}}}{3} \qquad [9]$$

and the collapse voltage is given by

$$V_{\text{col}} = \sqrt{\frac{8k_s g_{\text{eff}}^3}{27S\varepsilon_0}} \qquad [10]$$

By using the above equations, one can calculate the membrane deflection for a given DC voltage. However, for time-varying voltages the equation of motion given in eqn [11] needs to be solved:

$$m\frac{\mathrm{d}^2x(t)}{\mathrm{d}t^2} + c\frac{\mathrm{d}x(t)}{\mathrm{d}t} + k_s x(t) = \frac{\varepsilon_0 S V(t)^2}{2(g_{\text{eff}} - x)^2} \qquad [11]$$

where c is the damping term accounting for energy loss from the vibrating top electrode. Eqn [11] is a nonlinear differential equation. For an arbitrary applied voltage, there is no analytical solution; therefore, eqn [11] should be solved by numerical methods. However, for small voltages one can linearize the differential equation and use the equivalent circuit approach.

2.14.2.1 Equivalent Circuit Model

Mechanical systems can be converted into electrical circuits by using the analogy between the mechanical and the electrical domain. One way to implement this analogy is to replace the forces in the mechanical domain by voltage sources and velocities by electrical currents. Then, an equivalent circuit of the system is constructed. This method becomes an even more powerful tool for the analysis of electromechanical systems where some parts of the system are already in the electrical domain. For example, equivalent circuit analysis is successfully used for piezoelectric transducers for their design and optimization (Mason 1948).

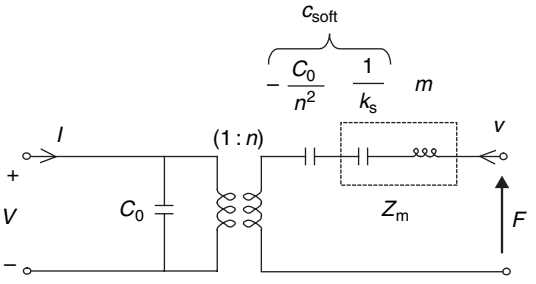

Figure 2 Equivalent circuit model.

Recently, the equivalent circuit model was employed for the characterization of cMUTs (Khuri-Yakub *et al.* 2000, Ladabaum *et al.* 1998). **Figure 2** shows the equivalent circuit for a cMUT transducer. In the electrical part, C_0 is the clamped capacitance of the device at the bias voltage. Spring softening capacitance and the mechanical membrane impedance constitute the mechanical part. The two parts are coupled together through an electromechanical transformer. For a parallel plate capacitor, the electric field and transformer ratio are given by

$$E_0 = \frac{V}{g_{\text{eff}} - x_0} \text{ and } n = E_0 C_0 \qquad [12]$$

respectively where x_0 is the equilibrium displacement under applied bias voltage V and can be calculated using eqn [6]). Note the negative sign in front of the spring softening capacitor.

When the transducer is operated in vacuum, the mechanical port of the circuit is short-circuited. For immersion devices, the mechanical port is simply terminated by the radiation impedance.

The maximum small-signal output pressure of the transducer can be easily calculated using the equivalent circuit method. The maximum output pressure is obtained at the resonant frequency of the membrane where all the reactive elements cancel each other out in the mechanical part of the circuit. At this frequency the output pressure per volt is given by

$$P_{\max} = \frac{n}{S} \qquad [13]$$

If eqn [12] is substituted in eqn [13] assuming that the electrode size is as large as the membrane itself, one obtains the following equation:

$$P_{\max} = \frac{\varepsilon_0 V}{(g_{\text{eff}} - x)^2} \qquad [14]$$

If the maximum DC voltage that can be applied to the cMUT is $V_{col,}$ then the maximum pressure per volt becomes

$$P_{max} = \sqrt{\frac{3k_s\varepsilon_0}{2Sg_{eff}}} \quad [15]$$

According to eqn [15], a smaller gap height and a higher membrane stiffness as well as membrane area improve small-signal output pressure.

Note that the aforementioned equivalent circuit analysis is only valid for voltages that are small compared with the bias voltage. As mentioned earlier, for large signals nonlinear equation of motion needs to be solved. In addition, the results derived can also be used for the receive mode where the membrane displacement is small compared with the gap height. In this case, stiffer and small membranes with small area result in improved sensitivity. The smaller gap height provides also higher sensitivity.

For a piston transducer, the equivalent circuit approach explains the basic operation principles and gives ideas about how to improve the performance. Recently, there were improvements to equivalent circuit to predict the sensitivity, output pressure, and bandwidth of immersion transducer (Lohfink *et al.* 2003, Yaralioglu *et al.* 2003). These models predict the behavior of cMUT when the membrane motion is parallel or around the first resonant frequency. However, more accurate results require finite element model (FEM) analysis.

2.14.2.2 Finite Element Model

FEMs (3D and 2D) have been developed for the cMUTs to calculate collapse voltage, output pressure, bandwidth, and crosstalk. Since the modeling of the whole transducer requires large computer resources, the symmetry of the transducer is almost always used for smaller and more practical models. The simplest FEM representation is a 2D axisymmetric model composed of a membrane and a fluid waveguide. This model represents a single membrane of an infinitely large transducer, and it is assumed that all the membranes move in phase (**Figure 3**).

A commercially available FEM software (ANSYS) was used in this study. The membrane and the fluid waveguide were meshed by planar elements. The electrical ports were added to the membrane by segmenting the gap into many parallel plate capacitors as shown in **Figure 3**. This approach neglects the fringing fields and assumes that the electric field is always perpendicular to the electrodes. Another important component of the model is the absorbing boundary that truncates the mesh at a certain distance from the membrane. This allows simulating the sound radiation into a fluid half space.

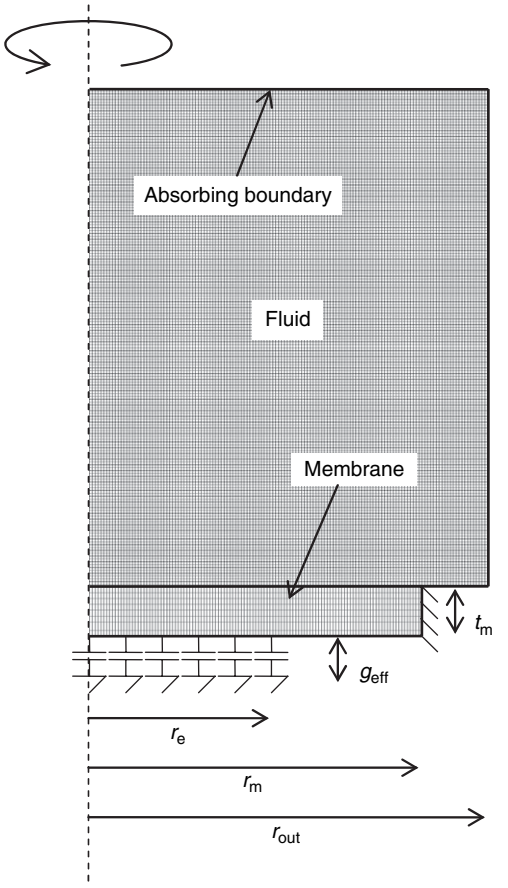

Figure 3 Schematic representation of the finite element model (FEM) model.

The model shown in **Figure 3** generates sound waves in the fluid when the membrane is excited. The field quickly converges into plane waves as it propagates away from the membrane and the wave fronts become parallel to the membrane plane and the absorbing boundary. Parallel incidence of waves on the absorbing boundary is essential to eliminate the reflections. Below a certain cutoff frequency, the fluid waveguide supports only the plane waves. However, if the frequency is high enough, there are also waves propagating at an oblique angle. The cutoff frequency of the waveguide is given by

$$f_c = 1.22\frac{v_L}{2r_{out}} \quad [16]$$

where v_L is the sound velocity in the fluid and r_{out} the radius of the waveguide. Above this frequency, due to the oblique incidence on the absorbing boundary, some part of the incidence wave gets reflected at the absorbing boundary. This results in standing waves in the waveguide. Therefore, care must be taken while examining the results of the model shown in **Figure 3**.

By using the above model, one can perform static, harmonic (small-signal frequency domain), and transient (large-signal time domain) analyses. Static calculations can be used to calculate the collapse voltage of the membrane. Static analysis is also needed to prestress the membrane before harmonic analysis. In this section, we will present the results of harmonic analysis.

The model shown in **Figure 3** was used to calculate the output pressure. The frequency spectra for various membrane radius and thickness combinations were determined. Initially, the collapse voltage was calculated. Then the membranes were biased at 80% of their collapse voltages using static analysis, and an AC voltage of 1 V was applied to the electrical ports for harmonic analysis. **Figure 4** shows the average pressure over the bottom surface of the waveguide including the membrane surface and the nonmembrane area between r_m and r_{out} for four different designs. For each design the thickness of the membrane is adjusted such that the resonant frequencies in vacuum are the same (19.14 MHz). The collapse voltage of the largest membrane ($r_m = 26\,\mu m$) was the highest (98.9 V) among the four designs. As the membrane gets smaller and thinner, the spring constant and the collapse voltage decrease. The collapse voltages of the other three designs are 59.8, 44.8, and 29.7 V. The membranes in this example are made of silicon. For silicon membranes, as the radius decreases, the spring constant-to-area ratio also decreases. To check the validity of eqn [15], we calculated the spring constants of the four designs and compared them with the graph shown in **Figure 4**. For example, eqn [15] predicts 1.7 times higher pressure for a 26-μm membrane than it does for a 16-μm membrane. The calculated result from **Figure 4** is 1.6.

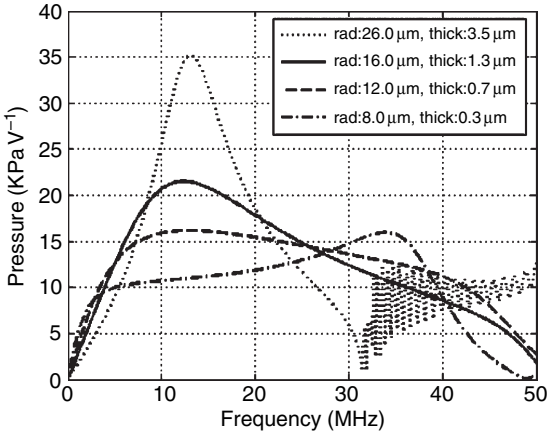

Figure 4 The gap height is 0.1 μm. The insulation layer thickness is also 0.1 μm. The top electrode is assumed to be under the membrane. The relative permittivity of the insulation layer is 3.9. (The equivalent gap height is 0.126 μm.) The membrane material is silicon ($E = 150$ GPa, $\sigma = 0.17$, $\rho = 2332$ kg m^{-3}). The radius of the fluid column is 12% larger than the membrane radius, resulting active (membrane) to total area (membrane + substrate surface) ratio of 80%.

The bandwidth is another important transducer characteristic. The lower cutoff (−3 dB) frequency is determined by the spring constant. As the spring constant increases, the bandwidth of the transducer decreases. The higher cutoff frequency is determined by the membrane mass and the complex loading impedance of the immersion medium as well as the second resonance of the membrane. For relatively softer membranes, the effect of the second resonance is more prominent. By carefully selecting the radius and the thickness combination, one can obtain a very large bandwidth as shown for the 12-μm design.

In the above analysis, we demonstrated small-signal calculations. The pressure output per volt increases for stiffer designs. However, the maximum attainable pressure is limited by the gap height. Calculations for large membrane displacements require nonlinear analysis.

Figure 5 shows large-signal response of the 16-μm membrane. Negative and positive 20-ns pulses (5 and 30 V) were applied to the membrane. The average and center displacements as well as the pulse levels were plotted in the figure. For small amplitudes, negative and positive voltage pulses generate similar amplitude displacement pulses. However, for large pulses, the pulse in the direction of the increased electric field over the gap generates higher amplitude displacement pulse than the pulse going in the other direction. Also, the average membrane displacement over the total area is four times less than the center displacement. This should be kept in mind while choosing the gap height to get the desired maximum output pressure.

Figure 6 plots the Fourier transform of the pressure pulses corresponding to the displacement pulses

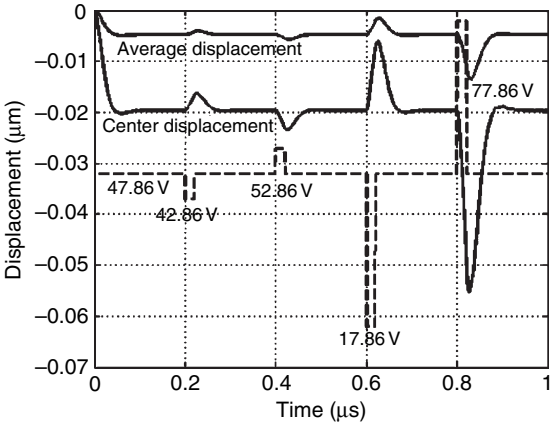

Figure 5 Average and center membrane displacements. The applied voltage waveform is also added on the graph. The membrane is biased at the 80% of the collapse voltage.

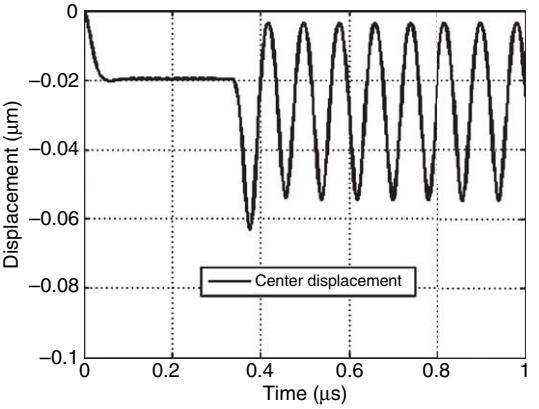

Figure 7 Center membrane displacement. The membrane is biased (47.86 V) at 80% of collapse voltage, and 30 V sine wave at 12.4 MHz is applied.

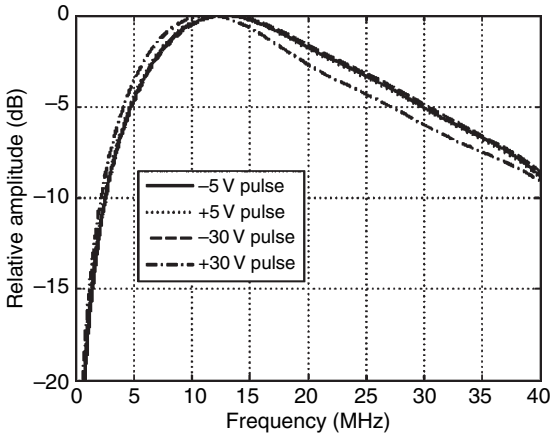

Figure 6 Frequency spectrum of corresponding pressure pulses of **Figure 5**.

shown in **Figure 5**. For small pulses and high negative pulses, the spectrum is very similar to the one obtained using linear analysis. However, for large positive pulses, the spectrum is shifted to the lower frequencies. Due to the nonlinearities, the DC bias voltage increases over the membrane for large positive pulses. This shifts the response of the membrane to the lower frequencies due to the spring softening.

By using large-signal analysis, one can also calculate the harmonic distortion or the amplitudes of the harmonic signals. Second harmonic generation is important for harmonic imaging. To demonstrate the calculation, a long sine wave was applied to the 16-μm membrane shown in **Figure 4**. The center displacement is plotted in **Figure 7**. Note that the instantaneous total voltage over the membrane exceeds the collapse voltage. However, the membrane does not collapse because there is a phase shift between the applied voltage and the displacement.

The fast Fourier transform (FFT) of the pressure waveform reveals the harmonic content of the output pressure. The results are shown in **Figure 8**. The figure depicts the first three harmonics. As expected, the harmonic distortion increases as the applied voltage amplitude gets closer to the bias voltage. The transducer generates a 15-dB second harmonic at high drive levels.

Figure 9 shows the peak-to-peak pressure amplitude and the amplitude of the fundamental frequency as well as the result of the linear calculation shown in **Figure 4**. The fundamental amplitude was calculated by filtering the harmonic amplitudes from the total

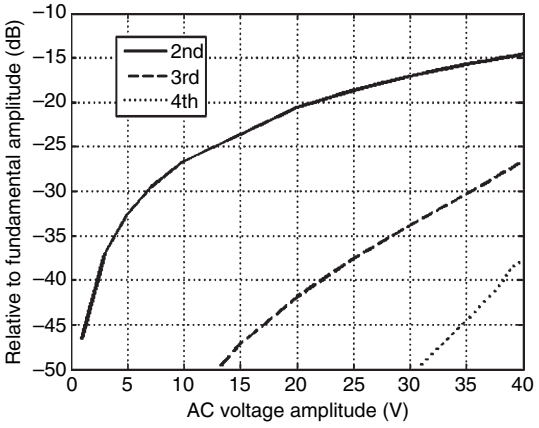

Figure 8 Relative harmonic amplitude as a function of applied AC voltage amplitude. The bias voltage is 47.86 V.

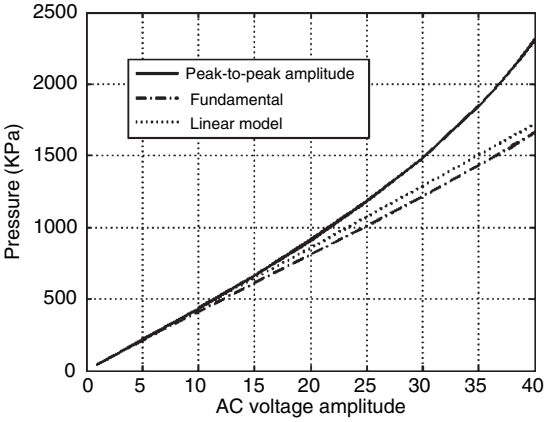

Figure 9 Peak-to-peak amplitude of the pressure waveform. The bias voltage is 47.86 V.

peak-to-peak amplitude. The linear curve is obtained by multiplying the peak-to-peak AC voltage amplitude by the pressure per volt value ($21.5\,\mathrm{k\,Pa\,V^{-1}}$) shown in **Figure 4**. The increase in the peak-to-peak pressure amplitude accelerates as the AC amplitude gets close to the bias voltage. However, the harmonic distortion in the pressure waveform also increases. The fundamental amplitude increases more linearly, and it matches very well with the linear calculation.

2.14.3 Fabrication Technologies

Various methods have been proposed for the fabrication of cMUTs. These methods use one of two manufacturing processes: the sacrificial release process or the wafer bonding process.

2.14.3.1 Surface Micromachining – Sacrificial Release Process

This process is called the sacrificial release process since the membrane material is deposited over a sacrificial layer that is later removed to leave a gap between the membrane and the substrate.

In this method, a conductive silicon wafer is used as the substrate. The wafer is doped to achieve high conduction at its surface, which is going to be the back electrode of the transducer. A silicon-rich, low-stress silicon nitride film is then deposited by using low-pressure chemical vapor deposition (LPCVD). Typically, the deposited films have a tensile stress of less than 100 MPa and a refractive index of 2.4. This layer, also called the insulation layer, must be sufficiently thick to protect the silicon wafer from the etchant during the long wet sacrificial layer etch. But, since the capacitance of the insulation layer is in series with the active gap capacitance, it should not be arbitrarily thick. Otherwise, the collapse voltage will be increased beyond practical limits. Typically, an insulation layer that is 1000 Å thick is sufficient to avoid problems with possible pinholes that are common in thin silicon nitride layers.

The next step is the deposition of the sacrificial layer. Various materials can be used for the sacrificial layer. Polysilicon can be etched easily in potassium hydroxide (KOH) while silicon nitride is very durable in KOH. Polysilicon is also available in most of the fabrication facilities. For these reasons, polysilicon is widely used as a sacrificial material.

Sacrificial layer deposition is done in two steps. The first deposition is followed by lithography and etch steps, so that the channels used by KOH to remove the sacrificial layer are thinner than the cavity thickness. The subsequent dry etch removes all the polysilicon except in the regions where the cavity will be formed. The dry etching stops at the silicon nitride layer (**Figure 10(a)**). Then, a second layer of polysilicon is deposited (**Figure 10(b)**). The thickness of the second polysilicon layer determines the thickness of the channels; the total polysilicon thickness from the first and second depositions determines the cavity height. For polysilicon, low-temperature depositions are preferred for better thickness control.

The cavity, membrane shape, and the etch channels are defined by another photolithography and dry etch steps. While the membranes can be in any shape, circles and hexagons are easier to model and thus are used more often. Because they determine the frequency response of the element, both the shape and the size of the membrane are critical cMUT design parameters.

In the next step, another layer of silicon nitride is deposited by LPCVD (**Figure 10(c)**) to form the membranes. The insulation layer and the membrane are of the same material. At this step, the membrane thickness is not finalized yet because another layer of silicon nitride will be added during the sealing step.

Small holes (etch holes) through the silicon nitride layer are opened through lithography and dry etch steps (**Figure 10(d)**). The etch holes are located on the etch channels. These holes provide access to the sacrificial layer for the etchant solution. When the wafer is immersed in KOH solution, KOH starts etching through these holes and etches its way into the cavity through the channels and releases the

membrane (**Figure 10(e)**). During the long KOH etch, the etch-stop layer protects the silicon wafer. The polysilicon etch rate of KOH depends on temperature. At room temperature, etching process may take several days, depending on the membrane size. This slow rate is due, in part, to the narrow and thin etch channels, which limit the diffusion of KOH. Near boiling point, the wet release may be as fast as several hours. However, because the etch selectivity worsens between silicon nitride and polysilicon at high temperatures, this fast release process is not always preferred. A moderate temperature is selected to give a reasonable release time while maintaining the high etch selectivity.

After the long release, the holes are sealed by another layer of LPCVD silicon nitride (**Figure 10(f)**). Because silicon nitride is deposited at low pressure, the cavity is considered to be vacuum-sealed for practical purposes. In immersion applications, including medical imaging, the cavity must be sealed; otherwise, fluid fills the cavity and hinders proper cMUT operation. If the cavity is not sealed, squeeze film damping will load the membrane vibrations, making the transducer inefficient. For the same reason (but with less effect), it is also undesirable to leave air inside the cavity while sealing.

The rest of the process establishes the electrical connections from the bond pads to the top and bottom electrodes. A lithography and an etch step open connections to the ground plane through the silicon nitride layers. Subsequently, aluminum is sputtered over the whole wafer and is patterned by lithography and wet etch (**Figure 10(g)**). Because it provides conformal coverage, sputtering is preferred for this step. This final lithography and etch step define the top electrode coverage over the membrane. After depositing the metal, it is best to anneal the wafer

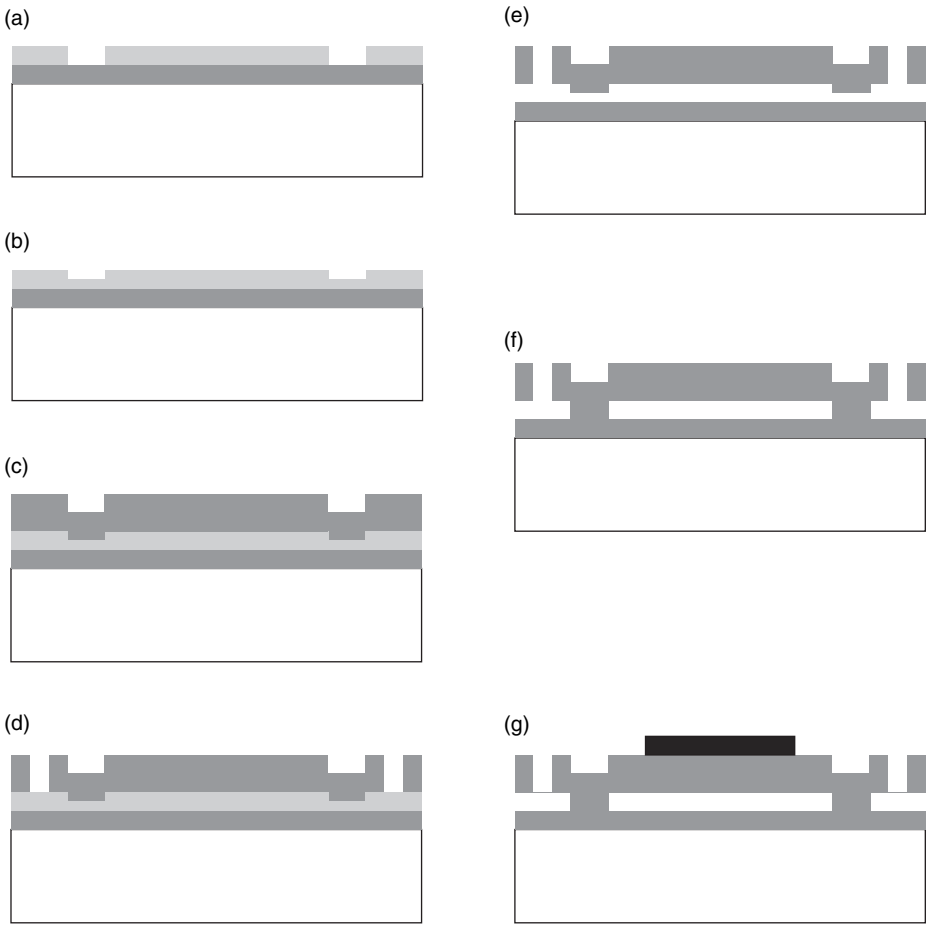

Figure 10 Sacrificial release process: (a) substrate doping, insulation layer deposition, sacrificial layer deposition, and patterning; (b) second sacrificial layer deposition; (c) membrane deposition; (d) etch holes; (e) KOH etch; (f) sealing; and (g) metal deposition and patterning.

to establish good ohmic contact with the ground. However, annealing generates high tensile stress in the aluminum electrode (around 500 MPa), which alters both the static deflection under atmospheric pressure and the mechanical resonant frequency of the membranes. Because a sufficiently good ohmic contact may still be obtained on a highly doped substrate, it is possible to skip the annealing step. Otherwise, high tensile stress must be accounted for in the cMUT design. **Figure 11** shows various membranes fabricated using the sacrificial release process.

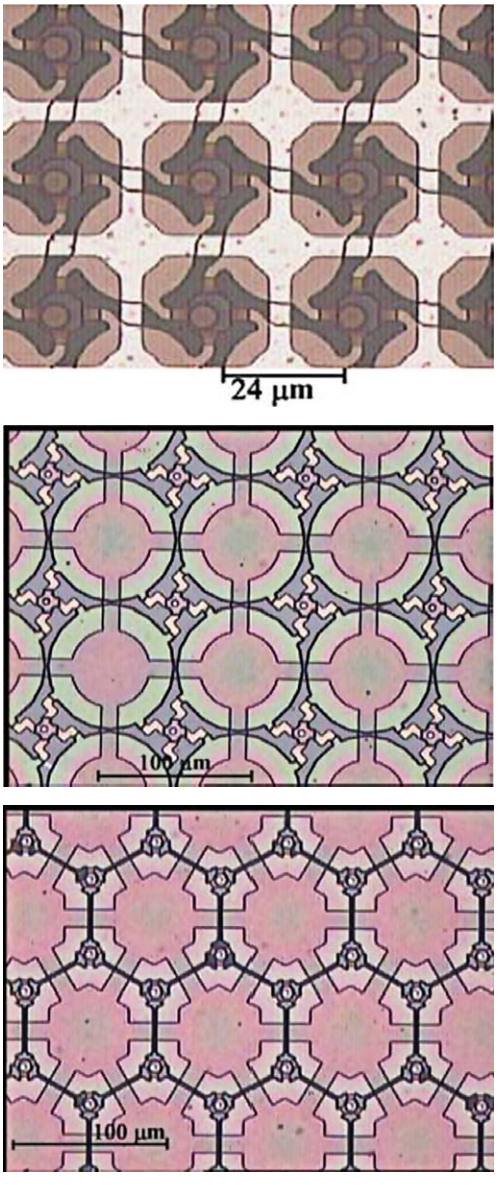

Figure 11 Various membranes fabricated using sacrificial release process.

There are several variations of sacrificial etch processing. For example, the fabrication may start with an insulating substrate such as quartz (Knight and Degertekin 2003). In this case, the bottom electrode should be formed by another deposited conducting layer. Instead of LPCVD nitride, one can use plasma enhanced chemical vapor deposition (PECVD) nitride (Caliano *et al.* 2000), which allows low-temperature processing. Another variation is the use of dry etching rather than wet etching to remove the sacrificial layer.

2.14.3.2 Bulk Micromachining – Wafer Bonding Process

In this technique, cavities are first defined on a silicon wafer, which is subsequently bonded to a silicon-on-insulator (SOI) wafer. The silicon layer of the SOI wafer forms the membranes after removing the handle part and the buried oxide (BOX) layer of the SOI wafer.

To define the gap height and the membrane shape, the prime quality silicon wafer is thermally oxidized to a predetermined thickness, followed by a photolithography step to define the cavity shape. The thermally grown silicon dioxide layer is etched with hydrofluoric acid solution (or dry etched) through the photoresist pattern all the way to the silicon, as shown in **Figure 12(a)**. After the photoresist is removed, another layer of silicon dioxide is thermally grown (**Figure 12(b)**). Because the membrane is silicon, which is not an insulator, the second oxidation isolates the conductive silicon substrate from the top electrode to avoid shorting.

Following the second oxidation, the SOI wafer and the prime wafer (after being RCA-cleaned and surface-activated) are brought together in vacuum, as shown in **Figure 12(c)**. As soon as the two wafers come in close contact, short-range van der Waals forces attract the two wafers, and weak hydrogen bonds develop between them. The wafers are immediately annealed/oxidized at 1100°C to form strong covalent bonds. After bonding and annealing, the handle of the SOI wafer (including the BOX layer) is removed to release the membranes (**Figure 12(d)**), either by wet etching or by dry etching. Wet etching of silicon, a well-known process, can be done with a solution of either KOH or tetramethylammonium hydroxide (TMAH). It is critical to ensure that the silicon dioxide layer on the back of the prime wafer holds off the wet etchant during this step. A better method is to grind/polish the handle portion of the

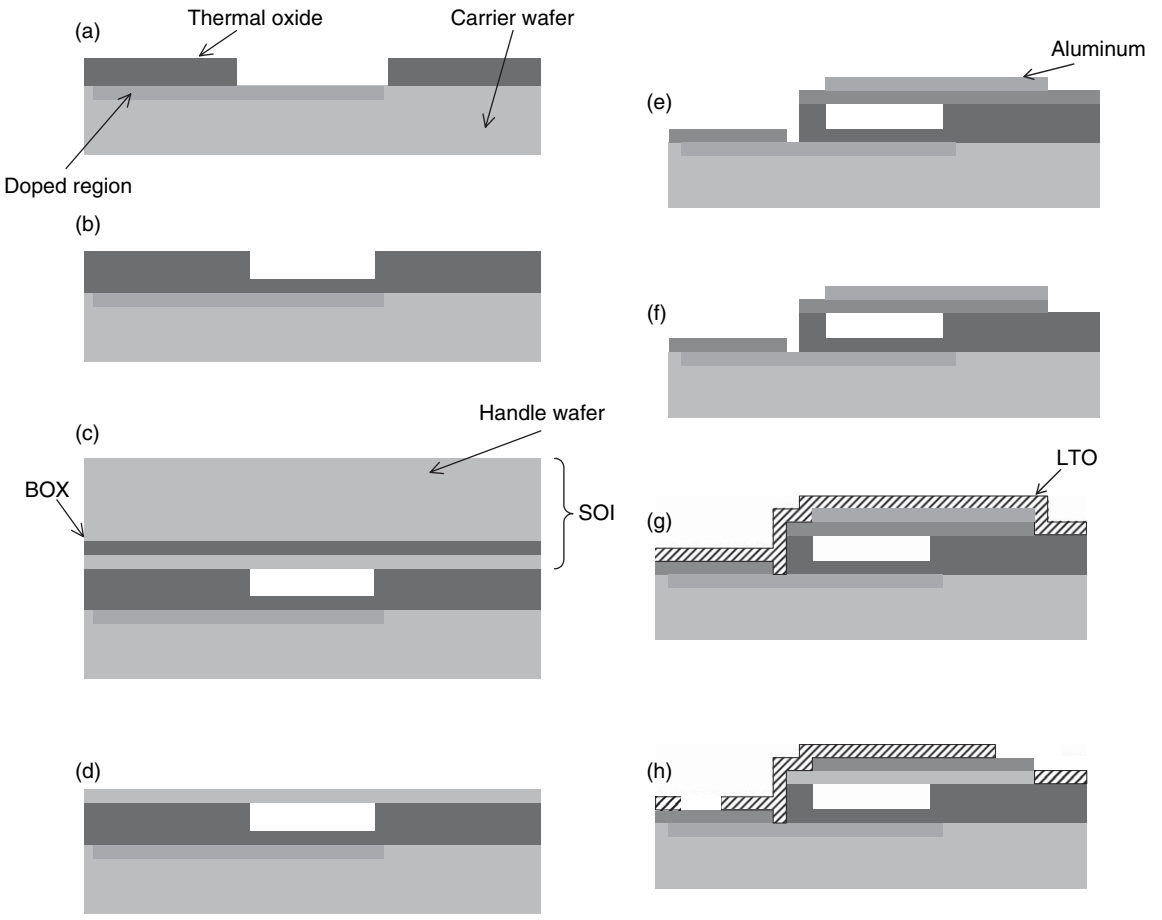

Figure 12 Wafer bonding fabrication steps: (a) cavity definition, (b) second oxidation, (c) wafer bonding, (d) removing handle part and buried oxide (BOX) layer, (e) metal deposition, (f) element definition, (g) low-temperature oxide (LTO) deposition, and (h) patterning of LTO for wire bonding.

SOI wafer down to 50 µm before the wet etch step, which relaxes the constraint on the thickness of the silicon dioxide layer on the back of the prime wafer. Because both KOH and TMAH have very slow etch rates for silicon dioxide, once the silicon etch is complete, the wet etch process will in effect stop at the BOX layer, which can then be removed with hydrofluoric acid. In this case, the silicon membrane acts as the etch stop. If the handle wafer is dry etched with deep reactive ion etching (DRIE), then the BOX layer serves as the etch-stop layer. Using recently developed DRIE equipment, this etch step may be 25 times faster than the wet etch, eliminating concerns about the serial nature (one wafer at a time) of the DRIE process.

The remaining steps of the wafer-bonded cMUT process are very similar to the surface micromachined cMUT process, with the exception of element definition. Openings through the silicon and silicon dioxide layers are defined with photolithography and dry etch steps to access the bottom silicon layer to make the ground connection. The top electrode is sputtered and patterned by another photolithography and wet etch step (**Figure 12(e)**). Because the wafer-bonded cMUTs have no surface topology at this step to cause discontinuity, the top electrode can also be evaporated. Finally, the elements are defined by etching isolating trenches, as shown in **Figure 12(f)**. Because the active silicon layer is not a good insulator, it must be etched all the way to the oxide layer to electrically isolate the elements. The trenches are defined with photolithography and then dry etched into the silicon. After defining elements, one can use low-temperature oxide (LTO) to passivate the metal electrode to provide an insulating surface (**Figure 12(g)** and **12(h)**).

2.14.4 Integration of Ultrasonic Transducer Arrays with Electronic Circuits

Modern ultrasonic imaging systems combine the use of multielement transducer arrays with digital circuitry and signal processing techniques to provide high-quality images at a relatively low cost. These systems also present real-time images at high frame rates. A typical commercial state-of-the-art ultrasonic imaging system is a massive instrument. Although this kind of a system can be moved around in a hospital environment, it does not quite fit to the modern definition of portable set by communication devices. The bulkiness of the ultrasonic imaging equipment is a result of the necessity to simultaneously process data coming from multiple transducer channels. A block diagram of the imaging system is shown in Figure 13. In a typical ultrasonic imaging system, the transducer array is located in a probe, which is connected to the processing unit through a bundle of cables. The processing unit contains a pulser, a low-noise preamplifier, a time-gain controlled amplifier, a low-pass filter, and an analog-to-digital converter for each channel. Digital circuits for transmit/receive (T/R) beamforming are also located in the processing unit. The total number of printed circuit boards in the unit can be as many as 40, depending on the number of ultrasonic channels. Channel counts in modern phased array systems can be as many as 256. During conventional phased array operation, all channels are active both in transmit and in receive.

The cable losses and parasitic capacitances degrade the noise performance of the imaging system and limit the achievable bandwidth. The integration of the ultrasonic transducer array with supporting electronics minimizes the parasitics and consequently improves the sensitivity and preserves the transducer bandwidth. Furthermore, integration helps decrease the number of interconnects between the transducer array and the signal processing unit to a manageable level by multiplexing several channels. For applications such as intraoperative navigation and intravascular diagnostic imaging, the size of the probe and the number of cables connected to the probe are even more important. Integrating the electronics with the array enables the realization of a compact probe with a minimum number of external connections. For large 2D transducer arrays with thousands of elements, multiplexing in the probe is a necessity.

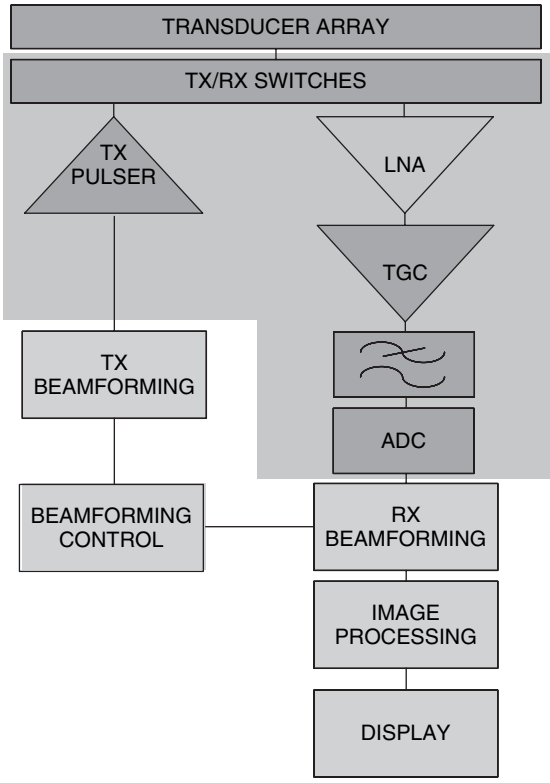

Figure 13 Block diagram of a medical ultrasonic imaging system. ADC, analog-to-digital converter; LNA, low-noise amplifier; TGC, time-gain control; TX, transmitter; RX, receiver.

Continuous scaling of microelectronics reduces the cost per function and makes it possible to pack more functionality on a single die. The increased computational power and the higher speed of microelectronic circuits can also ameliorate processing large amounts of data resulting from increased channel counts in next-generation ultrasound imaging systems.

In this section, different methods for integrating ultrasonic transducer arrays with electronic circuits are reviewed; important aspects of ultrasound transceiver design are also outlined.

2.14.4.1 Monolithic and Multichip Approaches

To integrate transducer arrays with associated T/R electronics, several interconnection schemes have been proposed. These schemes can be classified in two major groups: monolithic and multichip approaches.

Monolithic approaches integrate ultrasonic transducer arrays with supporting electronic circuits on the same substrate. This kind of integration can be achieved by post- or preprocessing standard silicon complementary metal oxide semiconductor (CMOS) integrated circuits (ICs). Monolithic integration of microelectromechanical systems (MEMS) with electronic circuits usually results in a compromise of the performance of one or both components. It has been demonstrated that a modified CMOS or bipolar CMOS (BiCMOS) process could be used to fabricate ultrasonic transducers on the same silicon substrate with electronic circuits (Eccardt *et al.* 1997, Niederer *et al.* 1999). Although this method provides a cost-effective means of integration, it is not suitable for 2D arrays because the usable active area is compromised either by the electronics, if the element area is shared with the electronics, or by the interconnect lines, if the electronics is placed on the periphery of the array and connected to the array elements through routing lines. In this approach, the number of available design parameters is also reduced due to the use of a standard process. An alternate method uses postprocessing to fabricate cMUT elements over the electronics chip, which is built using a standard CMOS process (Daft *et al.* 2004, Noble *et al.* 2001, 2002). The wafer with the electronics goes through passivation and chemical–mechanical polishing (CMP) processes before the cMUT fabrication process. This integration method, probably being only slightly costlier than the former, is suitable for 2D array integration because of its better area utilization. Because the preprocessed electronics limit the temperature of the postprocesses, a low-temperature process must be used to fabricate cMUTs over the electronics. Although a low-temperature cMUT process using PECVD has been tailored to achieve good control over the stress in the membrane and reasonable uniformity, a high-temperature cMUT process using LPCVD still results in better on-wafer and wafer-to-wafer uniformity and a higher yield.

The multichip approach requires that the electronics and the transducers be fabricated on separate wafers and that they be integrated in the final step. For arrays in linear configuration, the integration can be accomplished by wire bonding, which is viable if a larger footprint is acceptable and the level of tolerable parasitic capacitance is high. Flip-chip bonding is required if the transducer elements are densely packed, such as in a 2D array, or if the elements are very small so that a large parasitic capacitance would significantly degrade the performance. In the multichip approach, high-temperature processes can be used to fabricate high-density and high-performance cMUT arrays with high yield and uniformity. The integration of the cMUT arrays with the electronics comes at the expense of additional steps to the cMUT process, which are the fabrication of the through-wafer interconnects to bring the electrical connections to the backside of the silicon wafer and flip-chip bonding. Both of these processes are CMOS compatible. Because the electronics and the transducer arrays are fabricated on separate wafers, the overall yield of the manufacturing process is enhanced and the turn-around time is reduced. The cost reduction associated with the higher yield and a faster turn-around time compensates (probably surpasses) the increase in the cost due to the increase in the number of processing steps. The integration of array elements with electronics on the probe not only improves the performance but also reduces the number of external leads to a manageable level.

We have developed two flip-chip bonding techniques to integrate 2D cMUT arrays with front-end ICs. For both techniques, a Ti/Cu/Au metal stack is evaporated onto backside pads of cMUT arrays to enhance electrical contact and to establish the necessary under bump metallurgy (UBM) for flip-chip bonding. The first method is based on anisotropic conducting film (ACF). For this technique, a wire bonder is used to place 25-μm-diameter, 25-μm-tall gold stud bumps on the 50 μm × 50 μm bond pads on a matching chip, which can be an IC or a fan-out board. The gold studs are coined to obtain a uniform bump height across the whole die. ACF (FP1708E, Sony Chemicals, Tokyo, Japan) is then laminated on the matching chip. A flip-chip bonder (Model M8, Research Devices Inc., Piscataway, NJ) is used to align and bond the two parts by applying a pressure of 30 g per bump and a peak temperature of 190°C for 20 s. The ACF is cured at the elevated temperature. This film conducts at the points where it is squeezed between the cMUT pads and the gold bumps. Results obtained using this flip-chip bonding technique are shown in **Figure 14**. For the second flip-chip bonding technique, Sn/Pb solder bumps are deposited on the bond pads of the matching chip. These pads are first coated with 5 μm of Ni/Au with an electroless plating process to provide the appropriate UBM for the solder bumps. Solder bumps with diameters of 80 μm are placed onto these bond pads using a solder jetting process (Kasulke *et al.* 1998). Bumps can be alternatively

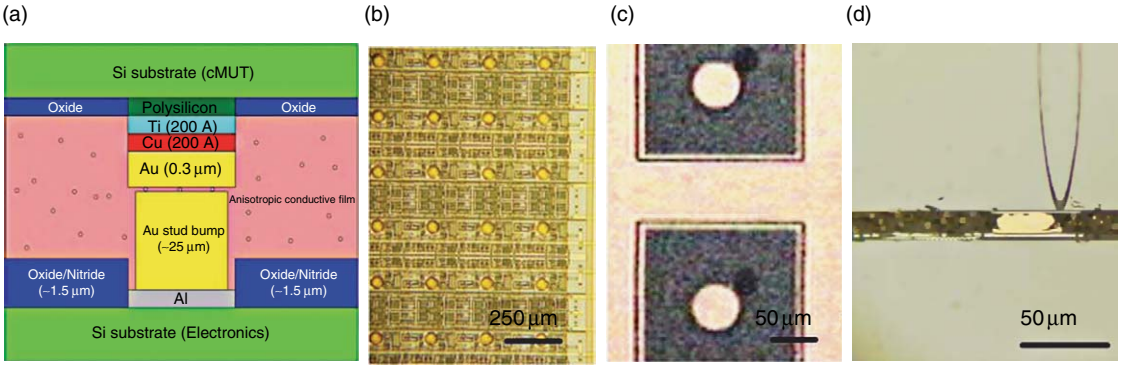

Figure 14 (a) Gold stud – anisotropic conducting film (ACF) flip-chip bonding technique. (b) Stud-bumped integrated circuit (IC) pads. (c) Backside bond pads on the capacitive micromachined ultrasonic transducer (cMUT) array. (d) Cross section of the flip-chip bonded sample.

placed on the backside pads of the cMUT array. The cMUT and IC are aligned and heated to 150°C with 4 g per bump pressure. Following the alignment, the samples are placed into an inert atmosphere oven and a reflow at 200°C is performed. The results from this second technique are shown in Figure 15.

2.14.4.2 Ultrasound Transceivers

Although digital circuits process data in the back-end for image reconstruction and enhancement, the signals transmitted and received by the transducer are fundamentally analog. Therefore, the analog front-end is critical as it sets limits on system performance

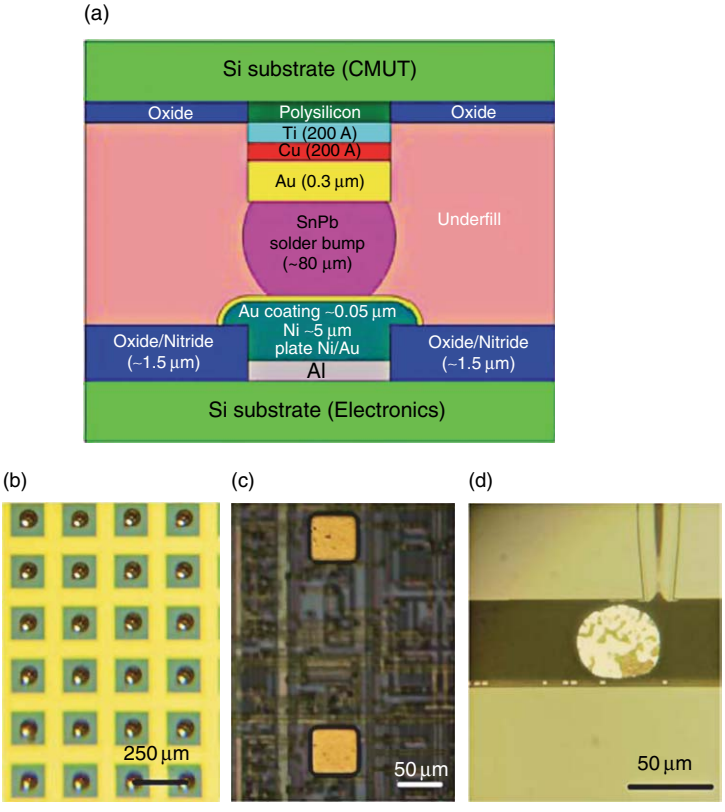

Figure 15 (a) Solder bump – Ni/Au plating flip-chip bonding technique. (b) Solder-bumped backside bond pads on the capacitive micromachined ultrasonic transducer (cMUT) array. (c) Electroless Ni/Au-plated IC pads. (d) Cross section of the flip-chip bonded sample.

(Schafer and Lewin 1984). In this section, the major trade-offs in the design of the analog front-end circuits are analyzed. The design considerations for ultrasound transceivers can be divided into three categories: the transmitter, the receiver, and the switching between the two.

The function of the transmitter is to excite the transducer to produce a short-duration pulse of acoustic energy. The transmitters in an array configuration are driven by pulses in a delay pattern determined by the transmit beamformer to produce a desired focal point. The pulses are amplified by the transmitter circuit driving the transducer. In more sophisticated systems the pulses might be generated by a digital-to-analog converter according to the timing information provided by the beamformer to shape the transmit pulses for better energy utilization or even for coding to improve the overall signal-to-noise ratio (SNR) of the system. The excitation voltages in existing systems can be as high as a few hundred volts to maximize the SNR. However, the excitation voltages cannot be arbitrarily high. There are limits on the total acoustic power set by the Food and Drug Administration (FDA), so that the acoustic radiation does not exceed the safe doses for the patient, e.g., $94\,\mathrm{m\,W\,cm^{-2}}$ maximum spatial-peak temporal-average intensity for fetal imaging (FDA 1997). It is difficult to measure the acoustic output power in different operating modes and to ensure compliance with FDA regulations (Patton *et al.* 1994). There are also other practical limits on the excitation voltages to control electromagnetic interference and to avoid a potential shock hazard to the patient. An additional practical limit for piezoceramic transducers is the gradual depoling caused by high-voltage pulses. For micromachined transducers, dielectric breakdown of thin films imposes an equivalent practical limit on DC bias and AC excitation voltages.

The major role of the receiver in an ultrasonic imaging system is to amplify the signals sensed by the transducer as a result of the echoes returning from the discontinuities within the tissue. The electronic circuits following the transducer in the receive signal chain should preserve the frequency characteristics of the received echo while adding minimum amount of noise. The overall bandwidth of the receiver should thus not exceed the signal bandwidth to prevent excess noise. The dynamic range of received signals in a typical ultrasound pulse echo system is quite large. The large dynamic range of signals is caused by two major physical mechanisms. First, there is a difference in amplitude between signals reflected from interfaces at different depths. This difference is due to the attenuation in the medium. Second, there is also a difference between the reflection coefficients of the reflectors at the same range. By assuming $1\,\mathrm{dB\,cm^{-1}\,MHz^{-1}}$ attenuation in tissue, a penetration depth of 5 cm results in a dynamic range of 100 dB at an operating frequency of 10 MHz. Adding another 60 dB accounting for the reflectivity variations results in a 160-dB total dynamic range (Brunner 2002). Such a dynamic range cannot be achieved by a practical receiver unless some sort of gain control is employed. Compared with radio receivers, ultrasound receivers fortunately are advantageous for implementing gain control. In an ultrasonic imaging system, part of the signal variation is due to the attenuation in the medium. Thus, changing the gain as a function of time compensates for this variation, leaving only the variation due to the reflectivity differences in the final image. The lower limit of the signal dynamic range is determined by the minimum detectable signal, which roughly corresponds to the integrated noise of the transducer-preamplifier combination. The upper limit of the signal dynamic range is set by the closest and strongest reflector in the field of view. The described gain control scheme is generally referred to as time-gain control or time-gain compensation (TGC). Other design considerations include low-phase distortion and high isolation of digital and analog signals if digital circuits are integrated on the same die with the analog circuits.

The T/R switch connects the transducer to the transmitter while isolating the receiver during the transmit cycle. Similarly, it isolates the transmitter and connects the transducer to the receiver during the receive cycle. The key features of the T/R switch are low loss and low distortion in the conducting state and good isolation in the nonconducting state. The typical implementation of the T/R switch is by using pn or pin junction diodes as shown in **Figure 16**.

As discussed earlier, exciting the transducer with a high-voltage pulse is advantageous to maximize the SNR of the received echoes. Generating high-voltage pulses is difficult in advanced process technologies that enable the increased processing power mentioned earlier. Increased processing power stems from the scaling of semiconductor devices; the continuous scaling of these devices enables faster operation, increased density and functionality, and lower power consumption. However, supply voltages need to be scaled as well; otherwise high electric field

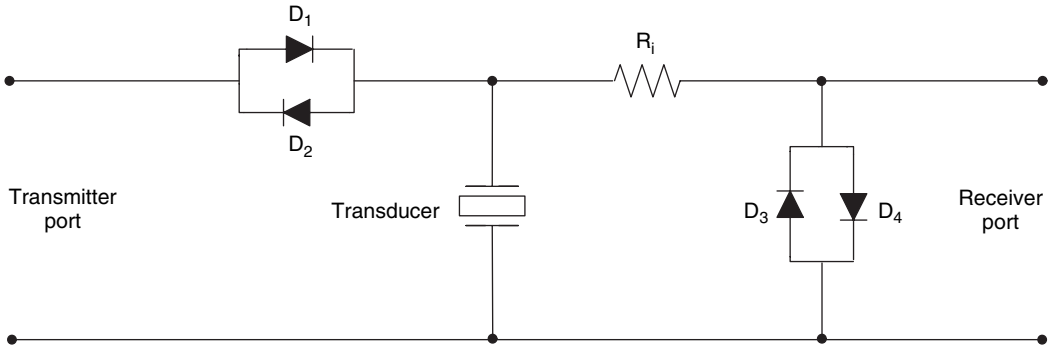

Figure 16 Conventional transmit/receive (T/R) switch.

intensities pose reliability problems. The major reliability-threatening mechanisms related to these fields are oxide breakdown, hot carrier degradation, and junction breakdown.

In systems involving both complex signal processing and high-voltage operation, it is usually preferable to perform most of the signal processing at low voltage and translate the result into high voltages as a last step. Although the integration of high-voltage devices and high-performance, low-power circuits is an attractive option, other system partitioning schemes that use multiple chips have also been proposed for ultrasonic imaging systems (Robinson and Mo 1992). However, for applications with a high channel count and a restricted area, these schemes are not feasible. The implementation of high-voltage circuits can be achieved by taking actions at the technology, layout, or circuit design levels.

One of the most straightforward approaches to implement high-voltage circuits is to use a process technology offering high-voltage devices along with low-voltage, high-speed transistors. These technologies require extra masks and processing steps and hence have a higher cost. These processes are also not as easily accessible as are mainstream standard CMOS processes. A more sophisticated and nonstandard approach for the implementation of high-voltage ICs is to design high-voltage devices with a standard, unmodified, low-voltage CMOS technology (Ballan and Declercq 1999, Maluf *et al.* 1996). In this approach, the designer uses the available layers in the given process but combines them in an unconventional way. For example, the n-well implant is very convenient to form lightly doped drain extensions in a high-voltage n-channel MOS transistor. In a standard process the well implant is followed by a diffusion step, which causes lateral diffusion that can significantly reduce the effective gate length. Although this approach does not require any process modification, the high-voltage devices need to be characterized and appropriate models should be generated to enable the use of these devices in practical circuits. A third approach to allow high-voltage operation is to employ special circuit structures in which individual devices operate at allowed voltage levels, but at some nodes high-voltage signals can be generated without overstressing the devices. Although the supply voltages in modern ICs constantly decrease, these ICs still need to communicate with older-generation ICs, resulting in some systems having mixed-voltage input/output (I/O) (Dabral and Maloney 1998). Due to this necessity, new circuit structures have been developed for mixed-voltage I/O that can tolerate voltages exceeding the nominal supply voltage. Some of these I/O circuits are also capable of driving the outside components at the same high-voltage levels. Cascoding or stacking is a commonly used technique in these circuits to accommodate high-voltage signals, typically twice as large as the nominal supply voltages without overstressing any of the transistors in the circuit (Annema *et al.* 2001, Singh and Salem 1999). A 7 V buffer implemented in a 2.5 V CMOS process has also been reported (Prodanov and Boccuzzi 2001).

Using the circuit design techniques mentioned above, we have demonstrated several generations of front-end ICs in standard CMOS and BiCMOS technologies to interface with several cMUT arrays for practical imaging applications (Wygant *et al.* 2004, 2005a, b). The basic building block of these circuits is shown in **Figure 17**. The images obtained using these ICs with cMUT arrays are presented in the following section.

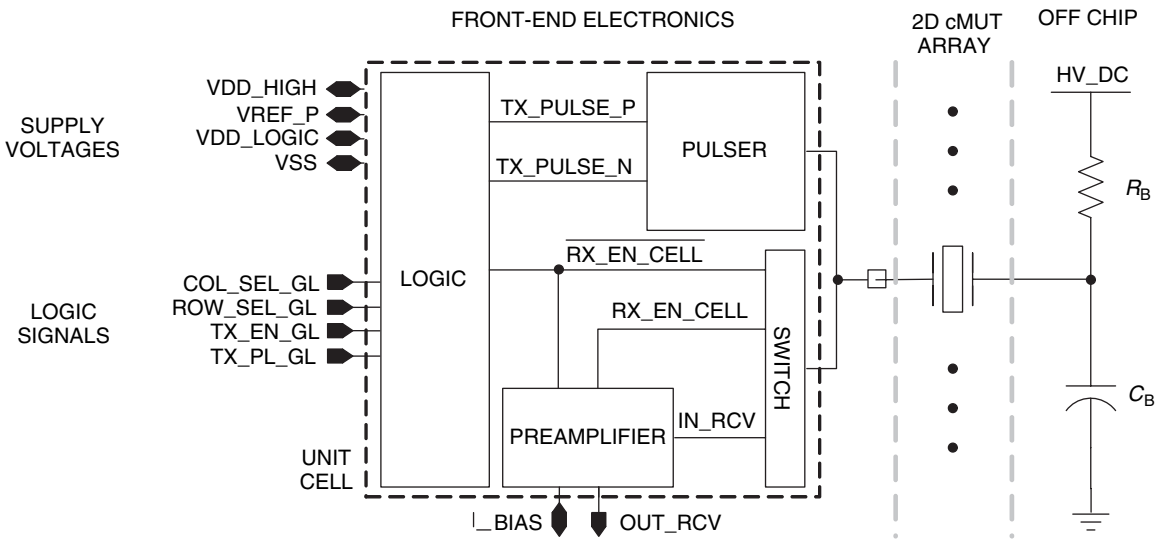

Figure 17 Basic building block of integrated front-end circuits for capacitive micromachined ultrasonic transducer (cMUTs).

2.14.5 Medical Imaging Applications

Although the medical applications of ultrasonic imaging followed the underwater and industrial applications chronologically, in terms of sophistication and impact, medical ultrasonic imaging has surpassed any other application. Ultrasonic imaging has several unique advantages compared with other medical imaging modalities. Ultrasound is a nonionizing radiation and is hence safe for diagnostic use even for obstetrical applications. The image presentation is in real time, allowing the study of moving internal structures. Ultrasonic imaging equipment is cost-effective and portable. All these features have made ultrasound a well-accepted and widely used imaging modality in medicine. Ultrasound is particularly useful in imaging cardiac structures, the vascular system, the fetus and uterus, abdominal organs such as the liver, kidneys and gall bladder, and the eye.

In this section, experimental imaging results from cMUT arrays are presented. These results demonstrate that micromachined transducer arrays integrated with supporting electronics enable many applications that have not been feasible with the existing piezoelectric transducer technology.

2.14.5.1 Conventional 2D Ultrasound Imaging

We have built 1D linear cMUT arrays of equivalent size, channel count, and operating frequency to state-of-the-art medical arrays employing piezoelectric transducers. These arrays contain 128 individually addressable elements, each 6 mm high by 200 μm wide. The element pitch is 250 μm, ideal for the chosen 3-MHz operating frequency. These arrays have been used along with a PC-based custom data acquisition system to demonstrate synthetic phased array cross-sectional images of a resolution test phantom (Oralkan *et al.* 2002). The resulting B-scan image of the resolution test target and the experimental and simulated axial and lateral point spread functions (PSFs) are shown in **Figure 18**.

2.14.5.2 Real-Time 3D Ultrasound Imaging

The implementation of real-time 3D ultrasound imaging systems relies on 2D transducer arrays. The small size of the elements in a 2D array causes degradation in acoustic output power and receive sensitivity. There are also severe difficulties in fabricating these densely populated 2D arrays and providing individual electrical connections to each element. Micromachined ultrasonic transducer technology is an ideal candidate to overcome these obstacles, preventing the realization of true 3D ultrasound imaging systems.

To demonstrate the potential of cMUTs for 3D imaging, we developed a system based on a 2D, 16×16 element, cMUT array. The target application for this system is endoscopic imaging to provide intraoperative guidance. Transducer arrays with operating frequencies ranging from 3 to 7.5 MHz

were fabricated for this system. The transducer array including DC bias pads measures 4 mm × 4.7 mm. The array elements are connected to flip-chip bond pads on the array back side with 400-µm-long through-wafer interconnects. The array pitch is 250 µm. The array is flip-chip bonded to a custom-designed IC that comprises the front-end electronics (**Figure 19**). Images of a vessel phantom using the described experimental synthetic aperture imaging system are shown in **Figure 20** (Wygant *et al.* 2004, 2005a, b). The system described here meets the challenges of catheter-based imaging. This prototype

system proves the feasibility of a compact probe employing a 2D array with integrated electronics.

2.14.5.3 Intravascular and Intracardiac Ultrasound Imaging

Forward-viewing ultrasound volume images are desired for many intravascular and intracardiac applications such as guiding treatment of chronic total occlusion, helping stent deployment, and monitoring ablation procedures in the heart. Because of the requirements for a guide wire in catheters, an annular ring is the preferred geometry for transducer arrays. However, it is very challenging to implement this geometry in a very small scale (1–2 mm) by using the existing piezoelectric transducer technology (Wang *et al.* 2002). On the contrary, cMUT arrays can be made in any arbitrary geometry with very small dimensions using photolithographic techniques and standard microfabrication processes. We used a 64-element, 2-mm-diameter cMUT ring array wire bonded to 64 T/R channels in a bank of four custom-designed ICs to demonstrate the feasibility of forward-looking intravascular ultrasound (**Figure 21**). In this experiment, the cMUT array has been operated in both conventional and collapse operating regimes by setting the DC bias voltage to 30 and 100 V, respectively. The resulting operating frequencies in the conventional and collapse (center of the membrane in contact with the bottom electrode) regimes are 8.5 and 19 MHz, respectively. We have imaged several phantoms including a small metal spring and deployed and undeployed forms of a Palmaz–Schatz coronary stent (Yeh *et al.* 2006). The 3D rendered images next to photographs are shown in **Figure 22**.

2.14.5.4 Photoacoustic Imaging

Traditional ultrasound images are formed by first transmitting ultrasound to a medium of interest and then receiving the ultrasound signals resulting from the interaction of the transmitted signals with the medium. This kind of an image is usually a representation of the mechanical properties of the medium and provides structural or anatomical information. The interaction of the medium with other forms of energy can provide additional information about the functional differences even in a structurally indifferent, uniform medium. For instance, when a short laser pulse is transmitted into a tissue, the introduced light energy is absorbed and scattered in a different

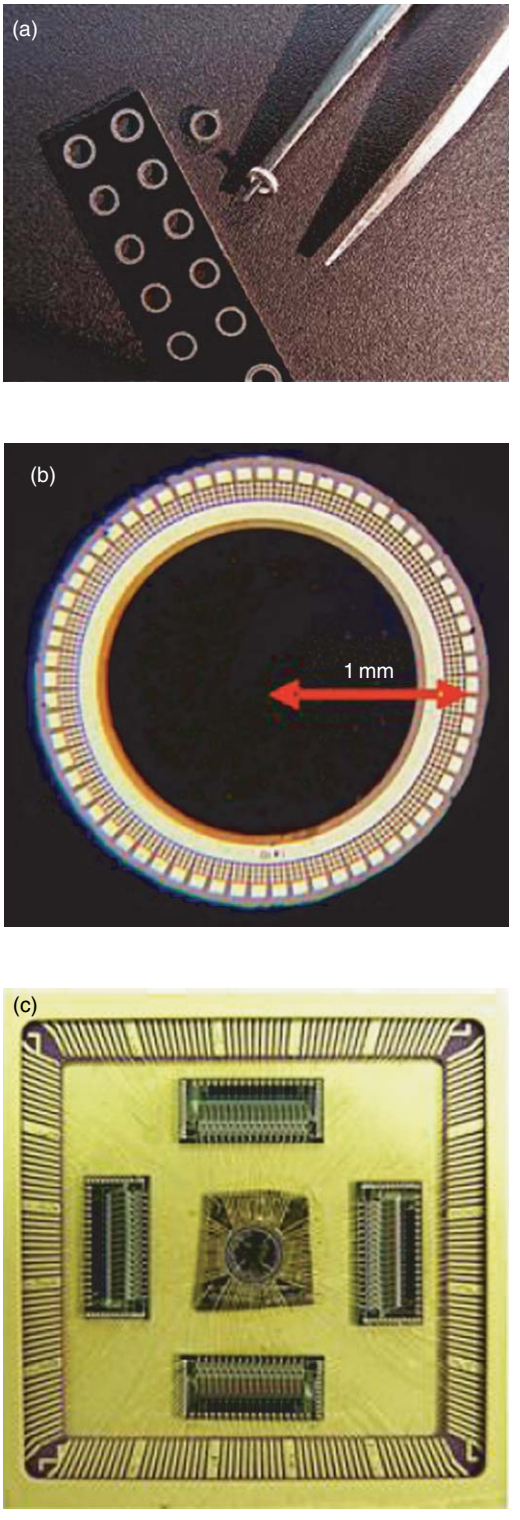

Figure 21 (a) Several capacitive micromachined ultrasonic transducer (cMUT) annular ring arrays. (b) Magnified view of a cMUT annular ring array. (c) cMUT annular ring array wire bonded to custom-designed front-end integrated circuits (ICs).

manner by different parts of the tissue. The optical absorption depends on the wavelength of the light and the properties of the medium at the molecular or even the atomic level (Esenaliev *et al.* 1999). The regions with stronger absorption characteristics in a tissue generate stronger acoustic signals via the thermoelastic effect, which is simply the thermal expansion of the imaging regions resulting in a mechanical disturbance and hence an acoustic signal. By collecting these light-induced acoustic signals using a transducer or array of transducers, one can construct an image that is a representation of light

absorption characteristics of the sample. One example of this approach is to image the microvasculature in tissue by detecting blood oxygenation, which is usually a sign of angiogenesis indicating a cancerous lesion (Ku *et al.* 2005). In this example, the increased light absorption of the oxygenated blood is used to create a high-contrast image.

Photoacoustic imaging has typically relied on a single mechanically scanned focused piezoelectric transducer for detection of the laser-generated ultrasound. Using a cMUT array in place of a mechanically scanned element has a number of advantages. Three-dimensional images can be acquired in one shot using large 2D arrays that can be reliably fabricated using cMUT technology. We demonstrated the potential of cMUTs for photoacoustic imaging by using a 2D array (Vaithilingam *et al.* 2006, Wygant *et al.* 2005c). The experimental setup is shown in **Figure 23(a)**. Both structural reflection-mode ultrasound images and functional photoacoustic images are obtained using a 16×16-element and 48×48-element aperture by using mechanical scanning. The overlaid images in **Figure 23(b)** and **23(c)** show that the optical contrast of ink is only visible in the photoacoustic image (red); structural information about all the three tubes is captured by the traditional reflection-mode ultrasound image.

2.14.6 Conclusions

Since the introduction of cMUT technology in the early 1990s, significant milestones have been achieved in modeling, fabrication, and applications. Today, the analytical and numerical models can reliably be used to design transducer arrays in a frequency range from tens of kilohertz to tens of megahertz. The fabrication techniques are capable of producing repeatable and reliable devices. Integration with supporting electronic circuits using monolithic and multichip approaches has been demonstrated. The once challenging applications such as real-time 3D imaging and forward-looking intravascular imaging have proven feasible with this new technology.

Extensive research efforts on cMUTs spanning more than a decade have finally brought this technology to a point where large arrays can be manufactured reliably, and a consensus has been reached that these transducer arrays indeed provide superior image quality. However, underlying fabrication techniques make the cMUT still open for further performance and cost improvements.

The future research on cMUTs can be directed toward increased levels of integration, higher operating frequencies, lowering the cost, providing therapeutic tools, or combinations of these depending on the application of interest. All these different directions have one thing in common: All can benefit from the use of cMUT technology. The versatility of this technology makes it especially attractive for implementing future generations of ultrasonic imaging systems.

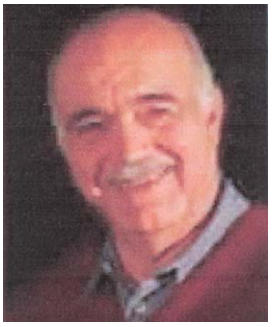
Biographies



Butrus (Pierre) T. Khuri-Yakub was born in Beirut, Lebanon. He received a B.S. degree in 1970 from the American University of Beirut, an M.S. degree in 1972 from Dartmouth College, and a Ph.D. degree in 1975 from Stanford University, all in Electrical Engineering. He joined the research staff at the E.L. Ginzton Laboratory of Stanford University in 1976 as a research associate. He was promoted to Senior Research Associate in 1978 and to Professor of Electrical Engineering in 1982. He has served on many university committees such as Graduate Admissions and Undergraduate Academic Council of the School of Engineering.

Professor Khuri-Yakub has been teaching at both the graduate and undergraduate levels for over 15 years, and his current research interests include *in situ* acoustic sensors (temperature, film thickness, resist cure, etc.) for the monitoring and control of integrated circuit manufacturing processes, micromachining silicon to make acoustic materials and devices such as airborne and water immersion ultrasonic transducers and arrays, and fluid ejectors, and in the field of ultrasonic nondestructive evaluation and acoustic imaging and microscopy.

Professor Khuri-Yakub is a fellow of the IEEE, a senior member of the Acoustical Society of America, and a member of Tau Beta Pi. He is an associate editor of *Research in Nondestructive Evaluation*, a journal of the American Society for Nondestructive Testing, as well as a member of AdCom of the IEEE Group on Ultrasonics Ferroelectrics and Frequency Control (January 1, 1994–January 1, 1997).

Professor Khuri-Yakub has authored over 450 publications and has been principal inventor or co-inventor on over 72 patents. He received the American University of Beirut School of Engineering Distinguished Alumni Award, May 2005, Stanford University Outstanding Inventor Award, June 2004, IEEE UFFC Distinguished Lecturer Award, 1999, Stanford University School of Engineering Distinguished Advisor Award, June 1987, and the Medal of the City of Bordeaux for contributions to NDE, 1983.

Arif Sanli Ergun was born in Ankara, Turkey, in 1969. He received his B.Sc., M.Sc., and Ph.D. degrees in 1991, 1994, and 1999, respectively, all in electrical and electronics engineering, from Bilkent University, Ankara, Turkey. He was a research assistant in Bilkent University between 1991 and 1999, and an engineering research associate at E. L. Ginzton Laboratory, Stanford University, Stanford, CA, between 2000 and 2006. He is currently a research scientist at Siemens Corporate Research.

His research interests are microwave electronics, ultrasound, ultrasound imaging, and MEMS/NEMS, with an emphasis on capacitive micromachined ultrasonic transducers (cMUTs). He is a member of the IEEE and the Electron Devices Society.

Ömer Oralkan received the BS degree from Bilkent University, Ankara, Turkey, in 1995, the MS degree from Clemson University, Clemson, SC, in 1997, and the Ph.D. degree from Stanford University, Stanford, CA, in 2004, all in electrical engineering.

He joined the research staff at the E. L. Ginzton Laboratory of Stanford University in 2004 as an engineering research associate. He was promoted to the rank of Senior Research Engineer in 2007. His past and present research interests include analog and digital circuit design, semiconductor device physics and fabrication, micromachined sensors and actuators, and medical imaging. His current research focuses on the design and implementation of integrated systems for catheter-based medical imaging applications, photoacoustic imaging, and chemical and biological sensor arrays.

Dr. Oralkan has authored and coauthored over 60 publications and received the 2002 Outstanding Paper Award of the IEEE Ultrasonics, Ferroelectrics, and Frequency Control Society. He is a member of the IEEE, SPIE, and AIUM.

Goksen Goksenin Yaralioglu was born in Akhisar, Turkey, in 1970. He received his BS, MS and Ph.D. degrees from Bilkent University, Ankara, Turkey, in 1992, 1994, and 1999, respectively, all in electrical engineering. From 2000 to 2006 he was an engineering research associate in the E. L. Ginzton Laboratory, Stanford University. Currently, he is a senior MEMS engineer at Invensense, Inc., Santa Clara, CA. His past and present research interests include design, modeling, and applications of micromachined transducers, atomic force microscopy at ultrasonic frequencies, and acoustic microscopy.

2.15 Tissue Engineering

Jeffrey T. Borenstein, Draper Laboratory, Cambridge, MA, USA

2.15.1 Introduction

The field of tissue engineering has emerged in the 1980s in response to an ever-increasing shortage of donor tissues and organs available to patients suffering from end-stage tissue and organ loss (Langer and Vacanti 1993, Vacanti and Langer 1999). Advances in surgical techniques and transplantation medicine have enabled clinicians to save the lives of hundreds of thousands of patients suffering from failure of vital organs such as the heart, the lungs, or the liver. An enormous number of people suffer from the loss of other tissues such as skin, bone, and cartilage that results from injuries such as burns, fractures, or overuse or is caused by illnesses such as diabetes. For these patients, donor tissues can provide a permanent solution but may generate additional complications depending on the source of the replacement tissue. It is the goal of the field of tissue engineering to provide an unlimited source of replacement tissues and organs for transplantation, thereby easing the growing crisis facing the nation's health care system. In this chapter, the emerging role of microsystems technology as a platform for tissue engineering is described.

2.15.1.1 Clinical Need for Engineered Tissues

Pioneering advances in the 20th century established transplantation of cadaver organs as a viable and often lifesaving treatment for patients suffering from end-stage organ failure. Kidney, heart, liver, and lung transplants, for instance, are now common and often lead to long-term survival of the recipient. However, these patients have to endure increasingly long waiting periods for a suitable donor organ and often do not survive till then. In addition, the use of allograft tissues and organs necessitates the use of immunosuppressive drugs in order to prevent donor graft rejection; these compounds are both expensive and responsible for severe side effects. The numbers of US patients waiting for a donor organ to become available for specific organ types are summarized in **Table 1**.

In parallel with advances in the transplantation of donor organs, a revolution in the development and use of mechanical organ assist and organ replacement devices is under way. For those patients suffering from kidney failure, renal dialysis provides a means for removing toxins from the blood and is capable of

Table 1 June 29, 2007 data on size of waiting list in United States for waiting list candidates for vital organ transplants. Source the Organ Procurement and Transplantation Network (OPTN)

sustaining patients for many years. Such extracorporeal approaches for liver and lung assist devices may provide a bridge to transplant but do not represent viable long-term strategies. The use of extracorporeal membrane oxygenators (ECMOs) and more recently intravascular oxygenators has provided cardiopulmonary support to neonates and to pediatric and adult patients suffering from acute lung or heart failure. Despite extraordinary progress in mechanical assist devices such as the totally implantable mechanical heart, these mechanical organ replacement devices still face many difficult challenges in providing safe and effective short-term therapy. Ultimately, such mechanical devices may never represent a long-term viable strategy for organ replacement because of foreign body reactions and logistical challenges related to the size, power requirements, and operational incompatibility of the devices with human physiology.

Approaches extending beyond cadaveric organ transplantation and mechanical devices are also available for many organs and tissues. For example, split liver transplants have enabled genetically related individuals to provide a part of their organ to a recipient, by taking advantage of the regenerative capacity of the liver so as to ensure long-term liver function in the donor. However, such partial organ transplants remain rare and present the unfortunate possibility of morbidity or mortality for the healthy donor. In addition, a patient with a burn injury, a diabetic ulcer, or a damaged blood vessel, for instance, may provide an autograft for transplant from a different site in their body. These approaches, though common, do present a significant problem for the patient in terms of donor site morbidity. Another avenue for addressing the shortage of donor organs involves the investigation of animal organs as a potential source for transplants (Seebach *et al.* 2001). Known as xenotransplantation, this field focuses principally on the use of pig (porcine) organs, because of phenotypic and physiological similarities between porcine and human tissue. The principal obstacle to the use of xenotransplantation involves genetic differences between humans and pigs and the possibility of passing genetic viruses between species.

The challenges facing the various routes to addressing the shortage of donor tissues and organs have spawned the field of tissue engineering (Berthiaume and Yarmush 1995, Kaplan *et al.* 2005, Lysaght and Reyes 2001), where cell-based grafts and devices are generated in the laboratory and transplanted into the recipient. Most of the advances in tissue engineering in the 1990s have involved simpler tissue systems such as skin and cartilage. These structures are simpler than vital organs for several reasons: they involve fewer cell types, possess less complex microstructures and microenvironments, and often do not require an intrinsic vascular supply. Tubular structures such as the intestine, ureter, pulmonary artery, and even the bladder have been constructed in the laboratory using tissue engineering (Mooney *et al.* 1994, Niklason *et al.* 1999) and have been transplanted successfully into patients. These examples provide a glimpse of what will one day be possible as the field of tissue engineering advances, enabled in part by microsystems technology as will be described in later sections.

2.15.1.1.1 Shortage of tissues and organs for transplant medicine

Tissue loss and failure represent enormous challenges in terms of impact on quality of life and economic burden (Langer and Vacanti 1993, Palsson and Bhatia 2004). While organ failure is more directly associated with patient mortality, for elderly patients even seemingly non-life-threatening events such as a hip fracture are associated with high death rates within 2 years of transplantation. For younger patients, the loss of skin, bone, connective tissues, or muscle can present devastating consequences such as immobility and its long-term complications. Over 1 million burn patients in the United States would benefit annually from an engineered tissue solution to heal the damaged site, according to the American Burn Association. Pressure sores or pressure ulcers in bedridden patients, vascular disorders, and diabetes are responsible for another 1.25 million US patients per year. Nerve and spinal cord defects present another challenging and tragic situation amenable to an engineered tissue solution. Nearly 1.5 million patients in the United States suffer from ailments requiring bone grafts, hip and other joint replacements, or internal fixation. In terms of connective tissues, enormous numbers of patients undergo knee surgeries involving the patella or meniscus, as well as tendon and ligament surgeries. At the national level, millions of patients suffer from the loss of teeth and dental tissues, potentially resulting in nutritional deficiencies and other complications. In all of these cases, the ability to generate healthy replacement tissue in the laboratory would revolutionize patient care.

An ever-increasing shortage of donor organs has led to a crisis in the nation's health care system. Over

100 000 patients are now listed on the UNOS list of those waiting for an organ transplant. Each year, although 30 000 patients with liver failure caused by diseases such as cirrhosis and hepatitis await organ transplants, only 3000 livers are transplanted. Even for those patients fortunate enough to receive a donor organ, the potential for immune rejection often leads to a lifetime of expensive and potentially dangerous immunosuppressive drugs. Similar crises exist for patients with lung and heart failure. Over 1 million patients suffer from cardiac and blood vessel ailments for which engineered tissue replacements would provide critically needed long-term solutions. Tubular structures such as the intestine, the urethra, and the bladder are the subjects of intensive efforts to develop engineered tissue solutions.

The explosion of type II diabetes, as a result of the aging population and the surge in obesity and metabolic disorders, has further contributed to the critical shortage of tissues and organs. This is manifested directly by the need for healthy pancreatic islet cells as well as by diabetic complications that damage the heart, blood vessels, and kidneys. More than 500 000 patients suffer from kidney diseases requiring long-term support or transplantation. As described in Section 2.15.1.1.2, renal dialysis provides a chronic approach for organ assist but has many drawbacks in terms of quality of life and long-term prognosis. Finally, neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease present opportunities for cell-based therapies that may not comprise conventional engineered tissues such as skin or organ replacement but may also benefit from microsystems-based approaches for cell transplantation that are synergistic with the microtechnology platforms described herein.

2.15.1.1.2 Organ assist devices

The most prevalent organ assist device in use is the kidney dialyzer. A typical therapeutic regimen involves three 4-h treatments per week, in a clinical setting such as a dialysis center. The requirement for such expensive and frequent treatments to occur in the clinic presents enormous challenges for both the patient and the health care provider. Furthermore, the long-term prognosis for kidney dialysis patients suffering from end-stage renal failure is grim, with a 20% 5-year survival rate and staggering complications because of the cyclic nature of toxin levels in the blood as well as inflammatory responses. Pioneering work by Kolff, Berk and colleagues (Kolff, Berk *et al.* 1944) resulted in the first kidney dialysis machines, which were bulky and complex, but demonstrated the ability to sustain life in patients. These devices typically operate by passing the patient's blood through a series of nanoporous vessels, in the manner of an external microcirculation. Small molecules such as urea and creatinine, which are toxic at high levels, are removed from the blood, as in a healthy kidney. In addition, other small molecules such as electrolytes and glucose, as well as large amounts of water, are also removed. In a healthy kidney, these blood components are reabsorbed via active transport to maintain homeostasis and the fluid–electrolyte and nutritive balances. In kidney dialysis, the cartridge serves only as a passive filter, and therefore, essential blood components must be manually restored to the patient.

In the past several decades, several generations and versions of kidney dialyzers have been developed and demonstrated, using configurations involving hollow fibers, flat plates, spirals, and rolled tubes. In each case, the dimensions of the smallest structures within the cartridge are much larger than those found within the nephrons of the kidney, principally because of limitations in the technology used for constructing the dialysis cartridge. For instance, the small vessels in the glomerulus are in the range of 10 μm in diameter (Guyton and Hall 2000), whereas hollow fibers have diameters of several hundred microns. Therefore, the clearance efficiency of small molecules is dramatically reduced because of longer diffusion distances in conventional dialysis, presenting an opportunity for the development of a microelectromechanical systems (MEMS)-based renal dialysis system using microsystems technology (Kaazempur-Mofrad *et al.* 2004). Efforts toward a tissue-engineered kidney (Humes 1996) for acute renal failure (ARF) are also progressing rapidly.

Liver assist devices are less well developed than renal assist systems, principally because renal function can be substantially replaced by passive filtration and manual replacement of essential blood components, whereas liver function cannot (Allen and Bhatia 2002). In the case of the liver, protein and drug metabolism represent very complex functions that are only a fraction of the full spectrum of the key roles played by the liver. The complexity of these functions necessitates the use of viable liver cells in most systems; however, some liver assist systems do not contain living cells or tissues. In either case, liver assist devices have been demonstrated to be efficacious only in short-term applications such as recovery from acute liver failure or as a bridge to

transplantation. Microsystems technologies have played a key role in the understanding of liver cell function in *ex vivo* and laboratory systems (Allen and Bhatia 2002), as will be described later.

Cardiac assist devices are plentiful and have been highly successful. The totally implantable artificial heart represents the most challenging and complex of these assist devices (Dowling *et al.* 2000). Other systems include pacemakers, implantable cardioverter defibrillators (ICDs), and ventricular assist devices. In each case, these devices require sources of power, electronics and mechanical components, and the capability to replace one or more aspects of normal physiological cardiac function. Microsystems technologies have already enabled dramatic advances in cardiac assist devices, such as in the case of the ICD, where a MEMS accelerometer is used to detect the patient's motions as part of the feedback circuit that controls the activation of electrical stimulation.

Artificial lung devices have evolved over the past several decades and implantable versions are now being developed (Lund *et al.* 2002). These systems provide cardiopulmonary support by supplying oxygen from the blood through a membrane oxygenator. Microsystems technologies are now being explored to provide smaller versions of the membrane oxygenators, with smaller dimensions for the circulatory channels, as well as microtechnology-based approaches to provide novel oxygen sources for the device. In the cases of heart, lung, liver, and kidney assist devices, as well as for other applications, the central goal is to replace organ function in a manner that is as physiologically compatible and realistic as possible. Microsystems technologies are playing an increasingly important role because of their ability to miniaturize structural components and overall systems, as well as because of their potential for smart systems containing sensors for autonomous operation and real-time control.

2.15.1.1.3 Platforms for drug and vaccine discovery

Cell-based systems for transplantation as a therapeutic avenue for end-stage tissue or organ failure represent the largest set of potential applications for tissue engineering, but by no means the only one. In addition to generating devices for surgical transplantation, tissue engineering is capable of providing laboratory-based systems that mimic the behavior of human tissue *in vitro*. Initially, these systems were used as basic research and discovery tools, but there is increasing interest in the use of engineered human tissues as a platform for testing of drug safety and efficacy, and as a tool for high-throughput assays for small molecules, polymers, and genomes. Vaccine discovery is another opportunity for engineered tissues based on human cells, because of the well-known problems with efforts to develop vaccines based on safety and efficacy information derived from animal studies. Progress toward an engineered thymic organoid (Poznansky *et al.* 2000), for instance, relies heavily on the ability of a microstructured scaffold to replicate the microenvironment in which B cells and T cells gain their targeting abilities against specific antigens. Microfabrication technology provides an avenue for producing a microenvironment that mimics that found in human physiology, because of the relevant dimensions of cells and organ microstructures at size scales of roughly 10 μm. In addition, the batch processing aspect of microfabrication techniques enables low-cost replication of microfluidic cell-based assays with fluorescent readouts, thereby providing a path for high-throughput screening.

2.15.1.2 Convergence of Microsystems and Biology

Early efforts in the field of microsystems utilized silicon-based microsensors comprising mechanical and electrical components on a chip that were used for measuring pressure, flow, or inertial motion. As the field progressed, applications in the life sciences began to emerge, but even here the first products were still silicon-based microelectromechanical sensors for blood pressure or other basic measurements. However, since the late 1990s, microsystems technologies have become an integral part of life sciences and biomedical research (Khademhosseini *et al.* 2006), because of their ability to interact with and control biological materials such as cells and proteins, and because microfabrication techniques capable of constructing 3D biological systems have now been developed. Before the advent of microsystems technologies and microfabrication techniques, it was not possible to engineer the microenvironments responsible for biological processes such as development and reproduction, injury, disease, and regeneration. The resolution and scalability of microfabrication technology, combined with its flexibility with regard to materials and chemistry, make it the ideal toolset for exploring biological systems.

Environmental cues associated with triggering cellular processes such as adhesion, migration, proliferation, differentiation, and apoptosis have been

difficult to reproduce *in vitro* because of the timescales and spatial dimensions involved (Liu and Chen 2005). Microfabrication-based tools such as replica molding, microcontact printing, and photodefinable matrices have been successfully applied to the investigation of spatiotemporal cues for cellular processes and ultimately have been used to construct engineered tissues and organ replacement devices by mimicking physiological systems at the macroscale and at the microscale. These environmental cues take several forms, including those associated with the matrix and the substrate, those associated with soluble factors, cell–cell interactions, and dynamic effects related to fluid stresses and other time-varying phenomena.

2.15.1.3 Investigations of Interactions of Microstructures and Cells

Topographic control of cell behavior has been investigated for several decades, first at the microscale but more recently at the submicron level, as investigators have discovered that nanoscale phenomena in numerous tissues are critical in determining cell behavior and tissue development (Flemming *et al.* 1999). Other interactions between substrates or matrices and cells have been probed using microfabrication techniques. The most typical means of controlling cell–substrate interactions has been through the use of chemical deposition or modification to create patterns of adhesive and nonadhesive regions (Bhatia *et al.* 1997, 1998a, b). Modulation of the size and distribution of adhesive regions has been shown to control cell-specific functions and proliferation (Chen *et al.* 1997). These pathways appear to be switched on and off by varying the spatial distribution of surface adhesion molecules, often through the use of self-assembled monolayers (SAMs). Limitations in the flexibility of SAM processes with regard to surface chemistry have led to the emergence of several other microsystems-based methods for patterning and engineering surfaces. For instance, microcontact printing with proteins has been exercised in concert with polyethylene glycol (PEG) surface coatings to generate adhesive and nonadhesive regions (Albrecht *et al.* 2006). Optical tweezers-based methods have been used to trap cells and form organized cellular arrays, as have been electric- and magnetic field-based approaches such as dielectrophoresis (Voldman *et al.* 2002).

Interactions between cells are known as homotypic interactions if the cells are of the same phenotype and as heterotypic interactions if the interactions are between different phenotypes; these interactions are a second critical aspect of engineered tissue formation. One of the seminal examples of the use of microfabrication technology to investigate heterotypic interactions for tissue engineering applications was the work of Bhatia *et al.* (1998b) involving interactions between hepatocytes and fibroblasts. Micropatterns of collagen were applied to substrates in order to provide a template for hepatocyte adherence, followed by culturing with fibroblasts to fill in the remaining spaces on the 2D substrate with fibroblasts (Bhatia *et al.* 1999). These studies probed the influence of hepatocyte/fibroblast spacing and densities on liver-specific functions and ultimately investigated the degree to which these heterotypic interactions are mediated by direct contact versus communication through exchange of soluble chemokines. Other studies have utilized microfabrication techniques to probe mechanisms involved in the downregulation of cell proliferation (Nelson and Chen 2003). In a fashion analogous to contact guidance phenomena between cells and a substrate, contact inhibition governs cellular proliferation via signals generated by contact between neighboring cells. Microfabrication techniques have been used to separate cell density effects from contact inhibition effects, highlighting the significance of specific cell–cell contacts (cadherins) in vasculature.

Three-dimensional platforms for organizing and probing cell–cell interactions *in vitro* have been developed by Khademhosseini *et al.* (2005). In this approach, surface adhesion molecules are not necessary to form aggregates of multiphenotype arrays. Rather, cells are introduced into microwells via microfluidic channels that can be assembled and reassembled because of the reconfigurable nature of the polymer matrix. Subsequent channel assembly can be conducted along different axes to provide lanes of cells of each type introduced into the microwells, thereby forming a highly arrayed platform for high-throughput screening and other discovery applications.

Fluid mechanical effects, both through direct fluid mechanical forces and through dynamic generation and control of chemical gradients, are another avenue for investigating cellular interactions at the microscale. Laminar flow streams at very low Reynolds numbers can be used to control chemical concentrations locally, and a microfluidic gradient mixer has been developed to produce controlled gradients of surface-bound molecules

for cell and tissue engineering applications (Dertinger *et al.* 2002). Direct interactions modulated by fluid mechanical forces have been central to advancements in understanding endothelial cell behavior and its role in atherogenesis. Wall shear stress modulation has been shown to be a controlling factor in activating endothelial cells (Shen *et al.* 1992) and in the development of atherosclerotic plaques (Malek and Izumo 1996). Shear forces in other systems, such as liver bioreactors (Allen and Bhatia 2003), and in the renal proximal tubules of nephrons (Essig and Friedlander 2003) are believed to exert control over function and to be associated with disease processes.

Forces at the subcellular level may also be probed using microscale and nanoscale techniques (Raghavan and Chen 2004). Contact guidance phenomena represent one such approach for studying interaction between cytoskeletal structures and substrates. Other approaches involve measurements of surface buckling as a function of the subcellular forces exerted on an elastomeric surface. More recently, Tan *et al.* (2003) have pioneered the use of microstructures such as arrays of microneedles as a monitor for subcellular forces, using needle deflection as a sensing technique. The top of the microneedles is coated with surface adhesion molecules, whereas the floor of the microneedle array is coated with PEG or another chemical that inhibits cell adhesion. In this embodiment, surface chemistry can be independently controlled and varied relative to the mechanical parameters of the microneedles. Modulation of the mechanical sensing element can be achieved simply by varying the height and the diameter of the microneedles. **Figure 1** is an image of a microneedle array with the tips of the posts coated with fibronectin and smooth muscle cells (SMCs) attached to the microneedles (Tan *et al.* 2003). The full potential of microneedle arrays and other microfabrication-based tools for probing cell behavior is only beginning to be realized.

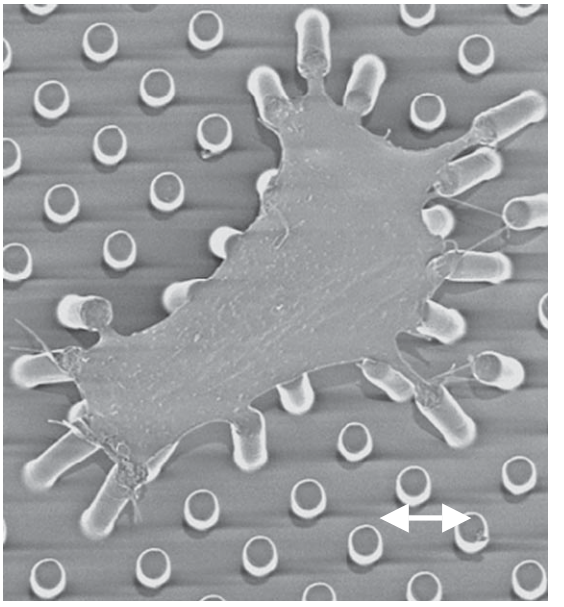

Figure 1 Smooth muscle cell attached to the tips of fibronectin-coated microneedles in poly(dimethylsiloxane) (PDMS). Bar, 10 μm. (Source: Tan J L, Tien J, Pirone D, Gray D S, Chen C S 2003 Cells lying on a bed of microneedles: An approach to isolate mechanical force. *Proc. Natl. Acad. Sci. U S A* **100**, 1484–9.)

2.15.2 Microstructures and Cellular Control

Engineered tissues rely on the control of a large number of experimental parameters in order to produce a construct that mimics physiological properties. These parameters include factors related to the cells that make up the engineered tissue, the biochemical environment and biochemical properties of the materials used to make up the substrate of the engineered tissue, and the structural properties of the scaffolding that comprises the backbone of the construct. The advantages of utilizing microfabrication and nanofabrication techniques to build scaffolds for tissue engineering relate principally to the ability of these fabrication methods to produce structures that resemble the mechanical microenvironment of living tissues and organs. The four components of the microenvironment that influence cell behavior in engineered tissues, spatial modes of control, topographic modes of control, the fluid mechanical environment, and the biochemical and surface chemical environment, will be covered in Sections 2.15.2.1–2.15.2.4.

2.15.2.1 Spatial Control of Cell Behavior

The spatial environment of cells in the various tissues of the body represents a critical element of control of cell behavior and the structure and function of tissues and organs. For instance, endothelial cells in the glomerulus of the kidney and the retina in the eye form fenestrations in the vessel walls that provide critical

functions. Liver sinusoids represent specific spatial microenvironments that are critical to the proper functioning of hepatocytes. In many instances, spatial control involves the formation of structures suitable for coculture of multiple cell types. The orientation and polarization of specific cells in the liver must be controlled to engender proper function; this is also true in the retina and the cardiovascular system.

Numerous microfabrication techniques that are capable of producing 3D spatial microenvironments using layering methods have been developed (Borenstein *et al.* 2002). As will be described later, many of these layering techniques involve the use of 3D microfluidic structures to produce microvascular networks, hepatocyte chambers, and other engineered cellular assemblies, as will be described in greater detail in a later section. Another approach, pioneered by Khademhosseini *et al.* (2005), utilizes the reconfigurable nature of poly(dimethylsiloxane) (PDMS) scaffolds to produce 2D assemblies of microwells for coculture of multiphenotype cell arrays.

Microfluidic and micropatterning techniques developed for spatial control of cell behavior in engineered tissues typically utilize surface chemistry to modulate cell function (Kane *et al.* 1999). These methods involve photolithography, either applied directly to the substrate or applied through an indirect class of methods known as soft lithography. Direct methods can involve photocrosslinkable materials (Nuttelman *et al.* 2002) or may use UV immobilization of proteins that modulate cell adhesion. These techniques are fairly limited in their applicability due to restrictions on the type of substrate and surface adhesion molecules that can be employed. Photocrosslinkable hydrogels and other materials are being developed to enable direct construction of scaffolds with patterned surfaces to enable the arrangement of multiple cell types and to localize growth factors within the matrix. Properties such as adhesion, migration, and differentiation have been influenced by spatially controlling either the arrangement of surface adhesion molecules or the degree of crosslinking within scaffolds.

There have been significant advances regarding the microfluidic methods for controlling the spatial environment of tissue engineering scaffolds. The simplest approaches utilize a high concentration source that forms a diffusion-controlled gradient. These approaches do not produce stable or controllable means for generating gradients necessary for precisely arranged cellular constructs. However, a new technique for producing precise gradients using microfluidic mixers has revolutionized the field, typically using chemotaxis as a means to attract particular cell types to specific locations within an engineered construct. Growth factors modulated within these gradient systems are being used to produce engineered neural and vascular tissues.

Micropatterning techniques employ soft lithography to modify the surfaces of both degradable and nondegradable polymer substrates. These materials include polylactic acid (PLA), poly(lactic co-glycolic acid (PLGA), and chitosan, with surface modification molecules such as RGD (arginine–glycine–aspartic acid) or PEG. In an early pioneering study, Chen *et al.* (1997) utilized soft lithography to produce a variety of patterns for cell adhesion to a substrate and determined that cell life and death can be controlled by the specific spatial patterns of surface adhesion molecules on a substrate. Seminal studies involving neurons and liver cocultures of hepatocytes and fibroblasts have been conducted using surface adhesion molecules patterned using soft lithographic stamps. In the case of liver coculture, micropatterns have provided a means to determine whether direct cell–cell contact or communication via circulating biomolecules is required for physiological cell function. Ultimately, engineered tissue formation will be enabled by 3D scaffolds combining microfluidics and micropatterning to organize cell cocultures.

2.15.2.2 Topographic Control of Cell Behavior

Signaling associated with the mechanical properties of substrates is now recognized as an extremely powerful modality for controlling cell behavior in tissues and organs. A revolutionary concept known as cellular tensegrity (Ingber 1993) models cells as mechanical structures in which the cytoskeleton and intracellular organelles are treated as the framework of the cell driven principally by mechanical interactions with the environment. A very large body of work associated with the investigation of topographic effects on cell behavior has emerged, with applications including the use of topography to prevent cell adhesion on implant surfaces, promote cell migration and differentiation in engineered tissues, and align cells for applications in which cell orientation is critically related to function such as in blood vessels and liver.

2.15.2.2.1 Contact guidance

The basement membrane, which makes up the underlying surface of most tissues and serves as the matrix on which cells reside, is a complex and rich mixture of components such as collagen, laminin, and fibronectin. The chemistry of these materials has a profound effect on many aspects of cell behavior, including adhesion strength, migration, and proliferation (Mooney and Hansen 1992). Numerous studies of special receptors known as integrin receptors have been conducted, leading to a greater understanding of the manner in which specific ligands present surfaces that enhance or inhibit various cell behavior. While these receptor-modulated interactions are largely chemical in nature, they are only a part of the spectrum of interactions that control cell behavior in physiological and engineered systems.

In addition to providing knowledge on surface chemical interactions, recent work has led to the discovery of an equally complex and significant family of interactions that are best characterized as types of mechanotransduction. Mechanical interactions between cells and the underlying substrate can take several forms, including topographic interactions as well as surface tensile forces. The advent of micromachining techniques for tissue engineering scaffolds has opened the door for topographic control of cell behavior at the microscale and at the nanoscale. These interactions are generally classified as contact guidance, in which the structural characteristics of a substrate influence the behavior of cells interacting with the surface. Cells that have been investigated include fibroblasts, epithelial cells, endothelial cells, astrocytes, and oligodendrocytes. Numerous techniques for producing micro- and nanoscale topography have been used, as will be described in the following sections.

First observed by Harrison in 1914, the influence of microscale topography on cell migration was termed as contact guidance by Weiss (1945), in a series of experiments utilizing available microtopographic substrates to characterize the influence of microscale surface architecture on cell motion. Microfilaments within the cytoskeletal structure are believed to play an important role in contact guidance, because substrate topography can limit the bundling or bending of microfilaments that normally occurs in cell motion. Contact points between cells and substrates are typically in the range of 1 μm in size, and therefore, microstructural features of that order are expected to have powerful effects on cell adhesion, motion, and function. In the 1980s, Brunette *et al.* (1983) used photolithography to pattern materials such as titanium to demonstrate the influence of microscale topography on the migration of fibroblasts and other cells. Brunette was also the first to use polymeric substrates for studies of topographic interactions with cells. Brunette later demonstrated that integration of dental tissue-engineered implants was improved when surface microtexture was applied to the scaffold surface. Others such as Den Braber demonstrated that the inflammatory response to an implant could be modulated by surface microtopography (Den Braber *et al.* 1998). Curtis and Clark (Clark *et al.* 1991) found that surface microtopography with specific properties could completely inhibit the adhesion of various cells to the surface, an effect that is totally independent of surface chemistry. Many of these studies have been conducted as a function of specific topographic features and have investigated the strength of the contact guidance interaction as a function of the lateral and vertical dimensions of the surface topography. In general, the strength of the contact guidance interaction for microtopographic surfaces increases as the depth of the feature increases and decreases as the width of the feature increases (Van Kooten *et al.* 1998). Interactions are enhanced, and cell behavior approaches that of the *in vivo* environment more closely, when the surface microtopography approximates cellular dimensions more closely. Bettinger *et al.* (2006a) have generated microscale patterns on the biodegradable elastomeric substrate polyglycerol sebacate (PGS) and have shown that bovine aortic endothelial cells (BAECs) cultured on these substrates respond strongly to the underlying topographic features. Cell alignment and elongation on micron-scale grids and gradients are dramatically enhanced relative to flat control substrates, as shown in **Figures 2** and **3** (Bettinger *et al.* 2006a). In **Figure 2**, the alignment of BAECs on gratings as a function of the grating parameters is graphed, and it is clear that the endothelial cells interact strongly with the surface texture in a way that aligns them very tightly around 0°; the pattern also elongates them severalfold when compared to an endothelial cell bound to a flat surface. In **Figure 3**, patterns of BAECs on a grid are shown.

The first studies of nanoscale topographic control over cell behavior were reported by Rosenberg (1962). More recently, numerous studies of the actual dimensions and features of basement membranes have been conducted. In addition to the typical

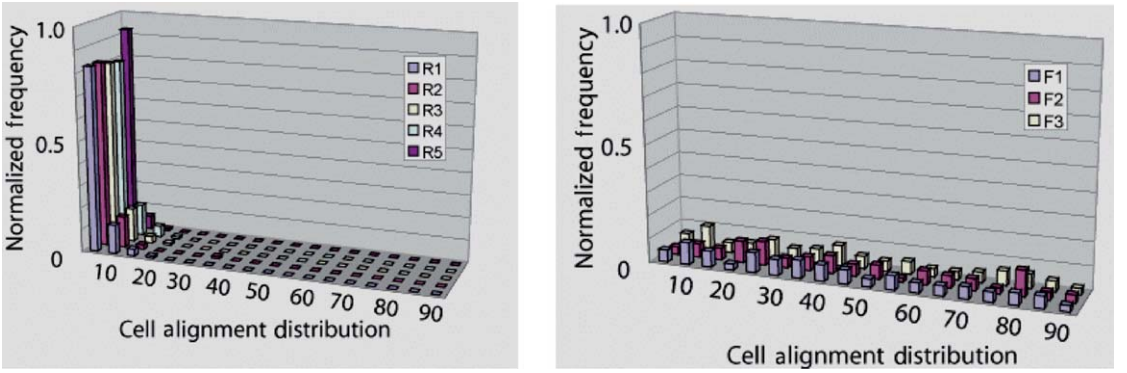

Figure 2 Alignment of bovine aortic endothelial cells (BAECs) for several experiments (R1–R5) for an ordered pattern of ridges and grooves (*left*) and for a flat substrate (*right*). appearance of pore-like structures, ridges and valleys in the basement membrane surface have been observed in experiments involving microscopic analysis of the membrane itself or a cast thereof. One of the most studied surfaces is the corneal epithelial basement membrane, which is characteristic in the macaque monkey and in humans (Abrams *et al.* 1997). In these investigations, characteristic dimensions in the range of 70–190 μm were identified for the height and width of specific features. The basement membrane of the glomerulus in the rat and the bovine kidney has also been studied by several groups, leading to the identification of features in the range of 10 nm. These and other findings have led to a significant concern related to the large body of literature associated with microtopographic control over cell behavior. Namely, this concern relates to the fact that most of the studies conducted on microfabricated substrates and contact guidance of cells have been done at dimensions of 1 μm or larger, while it is believed that the actual topography of physiological basement membranes occurs predominantly at the scale of 100 nm or less. Therefore, recent investigations have begun to focus on the sub-500-nm range for investigations of contact guidance.

Numerous methods have been used to produce features in the range of 500 nm or less. Clearly, most etching techniques are easily capable of producing vertical groove depths much less than 500 nm, most utilizing standard photolithography and reactive ion etching. Clark *et al.* (1991) used X-ray lithography to produce grooves with widths near 100 nm, while other researchers utilized techniques that are less controlled. For instance, Goodman utilized casting of polymethylmethacrylate (PMMA) polymer films into an actual basement membrane to create a master mold for subsequent polyurethane (PU) casting of substrates with dimensions near 100 nm (Goodman *et al.* 1996). Sandblasting and sanding have been used to produce features as small as 100 nm or less. And as mentioned earlier, Curtis has patented a technique for preventing cell adhesion by using a specific nanotopographic pattern.

2.15.2.3 Fluid Mechanical Control of Cell Behavior

Beginning with the pioneering work of Gimbrone *et al.* (1974) and Jaffe *et al.* (1973), the influence of fluid mechanical forces on endothelial cells

(Garcia-Cardena *et al.* 2001) has been the subject of intense investigation. Flow-induced alignment of endothelial cells at high flow rates is a well-studied effect, but more complex phenomena that are associated with shear stress have been the subject of intense investigation since the early 1990s. The influence of shear stress on endothelial cell function has been associated with the geometrically focal nature of atherosclerosis, in which atherosclerotic plaques form preferentially at the outer walls of blood vessel bifurcations. It has been shown that these regions along the outer walls of bifurcations more often experience low, time-varying levels of shear stress, whereas most arterial blood vessel walls experience shear in the range of 10–15 dynes cm^{-2}, a much more physiologically desirable level of shear. Endothelial cells experiencing physiological levels of shear are quiescent and exhibit a gene expression profile that is protection against the formation of atherosclerotic plaques. In regions of low oscillatory shear, endothelial cells become activated, exhibiting gene expression profiles that are atherogenic in nature. At very high levels of shear, in the range of 60–70 dynes cm^{-2}, endothelial cells can be physically damaged and may be mechanically sheared from vessel walls.

Most of the seminal studies conducted in the field of fluid mechanics and mechanotransduction on endothelial cell function have utilized some type of cone–plate viscometer arrangement that produces controlled levels of shear as a function of distance from the vertex of the cone. Cells are cultured on a flat plate positioned adjacent to a small-angle cone that provides controlled levels of shear stress. Microfluidic approaches to the analysis of shear are emerging, however (Weinberg *et al.* 2004). Recent computational fluid dynamic models of vascular networks for tissue engineering have accounted for wall shear stress effects in microfluidic channels, enabling the study of endothelial cell phenomena in microchannels with physiological features such as vessel distensibility (Krenz and Dawson 2002). These analyses treat shear stress as a control variable in the microfluidic system, enabling studies of endothelial cell function and development of functional blood vessels in microchannel networks. **Figure 4** illustrates a section of a PLGA-micromolded microvascular network generated by this computational model that results in a controlled, constant level of wall shear stress throughout the pattern of bifurcated channels (Weinberg *et al.* 2004).

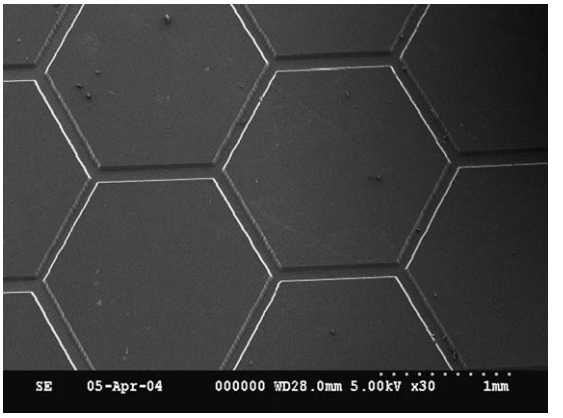

Figure 4 Section of a micromolded poly(lactic co-glycolic acid) (PLGA) scaffold machined with a microvascular network pattern generated to control the wall shear stress to a constant level through all channels. (Source: Weinberg E J, Borenstein J T, Kaazempur-Mofrad M R, Orrick B, Vacanti J P 2004 Design and fabrication of a constant shear microfluidic network for tissue engineering. *MRS Symp. Proc.*, Vol. 820, MRS Press, Warrendale, PA, pp. 121–6.)

2.15.2.4 Chemical Control of Cell Behavior

Microfabrication and microsystems technology are capable of generating controlled microenvironments and environmental cues based on engineered surface chemistry and circulating chemical factors. Chemical control can be accomplished using one of the following two principal approaches:

(1) Modification of an existing surface using physical or chemical means
(2) Deposition of a material with specific properties onto the substrate

One of the most common approaches for chemical control has been the application of micropatterned regions with adhesive and nonadhesive regions. Micropatterning typically utilizes photolithographic techniques, either by directly patterning the surface or by generating a stamp for microcontact printing of the surface adhesion molecules. In addition to the application of specific cell adhesion ligands, other types of surface modification can produce specific effects such as anticoagulation or prevention of biofouling with proteins. These modification techniques are critical for the development of devices such as liver assist devices and renal dialysis cartridges. PEG can be used to prevent protein adhesion and can be immobilized on surfaces using a number of microfabrication-based techniques. Heparin binding can be

accomplished in order to promote hemocompatibility and to reduce the incidence of clotting.

2.15.2.4.1 Circulating chemokines

Microtechnology can be used to control the spatial distribution of circulating chemokines, by leveraging specific fluid mechanical properties of microchannels. Typically, flow in microchannels is laminar, and therefore, streamlines can be maintained at channel bifurcations due to the absence of convection-driven mixing. Diffusive transport is typically very limited, and therefore, cells can be positioned at specific regions within merged streams in order to generate a particular microenvironment. Multiple flow streams can be processed in chambers that merge or split the flow, as well as in precision flow mixing chambers, thereby creating a gradient of soluble factors. A microfluidic gradient mixer, to be described in Section 2.15.5.1.2, generates a gradient of soluble molecules such as growth factors, but these soluble factors are typically bound to the substrate before the introduction of cells for culture and the development of engineered tissue constructs.

2.15.2.4.2 Surface-bound molecules

Tissue-engineered systems and artificial implantable devices must be designed so that contact with blood and other tissues does not result in adverse inflammatory and immune responses. The surface of an implant presents itself to the body only temporarily; proteins are rapidly adsorbed onto the artificial implant surface, and therefore, cells and body fluids react with the adsorbed layers (Wilson *et al.* 2005, Yang *et al.* 2001) rather than the bare implant surface. Integration of implanted devices depends critically on the cell–substrate with the adsorbed surface proteins, and therefore, the nature of this adsorption highlights the need to develop methods to present a controlled surface to the cells and blood. Materials such as fibronectin and vitrogen have been shown to promote the adhesion and migration of cells such as osteoblasts; as will be described in Section 2.15.3, tissue engineering substrates must be selected partly on their ability to adsorb proteins. Other applications, such as renal dialysis devices, utilize materials such as polyethersulfone (PES) that are selected because of their ability to impede protein adsorption, so that procedures such as hemofiltration can proceed without hindrance by the rapid buildup of proteins on the filtration membrane. As mentioned in Section 2.15.5.1.2, haptotactic signals, in which substrate adhesion mediates the motion of cells along surfaces, is another important mechanism by which control of the substrate presented to the cells is used to control cell behavior in tissue engineering applications.

In addition to adhesion and differentiation, the proliferation and differentiation of cells is strongly influenced by surface chemistry. Mechanotransduction via surface adhesion molecules influences cell apoptosis, as seen in the pioneering work of Chen *et al.* (1997), in which cell life or death is controlled by the spacing and geometry of microcontact-printed surface molecules. Trade-offs between surface adhesion and differentiation have been observed in many studies, and therefore, the entire spectrum of cellular activities must be considered when engineering the surface chemistry of tissue-engineered devices and implants.

Surface energy and surface charges, often associated with the level of hydration and wettability of surfaces, are other important factors to consider in engineering substrates for engineered tissues. Many biomaterials such as titanium are selected because of their hydrophilicity, an important factor in the success of hip implants. However, numerous biodegradable polymers are typically hydrophobic, and therefore, surface modification must take place in order to prepare them for seeding with cells. This is also true with nondegradable materials such as PDMS, where oxygen plasma treatment generates a transient hydrophilic nature that enables layer-to-layer bonding. Cell adhesion on positively charged surfaces is strong and distributed, whereas neutral or negatively charged substrates allow cells to adhere at specific points of contact. In addition to having direct effects on cells, surface charges influence the subsequent adsorption of proteins such as fibronectin and vitrogen.

2.15.3 Biomaterials and Scaffolding for Tissue-Engineered Microsystems

Most applications of biomaterials in tissue engineering follow the paradigm set forth by the seminal work of Vacanti and Langer (1999) in which a biomaterial scaffold is seeded with cells, the resulting device is cultured *in vitro*, and is then implanted to augment or replace a failing tissue or organ. These biomaterials span a range from completely synthetic materials such as silicon, metals, glasses, and ceramics and synthetic polymers such as polyesters and silicone materials to biologically based materials such as collagen, chitosan, and hyaluronic acid. Bioactive scaffolds that impart biological function such as

growth factors, drug delivery to minimize infection and inflammation, and other smart materials are emerging as part of the portfolio of candidate biomaterials for tissue engineering. The role of the biomaterial is to provide signals and cues that may be mechanical, chemical, or biological in nature and to provide a structure for population with cells that will control mass transport, cell adhesion and cell motion, and the deposition of extracellular matrix (ECM). Biodegradable materials that provide temporary chemical and structural functions are a critical element of this portfolio, from the standpoint of the need for an initial structural platform on which the new tissue will begin the process of formation and will ultimately replace.

2.15.3.1 Inorganic Biomaterials

In the field of biomaterials for tissue engineering and implantable devices, inorganic materials such as silicon, metals, glasses, and ceramics played a very important role until fairly recently. Metals such as titanium are still the standard approach for implants such as a hip prosthesis that requires high strength and minimal corrosion over decades. However, these inorganic materials possess mechanical, chemical, and biological properties, very different from native tissue, and therefore, their applicability in cell and tissue engineering is very limited (Yang *et al.* 2001). The mechanical robustness of these high-strength, rigid materials is paramount in certain implantable applications, but interactions between inorganic biomaterials and cells, both in the body and in engineered constructs, are not optimal, and therefore, a shift toward biomimetic materials such as engineered biopolymers has occurred for most tissue engineering systems.

2.15.3.1.1 Silicon

Silicon substrates are an ideal platform for investigations of cell behavior on microfabricated surfaces and in microdevices (Kaihara *et al.* 2000), because of the broad range of silicon processing techniques developed for microelectronics and MEMS applications. However, engineered tissues for clinical applications rarely consider the use of silicon as a substrate material because of its rigidity, brittleness, and relatively poor biocompatibility. Therefore, micromachined silicon structures have been utilized as a discovery tool rather than as a clinical end point in most tissue engineering research. Many cell culture studies have utilized silicon substrates, either simply as a surface for microcontact printing of surface adhesion molecules or as a substrate for etching microchannels or other features. One novel use of silicon as a scaffolding material for tissue engineering utilizes porous silicon as a mold for polymeric scaffolds (Chin *et al.* 2001). While crystalline silicon is mostly used as a substrate for *in vitro* experimentation, porous silicon shows evidence of biodegradation and other biocompatibility-related features that have drawn increasing attention for tissue engineering applications.

2.15.3.1.2 Metals

The biocompatibility of metals such as titanium and tantalum is well known, and numerous medical devices have been based on these excellent properties. Other metals used in implants include stainless steel and cobalt-based alloys. The hip prosthesis represents an excellent example of a long-life (20 years) implant that has provided long-term mechanical strength while minimizing undesirable responses such as inflammation, foreign body response, and the formation of bacterial biofilms. However, metals are not biodegradable and have a very limited flexibility in terms of processing.

While metals are not typically utilized for microfabricated scaffolds in tissue engineering, they have played a critical role in the establishment of fundamental mechanisms in cell behavior leading to the development of engineered tissues. Early work by Brunette and coworkers led to the observation that epithelial cell migration can be dramatically influenced by microscale topography on titanium-coated surfaces. These studies are important because of the role of epithelial cell migration in the loss of teeth and dental implants, and in the development of tissue-engineered approaches for dental (Young *et al.* 2002), craniofacial (Warren *et al.* 2003), and other applications. Initial studies utilized grooved silicon substrates with groove dimensions and periodicities in the range of 10–150 μm, covered with a thin layer of titanium (Brunette *et al.* 1983). Enhanced motion of epithelial cells associated with particular groove geometries suggested pathways for the prevention of cell migration using specified surface architectures.

2.15.3.1.3 Glasses and ceramics

As in the case of silicon, most of the tissue engineering research conducted with glasses has aimed at the establishment of fundamental mechanisms in cell culture and coculture. Glasses are an ideal substrate for microfabricated cell culture studies because of their transparency, ease of fabrication,

controllable surface properties, and relative biocompatibility. Micropatterning of surface adhesion molecules on glass substrates has led to seminal discoveries regarding hepatocyte culture, in the work of Bhatia *et al.* (1998a). In one study, borosilicate wafers, a low-cost amorphous glass substrate typically used for anodic bonding processes in MEMS devices, were used as the platform for micropatterned coculture of rat hepatocytes and 3T3 fibroblasts. Standard photolithography, which works well with borosilicate wafers as long as surface humidity is controlled, was used to pattern the surfaces. Surface modification via silane coupling was used to pattern the glass surface with surface adhesion moieties. Thiol-based coupling can also be used for surface modification, typically in concert with PEG in the non-adhesive-patterned regions in order to prevent cell adhesion in these areas. Cocultures of hepatocytes with other cell types such as biliary epithelial cells, stellate cells, and other cells have been investigated, but in this investigation, primary rat hepatocytes have been cocultured with 3T3 fibroblasts in order to investigate the critical elements of heterotypic interactions between different cell types in a microfabricated system.

Microfabricated ceramic scaffolds for cell culture have been applied to bone tissue engineering, using solid freeform fabrication (SFF) techniques that are described in Section 2.15.4.1. In one study, Chu *et al.* (2002) constructed orthopedic implant devices using a ceramic suspension that can be cured with UV light. These devices typically do not achieve a high resolution because of limitations in the fabrication technique. Strenuous efforts have been made to improve the resolution of stereolithography (SLA) and other SFF techniques, but these improvements are not typically translatable across all biomaterials, and therefore, the field of tissue engineering has not benefited as much as was anticipated from these technologies. Other materials such as hydroxyapatite are often used in bone tissue engineering in combination with SLA and other SFF techniques.

2.15.3.2 Biocompatible Polymers

Polymeric materials have emerged as the dominant scaffolding material for most tissue engineering applications, because of their superior biological and mechanical properties, low cost, and flexible processing capabilities. Biopolymers for tissue engineering can be natural, such as collagen, chitosan, glycosaminoglycans, and starch, and these materials have been successful in applications to skin, bone, and cartilage. Interactions between these materials and cells are far more optimal than for most of the inorganic scaffolding materials mentioned earlier, and bulk transport of nutrients and growth factors across these materials is also quite rapid. However, most of these natural materials are difficult to process and to control, and their mechanical properties are not optimal. Therefore, synthetic biodegradable polymers have emerged as the basis for most applications in tissue engineering.

2.15.3.2.1 Silicone elastomers

PDMS has served as the predominant structural material for the development of microfluidic devices and soft lithographic applications due to a combination of desirable properties. These include its high mechanical strength and flexibility, transparency, compatibility with sterilization, low cost, and ease of fabrication. The biocompatibility of PDMS, a silicone rubber material typically produced from a two-part mixture of curing agent and base, is still the subject of intensive investigations, although silicone materials are used in numerous clinical applications including catheters and membrane oxygenators. High oxygen diffusivity through the bulk of PDMS is an important factor when considering bioreactor applications, particularly with highly metabolic cells such as hepatocytes. Its ultimate utility in tissue engineering applications will likely be limited to laboratory devices, extracorporeal systems, and short-term implantable devices because it is not biodegradable and is ultimately prone to thrombosis due to nonoptimal hemocompatibility.

2.15.3.2.2 PMMA, PU, and other polymers

Microstructures built using a variety of polymeric materials have been investigated for cell culture and tissue engineering applications. One comprehensive study of various nondegradable polymeric materials microfabricated for culturing SMCs (Li *et al.* 2000) investigated PMMA, SU-8 epoxy resin, and PDMS. The SU-8 microstructures were fabricated using standard photolithographic techniques as described in Section 2.15.4.2.1, while the PDMS structures were formed directly from SU-8-negative master molds. For PMMA, the microstructures were produced using X-ray lithography to create high aspect ratio structures. For each substrate, a range of microstructural geometries were evaluated, including columnar structures, holes, and curved surfaces. In general,

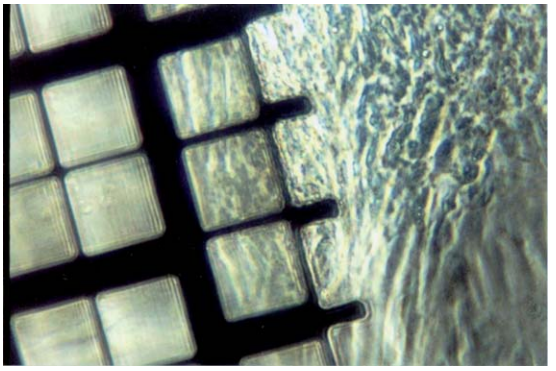

Figure 5 Smooth muscle cells cultured on polymethylmethacrylate (PMMA) columns, showing a significant barrier to cell spreading from the ~15-μm gaps. (Source: Li M, Glawe J D, Green H, Mills D K, McShane M J, Gale B K 2000 Effect of high-aspect-ratio microstructures on cell growth and attachment. *Proc.1st Annu. Int. IEEE-EMBS Spec. Top. Conf. Microtechnologies in Medicine and Biology*, Lyon, France, Vol. 66, Poster, 531–6.)

SMCs preferred curved surfaces, with much higher cell densities in culture than were observed in microstructures with sharp angles and rectangular geometries. This is commonly observed in cell culture on microfabricated substrates, likely because of the difficulty in establishing continuous layers of cells across sharp boundaries. **Figure 5** illustrates SMCs cultured on micromachined PMMA columns; note that small gaps between the columns limit the spreading of the SMCs (Li *et al.* 2000).

PU is a well-studied material with a long track record of use in biomedical devices. However, the mechanical and chemical properties of PU have limited its utility in certain tissue engineering applications, such as myocardial tissue. In one such application, McDevitt *et al.* (2003) have reported on micropatterning of a new class of biodegradable elastomeric PU in order to culture cardiomyocyte sheets. These novel materials have tunable degradation rates through the introduction of polycaprolactone (PCL) and a chain extender. Lines of laminin in the 10-μm range of width and spacing were microcontact-printed onto the biodegradable PU substrates, and the resulting robustness and stability of the cardiomyocyte lanes were enhanced.

2.15.3.3 Biodegradable Polymers

Biodegradable polymers represent the basis for most of the advances in tissue engineering applications for which cells are seeded onto a scaffold and implanted permanently. Resorption of the scaffold results in a fully natural replacement tissue without excess materials remaining in the body, clearly the ideal scenario for most applications. Most of these bioresorbable materials degrade via hydrolytic reactions rather than enzyme-driven processes, and therefore, the degradation process is highly controlled and relatively resistant to environmental variations between patients and between implantation sites.

The excellent performance of surgical sutures based on copolymers of polyglycolic acid (PGA) and PLA in the past has led to the use of these materials for numerous tissue engineering applications (Agrawal *et al.* 1997). These copolymers have highly tunable mechanical and degradation properties and therefore would seem to be an ideal substrate. However, the emergence of mechanotransduction as a significant factor in cell–substrate interactions (Ingber 2004, McKnight and Frangos 2003), and the fact that most basement membranes in the body are elastomeric in nature, has resulted in the pursuit of biodegradable elastomers for numerous tissue engineering applications. In addition, new classes of biopolymers have been developed in an effort to reduce the inflammatory response resulting from the degradation products of conventional PGA/PLA copolymers.

2.15.3.3.1 Biodegradable nonelastomeric materials

A number of biodegradable materials have been microfabricated for tissue engineering applications, including PLGA copolymers and PCL. These materials are not elastomeric and therefore exhibit a fairly high degree of rigidity that influences the ability to form constructs mimicking physiological tissues. Properties such as molecular weight, crystallinity, and the monomer ratios in biopolymers such as PGA/PLA copolymers can be utilized to tune the mechanical strength and degradation rate. Typically, high-molecular-weight PGA and PLA are generated using ring-opening polymerization (ROP) of the glycolide and lactide components (Yang *et al.* 2001). Each of these constituents provides specific properties to the resulting copolymer. The glycolides are highly crystalline, with glass transition temperatures near 50°C and melting temperatures near 200°C. PGA is highly hydrophilic, and its resorption time is typically in the range of 3 months. The mechanical strength of PGA drops sharply during the early stages of the degradation process, a major problem for many applications that require better midterm

stability until the engineered tissue itself becomes sufficiently robust.

PLA is not as highly crystalline as PGA and has a similar glass transition temperature but a slightly lower melting point (Yang *et al.* 2001). There are three important isomers of PLA, resulting from the chirality associated with a methyl group on the α-carbon unit. These three isomers are referred to as L-lactide, D-lactide, and D,L-lactide. The degradation rate and the mechanical properties of these three stereoisomers vary substantially, and limits on the thermal stability of the various monomers place restrictions on the processing conditions that can be used with each material. Plasticizing action within the monomers can alter mechanical properties in unpredictable ways, and therefore, careful attention must be paid during processing of the PLA class of materials.

Combinations of PLA and PGA to form the copolymer PLGA are frequently utilized in tissue engineering applications. The well-known minimum degradation time for this system occurs at specific ratios of the two monomers. Several groups have reported successful microfabrication of PLGA for tissue engineering applications, including the work of King *et al.* (2002, 2004) in which 3D constructs were compression-micromolded and the work of Vozzi *et al.* (2003) in which PLGA was deposited by a microsyringe technique to produce multilayer cell-seeded constructs. In a more recent development, Ryu *et al.* (2006) have fabricated devices from PLGA and polydioxanone (PDO) into 3D scaffolds suitable for engineered tissues; in **Figure 6**, a 3D PDO scaffold with feature sizes in the range of 20 μm is shown.

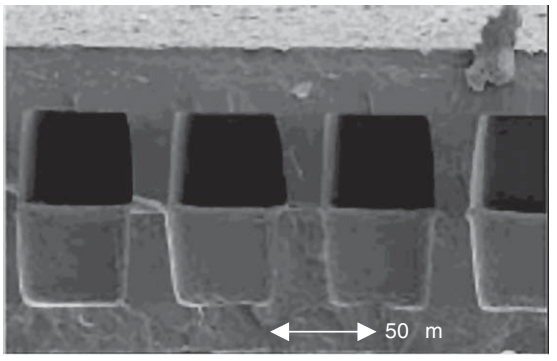

Figure 6 Scanning electron microscope (SEM) cross section of 20-μm structures micromolded into a 3D scaffold constructed from polydioxanone (PDO). (Source: Ryu W, Min S, Fasching R J, Prinz F B 2006 3D multi-layered microfabricated tissue scaffolds of biodegradable polymers. *Soc. Biomater. Conf.*, Pittsburgh, PA, USA.)

Another significant biodegradable nonelastomeric material is PCL, also produced by ROP to produce a polymer with a very low melting point near 60°C, roughly the same as the glass transition temperature. The degradability of PCL is because of an ester linkage that is subject to hydrolysis. Biocompatibility is considered to be very high, but the degradation time is so long (2 years) that numerous techniques have been pursued to speed resorption. Copolymers with PLA have been used to produce more rapidly degrading substrates. Like PGA/PLA, PCL is a relatively stiff material and therefore is not suitable for tissue engineering applications such as for blood vessels (Ziegler and Nerem 1994), heart muscle, and other soft tissues. Another limitation relates to the difficulty in functionalizing materials such as PLGA, although recent work by Keegan *et al.* (2003, 2004) has resulted in the demonstration of biomimetic scaffolding for tissue engineering and drug delivery.

2.15.3.3.2 Biodegradable elastomers

As described in the previous section, biomaterials such as PCL and polylactic co-glycolic acid (PLGA) have served as cornerstones in the field of biodegradable scaffolding for tissue engineering, as demonstrated by the numerous instances in which these materials have been implanted in animals and in humans for tissue engineering applications. In the case of PLGA, degradation times can be tuned by varying the lactic/glycolic ratio, as well as other variables in the copolymer preparation process. For PCL, degradation times are typically much longer, in the range of 1–2 years, but can also be modified to a lesser degree. One of the principal drawbacks of these and other thermoplastic materials is the fact that mechanically they do not resemble ECM, the proteinaceous substructure underlying cells and forming the mechanical scaffolding for tissues. In most cases, ECM is very strong yet highly elastic, resembling vulcanized rubber much more closely than the rigid polystyrene-like mechanics of PLGA and PCL.

Several efforts to develop tissue engineering scaffolding materials that resemble natural ECM more closely have been reported. Hydrogels with soft, rubbery mechanics have been developed, based on alginates as well as PEG chemistries. Pioneering work by David Tirrell (Petka *et al.* 1998) has led to the development of a periodic table of artificial proteins with elastomeric properties. A class of materials

based on polyhydroxyalkanoates has been applied to tissue engineering applications by Sodian *et al.* (2002). In each of these cases, the combination of distensibility and mechanical toughness does not approach that of natural ECM, and therefore, the applicability of these materials for scaffolding is limited. A new biodegradable elastomer known as PGS, or biorubber, has been reported by Wang *et al.* (2002). This new material is less expensive, tougher, and more distensible than the aforementioned biodegradable elastomers. In addition, PGS appears to be more biocompatible in implantable applications, producing less inflammatory response in early *in vivo* studies with small animals. The degradation of PGS occurs through hydrolysis through an ester chemical bond, with a low density of crosslinking to preserve the elastomeric properties. The monomers that comprise PGS are nontoxic and have been approved by the FDA for numerous applications.

2.15.3.3.3 Hydrogels

Elastomeric hydrogels referenced in the previous section are based on alginates as well as on PEG chemistries. Recent progress in calcium alginate hydrogel processing has led to a microfluidic biomaterial (Cabodi *et al.* 2005a). This material has been utilized in tissue engineering applications because of its low cytotoxicity and relatively high mechanical stability. Another powerful advantage of this material when compared to many of the previously mentioned biopolymers is the high degree of diffusive mass transport through the bulk of the scaffold. Microsystems-based scaffolds such as PDMS, PMMA, and PGS do not exhibit significant levels of mass transport of nutrients through the bulk of the material, other than the high oxygen diffusivity through PDMS. Therefore, transport of small molecule nutrients must take place within microchannels or through semipermeable membranes within the constructs. In the case of a calcium alginate hydrogel, by contrast, small molecule transport occurs readily within the bulk of the scaffold, as demonstrated by experiments using fluorescein- and rhodamine-labeled dextran as simulants for nutrients. The scaffold networks are assembled using soft lithographic preparation of master molds and casting of calcium alginate slabs with microchannel networks. Adjacent slab layers of the calcium alginate can be readily bonded. **Figure 7** illustrates a microfluidic network, constructed from micromolded calcium alginate, which has been infused with rhodamine-labeled fluid (Cabodi *et al.* 2005a).

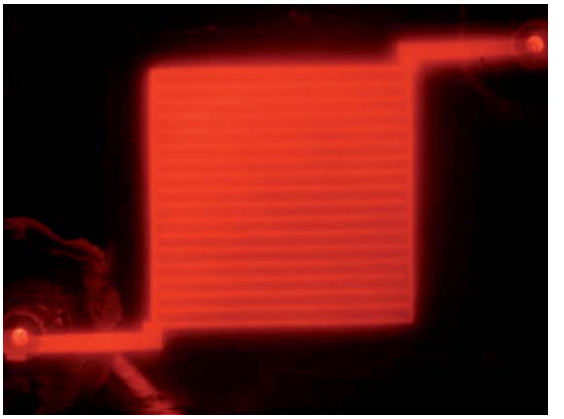

Figure 7 Rhodamine B isothiocyanate (RITC)-labeled dextran infused in micromolded channel network in calcium alginate gel. (Source: Cabodi M, Choi N W, Gleghorn J P, Lee C S D, Bonassar L J, Stroock A D 2005a A microfluidic biomaterial. *J. Am. Chem. Soc.* **127**, 13788–9.)

2.15.3.4 Biological Materials

Synthetic materials such as polystyrene, PDMS, and biodegradable materials such as PLGA, PGS, and PCL form the basis of most microscale technologies in tissue engineering (Armani and Liu 2000). The ability to tune these materials, including mechanical, chemical, and degradation properties, as well as surface modification techniques such as protein adsorption or chemical modification, represents powerful means to achieve specific behaviors that promote the development of healthy tissue with physiological properties. However, biological materials such as collagen, laminin, and fibronectin benefit from the fact that their interactions with cells are known to result in structure and function that enables long-term stable tissues and organs. These materials are often used to coat synthetic microfabricated scaffolds in order to render the scaffold surfaces more biocompatible. For instance, culturing of endothelial cells on uncoated PDMS substrates results in poor adhesion and scant coverage (Borenstein *et al.* 2002); cell culture on microfabricated PDMS scaffolds coated with fibronectin, for instance, results in a much more extensive coverage with endothelium. As will be described in a later section, micropatterning of surfaces with laminin produces axon formation and polarization. Therefore, these materials represent powerful tools for eliciting specific cellular responses in tissue engineering and may be used either as patterned surface coatings or as substrates themselves for engineered tissues.

2.15.3.4.1 Collagen

Collagen is the most prevalent protein in the connective tissues and is found in more than two dozen types, including type I collagen, found in bone and tendons, and type II collagen, found in articular cartilage. Mechanically, collagen is strong and nonelastomeric and forms the mechanical support structure for skin, cartilage, tendons, ligaments, and bone. Collagen is formed from subunits in the range of a few nanometers in length and is in the range of a few nanometers; these strands are twisted into a helical structure that provides the functionality of the material. Collagen has been used in skin substitutes for burn patients and is commonly used in cosmetic surgery. As will be described in a later section, many investigators utilize collagen as a surface adhesion molecule for micropatterning studies for tissue engineering applications.

Numerous methods for microfabricating collagen scaffolds for tissue engineering applications have been developed. In one approach utilizing excitation by light, the Campagnola group (Basu *et al.* 2005) has reported a technique known as multiphoton excitation to produce 3D ECMs with a 3D structure. This approach utilizes multiphoton confinement within a narrow focal plane for nanoscale architectural control and is capable of reproducing the topographic as well as the biochemical cues that are critical in defining the properties of skin and other tissues. In another study, Downing *et al.* (2005) utilized micromolding of collagen to produce an analog of the basal lamina. Silicon master molds were fabricated with lines, ridges, and other features in the 50–200 μm range of depth and width, as inspired by observations regarding the actual geometry of the basal lamina of skin. Keratinocytes cultured on microtextured collagen substrates showed that stratification and differentiation of the resulting epidermal layer increased as the interaction between keratinocytes and the microtexturing was increased, by increasing the depth of the features and by reducing their width. These studies suggest that microfabrication of biological materials such as collagen and laminin represents an important component of scaffold development for engineered tissues.

2.15.3.4.2 Silk

The superior mechanical and biological properties of silk fibroin make it an excellent candidate for scaffolding for tissue engineering applications. Silk has been FDA-approved for numerous applications and is extraordinarily strong and flexible, with highly tunable properties. Spider silk can be processed to form porous matrices, films, fibers, and hydrogels, and can be functionalized with surface moieties such as bone morphogenetic protein (BMP) for bone tissue engineering applications. There have been recent investigations on the combination of spider silk with biosilica (Foo *et al.* 2006), a material found in the structure of single-celled organisms such as diatoms, insect exoskeletons, and many higher-order animals. New silk–silica nanocomposites present an opportunity for both *in vitro* tissue engineering and *in vivo* regeneration, and these materials may also be compatible with microfabrication and nanofabrication techniques to produce engineered microenvironments for the replication of tissue structure and function.

2.15.4 Microfabrication Processes for Engineered Tissues

Microfabrication processes for tissue engineering include lithography-based processes such as micromachining and micromolding, as well as SFF methods in which scaffolds are formed directly by curing or sintering (Hutmacher 2001, Hutmacher *et al.* 2004, Leong *et al.* 2003, Tsang and Bhatia 2004, Yang *et al.* 2002). The principal advantage of SFF methods is that they are inherently 3D in nature, while the advantage of conventional lithography-based methods is superior spatial resolution. Each set of methods has been successfully applied to biodegradable polymer scaffold fabrication in various tissue engineering applications.

2.15.4.1 Solid Freeform Fabrication

SFF techniques include SLA, selective laser sintering (SLS), and other methods in which a laser is used to cure precise regions of a scaffold through photopolymerization or sintering. These processes use computer-aided design (CAD) to generate a 3D recipe for the scaffold, which is organized into 2D slices typically a few hundred microns in thickness. Scaffolds are produced by mechanically controlling the laser within the horizontal plane, forming the pattern by polymerizing the monomer in specified locations according to CAD. The vertical and lateral resolution of these techniques depends on numerous factors; lateral resolution is typically in the range of 50–250 μm. The laser spot size is a principal driver of resolution; the other issue is the manufacturing time

for scaffolds, which increases dramatically as the spatial resolution is improved. Vertical resolution is determined by the heat-affected zone depth in the photopolymerization process and by the stepper motor controlling the step size in the vertical dimension.

2.15.4.1.1 Stereolithography

SLA and the advanced version known as microstereolithography are mainstays of numerous industries and have been applied to several tissue engineering applications as well. Recent advances by Cooke *et al.* (2003) have enabled the scale-up of SLA toward sizes suitable for bone tissue engineering applications, overcoming a previous barrier to the achievement of structures of sufficient size for engineered tissues. These workers reported on bone defect repair with a matrix of poly(propylene fumarate) and diethyl fumarate. Biodegradable materials have been utilized in SLA scaffolds.

The close cousin of SLA, SLS, utilizes a laser to bond microparticles in a powder bed (Yang *et al.* 2002). The porosity of SLS scaffolds is typically much higher than that of SLA scaffolds. Scaffolding materials used in SLS include natural materials such as calcium phosphate, as well as biodegradable materials such as PCL and PLGA. Each of these techniques is a direct write method that requires substantial processing time in order to produce a scaffold of sufficient scale and resolution for complex tissue engineering applications. However, as will be described in Section 2.15.4.1.2, these techniques possess fundamentally 3D aspects that lend them to engineering large and complex tissues and organs.

2.15.4.1.2 Three-dimensional printing

Three-dimensional printing (3DP) (Kim *et al.* 1998) utilizes a different technique to solidify a powder bed to form a scaffold for tissue engineering. In a manner similar to that used in SLA and SLS, 3DP utilizes a scanning system that directs a writer toward specific positions in a 2D plane and then steps down in the vertical dimension to write the next slice. However, 3DP utilizes a print head similar to an ink-jet printer cartridge to apply a jet of chemical binder toward a powder bed. Subsequently, fresh layers of powder are deposited, and adjacent layers are joined by the binder. Once the part is completed, powder that is not sintered by the binder is removed, and the scaffold is removed.

One of the principal advantages of 3DP is that it can be conducted under ambient conditions. Unbound powder may be readily removed, but powder that resides within internal recesses of the scaffold is more difficult to extract. Therefore, the porosity of 3DP scaffolds is a challenge. Resolution challenges relate to the accuracy of the servo controlling x–y positioning of the ink-jet printer head, as well as the nozzle size. Another challenge with 3DP relates to the requirement for bulk scaffolding materials to be provided in a specific powder format. Sintering of the powder via binder deposition represents another challenge, in that each scaffolding material possesses its own limitations regarding agglomeration of powder. Surface properties such as roughness and microporosity are additional aspects of 3DP technology that require attention.

Numerous biodegradable scaffolding materials have been fabricated using 3DP, including PLGA, PCL, and polyethylene oxide (PEO). There exists a nearly unlimited array of scaffolding materials that can be fabricated using 3DP. Feature resolution remains a major challenge for 3DP; features of 200–1000 μm represent the minimum achievable geometries for most applications. Cytotoxicity of 3DP scaffolding materials represents a major challenge, and therefore, the impact of 3DP on tissue engineering has been limited to a fairly narrow group of specific applications. Natural materials such as water mixed with carbohydrates have been developed as binders, addressing the cytotoxicity problem but presenting other challenges regarding postpreparation processing.

2.15.4.1.2.(i) Other SFF techniques Other techniques such as fused deposition modeling (FDM) and ballistic particle manufacturing (BPM) have also been applied to tissue engineering applications with varying degrees of success. FDM technology utilizes an x–y plotter with vertical stepping capability (Zein *et al.* 2002). Molten scaffolding materials such as polymers or ceramics are ejected from a nozzle onto a surface containing FDM layers. Again, polymers such as PCL and high-density polyethylene (HDPE) have been used to produce FDM scaffolds, as have been materials such as calcium phosphate. Porosity is generally not as high as with some of the other techniques, and control over pore sizes and the tortuosity of the pore network are also difficult to control. The continuous deposition of molten material onto the solidified surface leads to challenges in vertical resolution.

Newer techniques have been developed to address some of the shortcomings of FDM and

BPM. One of these techniques, microsyringe deposition (MD), has been established by the group of Bhatia as a means to produce 3D high-precision cell-seeded scaffolds from PLGA. The syringe needle is roughly 20 μm in diameter, thereby leading to horizontal resolution far superior to all other SFF techniques. Another significant advantage of MD is the ability to integrate biological materials such as proteins into the scaffold as it is being constructed, due to the low processing temperatures. These low temperatures also contribute to an excellent degree of control over the vertical resolution. **Figure 8** is a schematic of the fabrication process for PLGA molding, using a PDMS transfer mold and a spinning process to produce a PLGA scaffold (Vozzi *et al.* 2003).

In general, SFF techniques represent an excellent way to produce tissue engineering scaffolds from a wide range of biomaterials, including polymers, metals, and ceramics. Large-scale, highly porous scaffolds have been produced using SFF techniques with tuned bulk mechanical and bulk transport properties, two of the major requirements for all tissue engineering applications. The CAD-driven nature of SFF lends itself to the development of customized scaffolds that can be produced in response to the specific requirements of a given patient, such as replacing the lost skin, cartilage, muscle, nerve, or bone tissue from a particular patient injury. Ultimately, the ability to produce scaffolding of a given size (e.g., for a pediatric patient) will enable made-to-order replacement organs.

The principal limitations of SFF techniques relate to their inability to reproduce the cellular microenvironment at the same size scale as that of physiological systems. For instance, it is known that

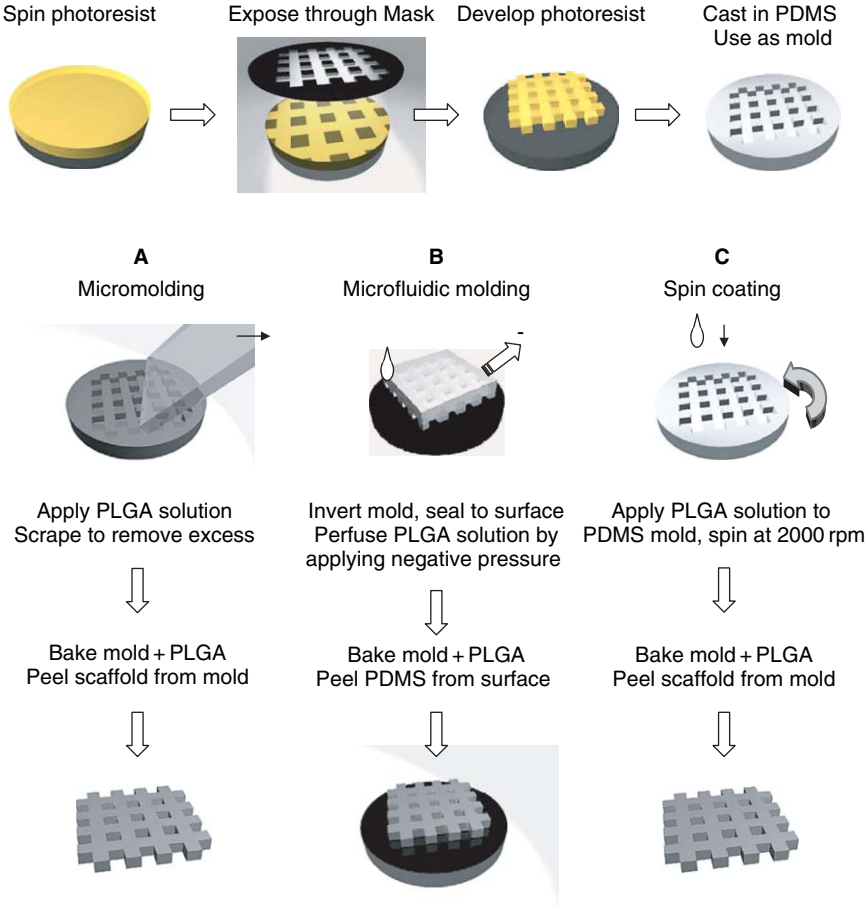

Figure 8 Schematic of microsyringe deposition process illustrating technique for producing 3D microfabricated scaffolds from the biodegradable scaffold poly(lactic co-glycolic acid) (PLGA). PDMS, poly(dimethylsiloxane). (Source: Vozzi G, Flaim C, Ahluwalia A, Bhatia S 2003 Fabrication of PLGA scaffolds using soft lithography and microsyringe deposition. *Biomaterials* **24**, 2533–40.)

specific arrangements of complex cocultures are required to reproduce functions in blood vessels, liver, and other tissues. These cocultures are not random in nature but rather involve precise collocation of multiple cell types in a manner that cannot be architecturally controlled by an SFF scaffold. While it is possible that the resolution of SFF techniques may be improved, this would undoubtedly be accompanied by a significant reduction in throughput. Therefore, it seems necessary that in order to produce scaffolding capable of replicating the cellular microenvironment, methods arising from MEMS fabrication techniques will be required. In Section 2.15.4.2, a brief overview of these techniques is provided.

2.15.4.2 Lithography-Based Technologies for Scaffolding

Photolithography, the central process for fabrication of integrated circuits and MEMS devices, has become a critical element in the development of engineered tissues. Many of the fundamental studies in the field of tissue engineering have utilized lithographic techniques to pattern biomolecules on surfaces to control cell–cell and cell–substrate interactions. These methods are often referred to as soft lithography and have been used to study parameters controlling cell fate, adhesion, migration, proliferation, and differentiation. As described in earlier sections, lithographic processes at the microscale and at the nanoscale have been used to demonstrate cell behaviors such as contact guidance and contact inhibition. Coculture experiments involving heterotypic cell–cell interactions have also utilized lithographic processes to define specific spatial relationships between various cell types and to answer questions such as whether cell functionality is driven by direct cell–cell contact or by communication via circulating biomolecules. In Sections 2.15.4.2.1–2.15.4.2.6, various methods used to fabricate structures for the purposes of probing cell behavior and assembling engineered tissues will be described in brief.

2.15.4.2.1 Conventional photolithography and etching

Lithographic and etching techniques for applications in microsystems have been described in detail in other chapters of this book and in other references. In this section, aspects of these processes specific to the development of engineered tissues are described in brief. Photolithography can be used to pattern substrates for many purposes, including the formation of topographic features, spatial features such as microchannels, or adhesive and nonadhesive regions. Conventional photolithography comprising the application of thin (~2 μm) layers of photoresist followed by plasma etching is the most common method for producing topographic or spatial features on silicon substrates, as described in numerous references addressing contact guidance phenomena and the formation of organoid structures. For micron-scale features, there are no special aspects of the lithographic process other than as a template for reactive ion etching or wet etching. For nanoscale features, advanced lithographic processes such as conformable contact lithography (CCL) (Goodberlet and Kavak 2002) or other methods capable of forming ~100-nm-scale features on the surface are used, particularly when investigating contact guidance phenomena requiring such high-resolution patterning.

Deep reactive ion etching (DRIE) is often used to transfer patterns from lithography into the bulk of a silicon substrate, either for direct cell culture onto the micromachined surface or for the formation of a master mold for replica molding of polymer films. The advantage of DRIE is the ability to maintain surface features with high accuracy, but a disadvantage is the nonphysiological nature of the etched surface, with vertical walls and sharp 90° angles. Isotropic plasma etching provides a more U-shaped sidewall, which is more compatible with cell adhesion but causes the etched via to become larger than the lithographic pattern as the etch depth increases. Wet etching techniques such as hydrofluoric/nitric/acetic acid (HNA) mixtures or crystallographic etchants (e.g., KOH) can also be used to form specific 3D structures within silicon wafers for cell culture of replica molding of polymers.

2.15.4.2.2 High aspect ratio photolithography

Many researchers in the field of tissue engineering do not have access to fabrication facilities with DRIE or other plasma etching tools, and therefore, high aspect ratio photolithography has become a method of choice for producing deep structures on the surface of silicon wafers for direct cell experimentation or for polymer molding. Before the development of SU-8 epoxy resin, now a standard bearer in the formation of deep structures on silicon wafers, researchers were forced to resort to LIGA (an acronym from German

words for lithography, electroplating, and molding) related techniques, in which high-energy beams in synchrotron facilities were used to expose thick polymeric films to obtain the result as is now realized simply and straightforwardly using SU-8. Layers of thicknesses from 25 μm to several hundred microns can be deposited and patterned with a single spin, and multiple spins of SU-8 can produce thicker layers or more complex 3D structures, including closed channel networks. The biocompatibility of SU-8 has been investigated in several studies and has been shown to be acceptable for cell culture applications. However, the principal utility of SU-8 is as a master for replica molding a host of polymeric scaffolding materials for tissue engineering.

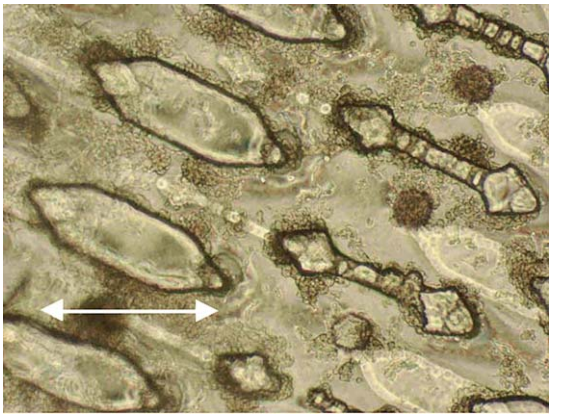

Figure 9 Hepatoma cells cultured in 3D poly(dimethylsiloxane) (PDMS) bioreactor. Bar, 10 μm. (Source: Leclerc E, Sakai Y, Fujii T 2003 A multi-layer PDMS microfluidic device for tissue engineering applications. *Proc. 2003 Transducers Conf.* pp. 415–18.)

2.15.4.2.3 Micromolding and embossing

Early studies in tissue engineering utilized polymeric scaffolds fashioned using SFF techniques, porogen leaching, electrospinning, and other techniques that do not produce micron-scale resolution constructs but rather much lower precision structures with the tuning of bulk properties such as porosity and biomolecular permeability. Scaffold preparation techniques were developed to produce foams and gels, and physiological features such as capillaries and high-precision organ-specific entities such as sinusoids could be produced only by using directed self-assembly from appropriate growth factors and other chemical cues. With the advent of polymer replica molding roughly in the late 1990s, led by Whitesides', Quake's, and Beebe's groups (Jo and Beebe 1999, Quake and Scherer 2000, Whitesides and Stroock 2001), a new avenue for producing high-resolution structures in a host of polymeric substrates has been established. These techniques are based on the principle that polymeric structures can be generated with micron-scale precision by casting, micromolding, or embossing the features from a micromachined silicon master. Predominantly, this technique has utilized the substrate material PDMS, an elastomeric silicone rubber that is transparent and highly biocompatible. Structures with minimum dimensions of 100 nm or less can be readily reproduced from micromachined silicon masters using solvent casting. Cell culture with endothelial cells, hepatocytes, embryonic stem cells, and numerous other cell types has been conducted in PDMS bioreactors. Multiple layers of PDMS micromachined films can be assembled into 3D structures using oxygen plasma bonding, which forms hydroxyl groups on the surface that result in permanent, high-strength bonds between layers. High oxygen diffusivity through PDMS enables sufficient oxygenation of cells within PDMS bioreactors even in the absence of oxygenated media, such as in the case of hepatocyte culture in 3D microfluidic devices. **Figure 9** shows a 3D microfluidic bioreactor for hepatocyte culture developed by Leclerc *et al.* (1993). The Takayama group at Michigan (Gu *et al.*, 2004) has reported a microfluidic cell culture system in PDMS using a refreshable Braille display; an image of the PDMS perfusion culture device is shown in **Figure 10**.

For applications in tissue engineering, a biodegradable scaffolding material is most often desired, and therefore, methods for molding or embossing a host of biodegradable polymers have been developed. As described in Section 2.15.3, these biodegradable polymers include PLGA, an FDA-approved polymer used for numerous applications such as vicryl sutures. Advantages of PLGA include its relative degree of biocompatibility, the tunability of the degradation time as a function of the lactic/glycolic ratio in the copolymer, and its use as a scaffold in the field of tissue engineering that is evidenced by a vast number of studies. Disadvantages include mechanical rigidity, sudden loss of mechanical strength and mass during the course of the degradation process, and acidic by-products of the hydrolysis reaction through which the material degrades.

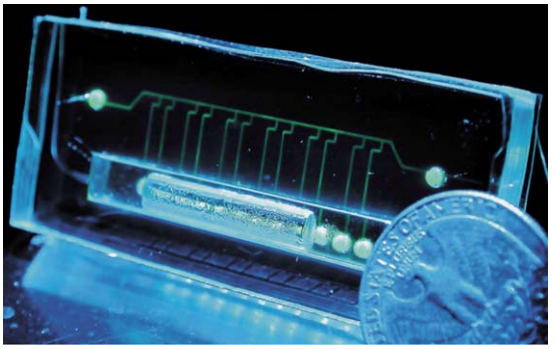

Figure 10 A microfluidic cell culture chip with fluorescein-loaded channels next to a US quarter. The channels are arranged to align to pin actuators on refreshable Braille displays, a tool typically used by the blind to read computer text. When the pin movement is interfaced appropriately with the microfluidic chip, one obtains reprogrammable microfluidic cell culture systems where the pins act as reconfigurable valves and pumps. (Source: Gu W, Zhu X, Futai N, Cho B S, Takayama S 2004 Computerized microfluidic cell culture using elastomeric channels and Braille displays. *Proc. Natl. Acad. Sci. U S A* **101**, 15861–6.)

Numerous techniques for constructing micromachined scaffolds from PLGA have been demonstrated. In one implementation, scaffolds with a minimum feature size of roughly 500 μm were constructed using a molding process, and multiple layers were sealed together by depositing metal films and alloying them together. In another embodiment, multilayer PLGA scaffolds were assembled without the use of any adhesive materials, by fusing the layers together at elevated temperature and pressure. The PLGA layers were constructed by a double-transfer mold process in which SU-8 lithographically patterned silicon master molds with the positive image of an interconnected microchannel network were used to produce negative molds in PDMS. The PDMS transfer mold is necessary because PLGA is rigid and cannot be separated from the silicon master mold. This double-transfer mold process preserves high-resolution features and is a robust means of producing fully degradable scaffold structures. A cross section of a multilayer microfluidic device constructed from PLGA is illustrated in **Figure 11** (King *et al.* 2004). Other embodiments assemble multiple layers by spinning films of PLGA successively to form 3D scaffolds, sometimes with cells and other biological materials interspersed within the layers.

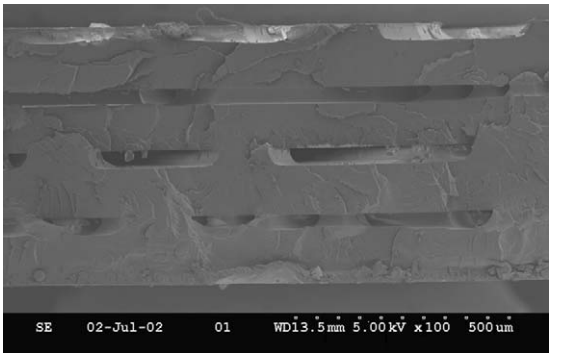

Figure 11 Cross section of 3D scaffold constructed from compression-molded poly(lactic co-glycolic acid) (PLGA).

2.15.4.2.4 Electroplating

Micromolding techniques for PDMS and biodegradable polymers based on photolithographically defined silicon master molds suffer from some limitations involving the ability to define true 3D structures. For instance, in the case of microvascular networks, simple lithographic patterning and etching of master molds results in microchannels with variable width but a fixed depth, a highly nonphysiological situation. The fluidic resistance of such channels is much larger than that of circular channels with a similar hydraulic diameter, and other properties such as the vessel wall mechanics, clotting cascades, and oxygen and nutrient transport capabilities are also widely divergent from natural vasculature. In order to achieve a closer approximation to physiological systems, multiple lithographic steps with precise alignment of layers must be utilized, to produce a single layout with varying-depth structures.

In order to obviate the need for multiple lithographic and/or etching steps, molds produced by electroplating processes may be used to produce complex multidepth structures. The process utilizes patterns of conducting islands on a nonconducting substrate patterned by a single photolithographic step. As electrodeposition progresses, islands of conducting material are joined to form larger and hence thicker structures, thereby enabling the formation of features of aspect ratios near 1:1. These electroplated structures may be used as master molds for solvent casting of PDMS and other biopolymer scaffolds with dimensions approximating physiological systems. **Figure 12** illustrates a mold generated by electroplating a pattern with features of varying height and width on a silicon wafer (LaVan *et al.* 2003).

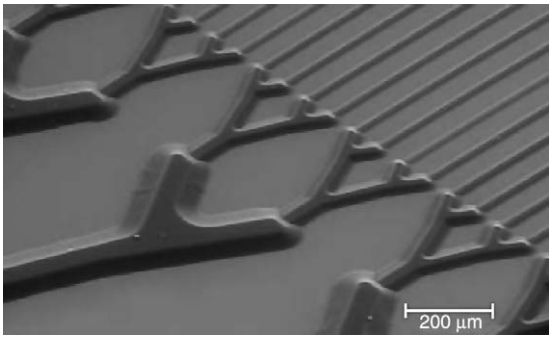

Figure 12 SEM of electroplated silicon mold for fabrication of polymer micromolded vascular networks, showing the capability of varying the height as well as the width of the features. (Source: LaVan D A, George P M, Langer R 2003 Simple, three-dimensional microfabrication of electrodeposited structures. *Angew. Chem. Int. Ed. Engl.* **42**, 1262–5.)

Figure 13 Multiphenotype array of embryonic stem cells, AML12 hepatocytes, and NIH-3T3 fibroblasts cocultured in reconfigurable poly(dimethylsiloxane) (PDMS) bioreactor. (Source: Khademhosseini A, Yeh J, Eng G, Karp J M, Kaji H, Borenstein J, Langer R 2005 Cell docking inside microwells within reversibly sealed microfluidic channels for multiphenotype cellular arrays. *Lab Chip* **5**, 1380–6.)

2.15.4.2.5 Assembly techniques

For applications in tissue engineering, microsystems-based polymeric scaffolds must take on three-dimensionality and be capable of reproducing complex structures. Therefore, methods to assemble large, complex 3D structures must be developed. Lamination techniques are required for stacking and integration of multiple microfluidic layers of polymeric scaffold materials. In the case of PDMS polymer layers, assembly may be accomplished simply by exposing layers to oxygen plasma and placing the layers in contact. Treatment with an oxygen plasma results in an extremely strong bond between layers, after which the interlayer bonds are stronger than the bulk material. Without plasma bonding, PDMS layers may be reversibly sealed together to form closed lumens capable of supporting fluid flow, but layers may be separated from one another to enable additional processing steps. Khademhosseini *et al.* (2005) have developed a technique for the culturing of multiphenotype arrays, in which microwells are micromolded into PDMS films, and then a top layer of PDMS with microchannels is placed over the microwell array to provide a means to fluidically address the microwells. Once these microwells are seeded with a given cell type, the microchannel layer is lifted off the top of the microwell array and additional microfluidic processing can occur. An image of multiple cell types cultured in such a reconfigurable microfluidic device is shown in **Figure 13** (Khademhosseini *et al.* 2005). This reconfigurable nature of PDMS has many benefits in the development of microfabricated cell culture systems.

Many of the biodegradable polymer systems have different and potentially more complex means of assembly into multilayer constructs. In the case of PLGA, thermal fusion bonding joins multiple layers together. Pressure and elevated temperature are used to establish a strong, irreversible bond between adjacent layers, as described by King *et al.* (2004); the process window for this treatment requires that the temperature and pressure excursion be sufficient to fully seal the layers without causing them to deform or collapse. In the case of PGS, sealing of layers is accomplished by joining partially wetted layers together to form large stacks. Crosslinking using multiple polymerization steps can be used to bond PGS layers together (Bettinger *et al.* 2006b). Conjugation of moieties using specific chemical routes can be used to bond layers, but there are significant limitations related to the chemistries and temperatures involved.

In each of the aforemetioned cases, integration of the multilayer stacks must be achieved and connectors placed to enable the introduction of cells and media. Devices for laboratory cell culture studies have different constraints than do systems that will ultimately function as extracorporeal or implantable organ assist or replacement devices. Contact with blood and limitations in the total fluid capacity of the latter systems require that numerous design rules be followed, because of concerns related to hemocompatibility and the potential presence of large

dead volumes or inadequate mixing. In general, such 3D microfluidic devices are assembled in such a way as to minimize dead volume and transients within the system due to distensible connectors and to avoid sharp corners that promote turbulence and thrombosis. Conventional tubing with large bore diameters may be avoided because of the large volumes of fluid in the connectors relative to the microdevice and because of potential incompatibility between the connector material and blood or other biological fluids involved. Attachment between the external tubing connectors and the microdevice may be done with microfabricated and molded connectors rather than by manual techniques involving macroscopic components. The trend is toward integration of the entire microfluidic network into a microfabricated platform with a minimum of connectors that may potentially serve as a nidus for a clot or an infection.

2.15.4.2.6 Nanostructured matrices

Engineered scaffolds and matrices with microscale dimensions provide spatial, topographic, and fluidic guidance at size scales similar to those of the cells populating these devices. However, many cell–matrix interactions occur at far smaller size scales, for reasons described earlier that involve interactions with the cytoskeletal components as well as through other nanoscale mechanisms. Matrices that promote the development of structural and functional tissues through the control of growth, differentiation, and development comprise a critical element of engineered tissues, and nanostructured matrices with highly developed properties have been applied toward cardiac, nerve, vascular, and other tissues. First reported by Zhang *et al.* (1993), these nanostructured matrices are formed via self-assembly of oligopeptides into hydrogels with high water content (Holmes *et al.* 2000, Kisiday *et al.* 2002). The nanostructured peptides consist of alternating units of positively and negatively charged amino acid groups. In one study (Holmes *et al.* 2000), the development of cultured neuronal cells in these nanostructured matrices was compared with prior studies in which neurons were cultured in other matrices. Proteins such as laminin, fibronectin, and collagen have also been used as matrices for neurite outgrowth, and these proteins are better as attachment motifs when compared to untreated tissue culture plastic, glass, and other standard substrates. Nanostructured peptides result in excellent neurite outgrowth with functional synapse formation, and *in vivo* studies indicate that nerve repair is possible using these novel materials. **Figure 14** illustrates the neurite outgrowth resulting from culturing with a nanostructured peptide (Holmes *et al.* 2000).

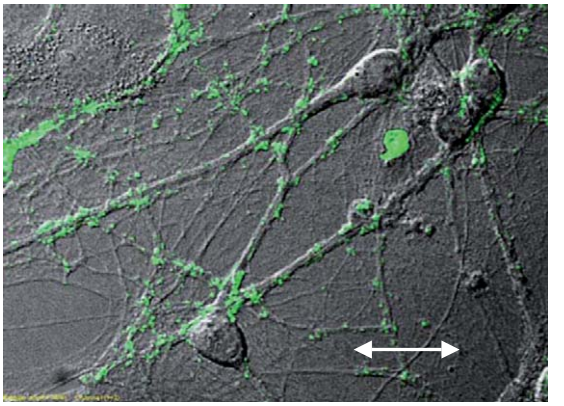

Figure 14 Primary rat hippocampal neurons form active synapses on the designer self-assembling peptide nanofiber scaffolds. The neurons were cultured on the peptide scaffold for ~2 weeks before active synapses were assessed. The confocal images show bright discrete green labeling indicative of synaptically active membranes following FM1-43 incubation of neurons. Active synapses on the peptide surface. The active synapses on these scaffold materials with high density indicate that the peptide scaffold is a permissible substrate for synapse formation. The same scaffold was later used in hamster mouse brain damage repair to bridge the optical nerve cap. Bar, 10 μm. (Source: Holmes *et al*. *Proc. Natl. Acad. Sci. U S A* 2000.)

2.15.4.3 Cell Printing Technologies

One of the most novel and exciting new methods for producing engineered tissues with high precision is the deposition of cells directly from a nozzle moving over a surface (Mironov *et al.* 2003). In essence, these techniques do not even use a scaffold to organize cells into agglomerates for tissue engineering applications but rather deposit cells and other materials directly onto the engineered construct. In one variant of this method, microsystems technology is applied to tissue engineering through the implementation of a microfabricated element (the ink-jet printer head) that deposits cells in a 3D matrix. Several methods for depositing the cells have been demonstrated, including spraying, ink-jet printing, and laser-guided deposition (optical tweezers). In the spray deposition technique, a liquid suspension of cells is deposited on the surface using an airbrush-type spray head. In one successful demonstration of this technique, NIH 3T3 fibroblasts and primary hepatocytes were cocultured

in a collagen sandwich in which collagen gel layers were deposited, interspersed by layers of sprayed cells (De Silva *et al.* 2005). Subsequent functional assays demonstrated that the cells were not damaged by the process; in fact, liver-specific function as monitored by cytochrome *P*450 activity was better than in control samples. An alternative to spraying, ink-jet printing of cells has been shown to maintain high levels of cell viability despite the high degree of stress associated with the deposition process (Xu *et al.* 2005). This system has been applied to Chinese hamster ovary (CHO) cells with excellent results. These systems essentially utilize a commercial ink-jet printer with a control program that draws the engineered cellular assembly. Higher-precision, noncontact direct deposition of cells has been achieved using optical tweezer systems. Cells are essentially steered toward the substrate by a laser/lens system that directs the flow of cells onto the surface. Extraordinarily high-resolution assemblies, essentially achieving 1-μm precision, can be achieved using this technique. Overall, however, each of these cell printing methods has as a drawback a slow rate of deposition, which results in lengthy processing times for scaffolds of relevant size scales.

2.15.5 Microsystems for Cell and Tissue Engineering

Microsystems for engineering cells and tissues in the laboratory are based on a combination of microfabrication techniques, biomaterial substrates and matrices, and cells and biochemical factors. Since the mid-1990s a multitude of experimental tools and devices based on microsystems technologies have been developed toward the goal of cell and tissue engineering, as will be described in this section. These systems may be inherently 2D in nature, as in the case of micropatterned surfaces for control of cell adhesion, migration, and function and chemical gradients to promote cell motion and the organization of cells into tissues. Three-dimensional systems comprise structures produced using the SFF techniques described earlier, as well as more classical microsystems-based approaches such as microfluidic bioreactors and microvascular networks. In addition, techniques such as polymer demixing and microscale templating have been employed to form a 3D architecture.

2.15.5.1 Two-Dimensional Microsystems

In Section 2.15.4, numerous techniques for forming 2D microfabricated structures for tissue engineering were described. These techniques can be broadly classified into those methods that form layers via photolithographic patterning of biomolecules on surfaces, techniques that generate chemical gradients using microfluidics, and laser patterning approaches. In Sections 2.15.5.1.1–2.15.5.1.3, these approaches will be described in greater detail, with an emphasis on how these approaches can be integrated into fully 3D systems in the subsequent discussion.

2.15.5.1.1 Micropatterning of surface adhesion molecules

Numerous surface modification moieties including PEG, RGD peptides, and biotin have been used to generate engineered cell and tissue constructs. These surface modifiers have been micropatterned using direct photolithographic techniques as well as microcontact printing. Scaffolding materials such as PDMS, PLGA, and chitosan have been modified using these techniques; however, these techniques are typically limited to 2D devices. The most common micropatterning approach is to pattern adhesive and nonadhesive regions on a tissue-engineered substrate, using techniques such as silane-based coupling agents or thiol-based systems. Surfaces with stable adhesive or nonadhesive properties, based on the degree of hydrophilicity, for instance, can be patterned by microcontact printing of surface adhesion molecules on specific regions, thereby creating a construct for patterned cell culture. Techniques other than surface adhesion molecule patterning can also be used; for instance, Curtis *et al.* (2001) have developed a technique in which specific topographic nanostructures can be used to prevent cell adhesion.

Specific ligand–receptor combinations such as RGD (arginine–glycine–aspartic acid) peptides and their integrins comprise a major system for modifying surfaces to control cell adhesion. This system can control cell growth and apoptosis, as well as differentiation and other critical functions. Covalent linkages of RGD have been used to modulate cell–surface interactions in order to mimic physiological interactions with the basement membrane of numerous tissues and with blood. Liver coculture systems have been studied using adhesive patterning of ECM analog collagen I. These studies have investigated the interactions between hepatocytes and fibroblasts with specific spatial relationships between the two cell

types. These studies utilized glass substrates patterned using photolithography, followed by collagen deposition and liftoff to remove specific regions of collagen. Hepatocytes were cultured on the surfaces, following the pattern of the lithographic mask, and then fibroblasts were added to form the coculture. These systems have been used to investigate and establish some of the fundamental principles involved in liver cell biology and underlying the critical elements of engineered liver assist devices.

2.15.5.1.2 Chemical gradient systems

The use of chemical gradients to control cell migration and to organize tissues is a critical element of the development of engineered tissues. Systems utilizing chemoattractive substances (chemotaxis), distributions of adhesion molecules (haptotaxis), or chemorepellent systems (fugetaxis) are a vital tool in the organization of cells within devices or matrices, in addition to fluid mechanical methods for distributing cells. Gradients of soluble factors have been the subject of numerous studies, but historically, gradients of substrate-bound molecules have been difficult to generate and maintain because of multiple experimental challenges. Pioneering work by the Whitesides Laboratory (Dertinger *et al.* 2002) has established a simple and highly novel technique for establishing and maintaining chemical gradients using microfluidic mixing chambers. Dertinger *et al.* reported the fabrication of a gradient mixer with long serpentine channels; the length of the channels must be sufficient to enable the substances to mix completely via diffusion. Networks are specifically designed to generate gradients suitable for particular applications; an image of the gradient mixer is shown in **Figure 15** (Dertinger *et al.* 2002). Gradients in substrate-bound moieties are achieved through adsorption of these soluble species from the liquid mixer. This gradient mixer that enabled the initial investigation of a smooth gradient, rather than of a sharp gradient, in ECM proteins is able to facilitate the early stages of neuronal development.

2.15.5.1.3 Laser-patterning techniques

The aforementioned techniques require the use of photolithographic equipment and photomasks, which are expensive and typically require a highly controlled environment for processing. Numerous types of lasers can be used to etch polymers by ablation processes that minimize damage to nonablated regions and maximize resolution by controlling the extent of the heat-affected zone and by sharpening

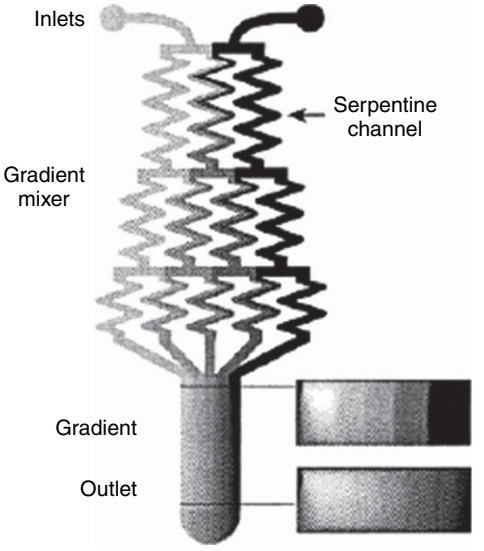

Figure 15 Schematic of microfluidic mixer using laminar flows in microchannels to generate substrate-bound chemical gradients. (Source: Dertinger S K W, Jiang X, Li Z, Murthy V N, Whitesides G M 2002 Gradients of substrate-bound laminin orient axonal specification of neurons. *Proc. Natl. Acad. Sci. U S A* **99**, 12542–7.)

the boundary between the laser-machined region and its surroundings. These techniques have also been used to fabricate microvalves and micropumps for other applications such as drug delivery (Mescher *et al.* 2003). Structures with minimum dimensions of 10 μm have been produced through the use of laser ablation. Lasers can also be used to modify surfaces through the incorporation of specific gas-phase chemistries under ambient conditions.

Another laser-based approach, known as nanosphere lithography, utilizes an organized array of nanoparticles to modify a laser beam irradiating the surface of a polymer, thereby creating nanoscale features on the surface of the substrate (Frey *et al.* 2000). Novel methods are used to generate the ordered array of nanoparticles, and numerous process parameters such as the properties of the nanoparticles, the laser energy, and the optical path can be used to tune the process. The principal limitation with nanosphere lithography is similar to that of certain other nanolithographic techniques in that the range of potential patterns that can be generated is bounded by the physics of the optical technique. However, this process is capable of generating nanoscale surface patterns that may be extremely useful in influencing cell behavior on biopolymer substrates at a cost much lower than that of comparable direct nanolithographic patterning techniques.

2.15.5.2 Three-Dimensional Microfluidic Systems

Three-dimensional cell culture systems and engineered devices and tissues are emerging as potential pathways toward novel therapies for patients suffering from end-stage tissue loss and organ failure. The 3D aspect of these devices and systems bears significance from multiple perspectives, including the behavior of 2D versus 3D cell culture, the requirement for a vasculature to deliver oxygen and nutrients, and the size and scale of devices necessary to augment or replace physiological function.

2.15.5.2.1 Biological basis for 2D vs. 3D culture

Recent evidence from the field of cancer biology has led to the inescapable conclusion that 3D cell culture is capable of replicating physiological function far more closely than 2D culture (Griffith and Swartz 2006). Cells grown on flat layers are deprived of the full array of environmental cues available from the 3D microenvironment of living tissue, including mechanical and biochemical cues originating from the ECM surrounding cells in most tissues. The pioneering work of the Bissell group (Weaver *et al.* 1997) first demonstrated that integrin receptors caused breast cancer cells to lose their cancerous properties, a finding that had never been observed in conventional 2D flat-plate culture. Three-dimensional cell culture has also demonstrated that metastasis of breast cancer cells occurs via mechanisms that require 3D systems in order to observe, namely, complex shape changes and migration enhancement that cannot be observed in 2D culture. Cell migration and proliferation in craniofacial tissue engineering studies have been dramatically enhanced in 3D culture as well.

Not just the spatial environment in the bioreactor but also the nature of the matrix itself has been shown to play a significant role in enhancing the performance of 3D systems. The paradigm of self-assembling biological systems for tissue engineering and other applications is emerging, with promising results in many areas (Zhang 2002). Amino acids that self-assemble into nanofibers, as reported by Stupp (Hartgerink *et al.* 2001), result in 3D properties that have led to advances in nerve tissue formation. Nanofibers of self-assembling peptides with 3D properties, as described in Section 2.15.3, have resulted in advances in cardiac and nerve tissue engineering, as well as in the formation of microvasculature. Microvascular network formation represents a significant challenge for which microfabrication techniques can make a major contribution.

2.15.5.2.2 Requirement for vascularization

Three-dimensional scaffolding and matrices have clearly been demonstrated to provide enhanced properties for tissue engineering in numerous applications. Another key observation that arises from the tissue engineering research over past several decades is the crucial role of vascularization in the development of engineered tissues and organs. Avascular tissues such as skin (Auger *et al.* 1995, Bell *et al.* 1981, Parenteau *et al.* 1996, Purdue *et al.* 1997) and cartilage (Athanasiou *et al.* 1998, Klien and Schumacher 2003) have been successfully reproduced in the laboratory using numerous approaches. However, thick, complex tissues that require a vascular supply have been far more difficult to produce in tissue engineering laboratories. Particularly for highly metabolic tissues such as cardiac or liver tissue, when the thickness of the growing construct exceeds a few hundred microns, cells along the inner regions become necrotic due to hypoxia. Nature addresses this problem by providing a rich, intrinsic vascular supply that reaches into these tissues such that no region is farther than 100–200 μm from a blood vessel. These organs possess a vasculature that scales from large arteries and veins down to capillary networks with diameters as small as 10 μm or less. These facets of complex tissues and organs have led to the conclusion that engineered tissues will require a means to develop an intrinsic vascular supply.

2.15.5.2.3 Microfluidic bioreactors for cell and tissue growth

Bioreactors for cell and tissue engineering have benefited dramatically from microfabrication and microsystems technologies, because of the ability to control the spatial, chemical, topographic, and fluid mechanical microenvironment in ways that mimic physiological systems more closely (Desai 2000). Microfluidic bioreactors for hepatic and renal support are emerging as viable means to treat acute or chronic failure of these organs, paving the way toward miniaturized and ultimately portable or even wearable or implantable systems. However, many enormous technical challenges remain, and therefore, the most important role of microfabrication

technology in many current studies is to elucidate more completely the critical elements of engineered cell-based systems that will provide long-term sustainable function. In the field of stem cells, bioreactors capable of promoting stem cell differentiation will ultimately provide crucial insights into the cell-sourcing issues that face many of these therapeutic avenues.

Hepatocyte bioreactors, a first step toward liver assist and liver replacement devices, have been constructed using a number of microfabrication-based approaches. Critical elements of hepatocyte bioreactors include fluid mechanical, structural, and biochemical properties that mimic the liver microenvironment, including cell–substrate interactions that simulate hepatocyte anchorage on the basement membrane as well as microvascular networks to provide oxygen and nutrients to the highly metabolic cells. The Fujii group (Leclerc *et al.* 2003) has reported the fabrication and testing of a multilayer PDMS bioreactor seeded with a human hepatocarcinoma cell line (HepG2) along with 3T3 mouse fibroblasts to provide the connective tissue element. Oxygen was delivered to the cells from the environment through the PDMS bioreactor walls, taking advantage of the extremely high diffusivity of molecular oxygen through the bulk polymer. Cells were observed to attach, consume glucose, and produce albumin over periods of days to weeks, confirming the basic viability of this type of device for culture of the robust hepatocyte cell line.

The work of the Fujii group leverages the significant foundation of microfluidic technology in the PDMS platform. For implantable applications, biodegradable substrates will ultimately be preferred, and Bettinger (Bettinger *et al.* 2006b) has reported on HepG2 cell culture in a PGS bioreactor consisting of multiple layers of microfluidic channels. In this case, oxygen diffusivity is markedly lower than in PDMS, and therefore, the cells must be supplied with oxygen through the media flowing through the microfluidic network. Hepatocyte viability was monitored by observation of long-term cell attachment to the constructs as well as through albumin production. In order to promote hepatocyte adhesion while minimizing the possibility of shear-related damage, the hepatocyte chamber was populated with a staggered array of posts surrounded by pressure-relief channels. This study confirmed for the first time that a large-scale biodegradable microfluidic bioreactor could be used in long-term culture of hepatocytes.

Culture of primary liver cells represents a more difficult challenge. Primary cells require specific substrate configurations, such as spheroids/aggregates, 3D matrices such as the nanostructured self-assembled peptides (sapeptides), or support cells such as fibroblasts in coculture (Bhatia *et al.* 1998b). Bioreactor configurations comprise single-unit systems in which all functions take place within one controlled microenvironment, as well as systems that divide the functions such as ammonia conversion and cytochrome *P*450 detoxification into separately controlled chambers. Bioreactor configurations are typically modeled based on physiological configurations, and therefore, radial flow parallel plate bioreactors are a common approach. Challenges with these approaches such as those of the cell density can be addressed by microfabrication, in that narrower channel heights result in higher cell densities per unit volume. The limitation in this approach is not the fabrication technique, rather it is the high shear stresses that develop in bioreactor chambers in which the channel height drops to 50 μm or less. The principal engineering limitation in all of the liver bioreactors is the requirement for high oxygen transport to feed the high oxygen consumption rate (OCR) of hepatocytes (Patzer 2004, Roy *et al.* 2001). Numerous efforts have been made to increase oxygen delivery to the cells, including hollow fiber-based approaches in which oxygen is directed through additional pathways toward the cells. Internal membrane oxygenation has shown very promising results in several studies and in multiple membrane configurations in which a second membrane is employed to reduce the quantity of toxins that reach the cells. Many of these efforts are aimed at reducing the ultimate cell volume that will be required to provide replacement liver function for patients suffering from liver failure.

Engineered microenvironments for stem cell control and regulation represent an extremely important application of microscale fabrication and microsystems technology. Cell sourcing represents one of the most significant barriers in the field of regenerative medicine, with traditional sources such as autografts, allografts, and xenografts experiencing limitations in availability and applicability. Both adult and embryonic stem cells are sources with enormous potential for tissue engineering. Microfabricated bioreactors containing mechanical and biochemical cues to regulate stem cells are now emerging. Embryonic stem cells can be encouraged to differentiate into a vast array of cell types based on the appropriate sequence

of environmental signals and cues. Adult stem cell microenvironments, such as those generated through nanostructured matrices described in a later section (Holmes *et al.* 2000), are capable of replicating the niches required to control their fate.

2.15.5.2.4 Large-scale microfluidic devices for cell-based systems

Cell-seeded scaffolds for tissue engineering can be produced using a wide variety of techniques, comprising a spectrum of approaches that rely to a varying extent on precision microtechnologies. The principal engineering limitation facing efforts to develop laboratory-grown complex tissues is the requirement for an intrinsic vascular supply for the growing tissue. Natural tissues solve mass transport challenges by providing a vast network of blood vessels organized according to principles that minimize the energy expended and maximize the effectiveness of oxygen and nutrient exchange. Therefore, these networks obey the principles that govern the structure, scaling, and integration of such vessels into an organization of channels that can be characterized by design rules involving vessel length and the average diameter of successive generations of vessels.

Great progress has been made in the development of engineered tissues using angiogenic methods to provide an intrinsic vascular supply. However, these approaches, which rely on the use of growth factors such as vascular endothelial growth factors (VEGF) and platelet-derived growth factors (PDGF) to produce vascularization (Peters *et al.* 2002, Richardson *et al.* 2001), still face challenges regarding long-term mechanical stability of the vasculature. Recent progress in multiculture systems (Levenberg *et al.* 2005) has resulted in successful generation of vascularized skeletal muscle tissue. For vital organs, the properties of the vascular supply are more challenging, however, and therefore, an engineering approach to this problem, through the use of microfabricated scaffolds containing vessel networks, has been developed. Such engineered vascular networks can be generated using polymer micromolding or embossing techniques followed by lamination of assembled micromachined layers (Borenstein *et al.* 2002, Lim *et al.* 2003, Wang *et al.* 2005), on a variety of scaffolding materials, as described in the next section.

Microvascular networks provide the basis for oxygen and nutrient transport in complex, 3D tissues and organs. Over the past several years, the use of photolithography and polymer replica molding has been applied toward the development of large-scale 3D vascular networks. Computational fluid dynamic models have been used to provide design rules for these networks, beginning with simple fluid mechanical principles but also encompassing a number of complex phenomena. These models are based on morphometric analysis of the microvasculature of vital organs, as obtained using casting techniques that employ waxes and other materials infused into the vascular bed, followed by etching or removal of the tissue, and subsequently detailed measurements of the cast replica of the vessels. Numerous morphometric studies have been reported (Escaned *et al.* 2001, Kassab and Fung 1994, 1995, Kassab *et al.* 1993), often accompanied by microfluidic scaling laws that provide a framework for microfabrication-based approaches to replicate the physiology of the network (Kaazempur-Mofrad *et al.* 2001). Laminar pipe flow as governed by the Hagen–Pouiseuille equation establishes the starting assumptions for network design. However, the mixed-phase nature of blood with a solid fraction of hematocrit and platelets, the distensibility and compressibility of vessel walls and erythrocytes, respectively, and small channel effects such as the Fahraeus–Lindquist effect all lead to far more complex analytical models. These networks have a fractal-like geometry, much like coral and many other structures found in nature. Computational fluid mechanical models incorporate these phenomena and these principles in order to provide a template for the construction of scaffolds comprising microvascular networks.

Once computational models have established a design target for the microvascular network, microfabrication technology is used to produce polymeric replicas of the bifurcated channel arrays. As described in a previous section, 2D network designs are applied to photomasks for photolithographic pattern transfer onto a silicon master mold wafer. Molds are generated using high aspect ratio lithographic negative molds, plasma etching techniques, or electroplating, as previously discussed. In physiological vascular networks, the blood vessels are cylindrical, while microfabrication technology typically produces rectangular vessel geometries. In addition, the ability to produce vessel networks with varying channel depths is limited by the increasing complexity of lithographic processes when they are used to superimpose structures with changing heights on a planar surface. Micromachined or electroplated molds can obviate this difficulty, thereby enabling

microvascular scaffolds with vessel geometries more closely approximating physiological systems.

These approaches have been used to generate single layers of planar microvessel networks; by stacking and laminating multiple layers with vertical interconnects, highly integrated 3D microvascular networks are developed. Applications aimed at *in vitro* studies or for *ex vivo* organ support may utilize biocompatible nondegradable scaffolding materials, but for implantable natural organ replacements, fully biodegradable scaffolds are preferred. In the former set of applications, PDMS is a preferred embodiment, due to its simplicity and ease of fabrication and assembly, and PMMA has also been investigated. For microvessel networks in a biodegradable embodiment, PLGA, PGS, silk fibroin, and calcium alginate hydrogels have all been successfully demonstrated. Endothelialization of the microvascular network has been shown to result in confluent coatings of endothelial cells on channels of varying dimension, providing a pathway toward functional capillary beds for oxygen and nutrient transport within tissue-engineered organ replacements.

Application of the microfabrication technology described in the previous section can be applied to specific organ structures as well as to blood vessel networks. Organs such as the heart, the liver, kidneys, and lungs are essentially microfluidic processing chambers, with vast arrays of microscale chambers for transport, filtration, generation, and excretion of fluids. Examples of these microfluidic structures include the liver sinusoids, renal proximal tubules of the kidney, and alveolar beds within the lung. In each of these instances, microvascular networks are essentially interpenetrated within networks or compartments of organ-specific structures. The microvascular networks supply oxygen and nutrients to the parenchymal cells of the organoid.

In the simplest embodiment, networks of microfabricated organ-specific structures such as liver sinusoids are cultured with hepatocytes and the cells are oxygenated by the surrounding environment. In the case of PDMS scaffolds, the permeability of oxygen in the bulk is high enough so that oxygen delivery through a separate microvessel network is not required (LeClerc *et al.* 2003). Oxygen and small molecule transport through alginate hydrogel is sufficient to sustain long-term cell viability. However, most structural biodegradable scaffolds made of PLGA or PGS, for instance, do not have oxygen permeability sufficient to support such a structure, and therefore, microvessel networks are placed proximal to the organ microstructures. In these cases, oxygen must be transported directly from the microvessel network into the parenchymal cells through open pores. Porous structures generated by porogen leaching, for instance, are possible, but a precision microfabricated device with micromolded compartments for the blood and parenchyma typically uses porous membranes to govern transport between compartments. Such membranes may be composed of materials such as polycarbonate, polysulfone (PS), or PES, depending on the requirements for protein fouling and hemocompatibility. Pores may be tortuous networks or line of sight as is formed by ion track etching, depending on the thickness and specific filtration requirements of the system.

An example of an acellular system constructed using the technology described above is the MEMS-based renal dialysis system (Kaazempur-Mofrad *et al.* 2004). In it, a microchannel network is juxtaposed beneath a dialysate layer, with an intervening PES membrane designed with a specific molecular weight cutoff (MWCO) for filtering molecules such as urea and creatinine in the blood. By increasing the MWCO of the filter, middle molecules may also be filtered more effectively than in conventional dialysis. The principal advantage of the microfabricated system is the ability to reproduce the dimensions of the glomerular capillaries more closely than in a conventional hollow fiber dialyzer. Cell-based systems such as liver bioreactors and renal replacement systems have also been demonstrated in a microfabricated construct, as will be described in Section 2.15.6.

2.15.5.2.5 Three-dimensional hydrogels

The application of photolithography-based processing to cell-seeded systems has resulted in promising new avenues for merging microfabrication techniques with cell culture in an integrated fashion. In one such technique, cell encapsulation techniques based on PEG have been merged with photolithography to construct and 3D scaffold with microscale features in a hydrogel network (Liu and Bhatia 2002). Living cells suspended in an uncrosslinked polymer solution are localized using photolithography to generate large-scale spatial organization of the cellular constructs. Numerous layers can be fabricated by a stepwise process in which each layer is patterned, the uncrosslinked cell-containing materials are washed away, and additional layers are photopatterned. Features as small as 50 μm in minimum dimension have been fabricated using this method, which has

the potential of being integrated with adhesion molecules, growth factors, and other substances.

An alternative approach that does not require the use of photocrosslinkable materials involves the use of micromolding technology to form structures such as microchannels in calcium alginate hydrogels (Cabodi *et al.* 2005a). Here, layers of the calcium alginate are micromolded against a PDMS transfer mold, which itself is produced from an SU-8 lithographically patterned silicon master mold. The calcium alginate films form a network of microchannels to support the flow of blood or media within the microfluidic construct. Multiple layers are bonded together by partially melting them with sodium citrate, a calcium ion chelator. Finished 3D hydrogel devices were used to study the transport of fluorescently labeled molecules, which flow through the microchannel networks and within the bulk of the hydrogel. Assisted extraction, in which pressure-driven flow occurs through the device, is compared with unassisted extraction, where there is no flow. This system represents a model for the development of a 3D scaffold in which microchannel networks and bulk transport can be engineered to support cell growth and tissue generation.

2.15.6 Applications of Microsystems Technology for Tissue Engineering

Applications of microfabrication technology and engineered microsystems in the field of tissue engineering span a range from skin, bone, and cartilage to complex vital organs such as the liver, kidneys, and lungs. The potential of microtechnology in this field is only beginning to emerge, and therefore, these investigations represent the first explorations in what promises to be a rapidly growing body of work in which the power of microtechnology in generating microenvironments suitable for cell culture is applied toward tissue regeneration and replacement. In the following section, several early applications of microscale tissue engineering will be discussed, with an emphasis on microfluidic devices with engineered biomaterials.

2.15.6.1 Skin, Bone, Cartilage, and Wound Healing

Skin and cartilage represent early successes in the field of tissue engineering, in that numerous commercial products have been developed and used successfully in a wide range of clinical applications. In the case of skin, patients suffering from severe burns and diabetic ulcers have benefited significantly from the ability to replace skin tissue using an engineered substitute, thereby avoiding donor site morbidity associated with a graft from another application. Cartilage tissue engineering leads solutions for huge numbers of patients requiring repair of meniscal tears and other injuries, and therefore, these applications represent the earliest realization of the promise of tissue engineering in the clinic. Together, they represent systems that have moved toward patient care most rapidly, in part because they do not require the use of an engineered microenvironment associated with a vascular supply or other complex microstructures. However, even in these cases, the tools of microscale tissue engineering can be useful in generating 3D structures for multicellular processes (Khademhosseini *et al.* 2006). In one recent example, Albrecht *et al.* (2006) have integrated multiple microscale tools to achieve chondrocyte biosynthesis, potentially leading to tissue repair after osteoarthritic injury. In this instance, photopolymerizable hydrogels were microfabricated in concert with dielectrophoretic forces in order to create 3D aggregates of approximately 20 000 bovine articular chondrocytes. This technology platform represents a potential pathway for investigation of fundamental mechanisms involved in embryonic development, cancer, and tissue regeneration.

In the field of bone tissue engineering, microfabrication technology has been utilized by Mata *et al.* (2002) to create 3D constructs. Based on the pioneering work of Caplan (Nakahara *et al.* 1991), in which the osteogenic potential of periosteal cells has been investigated, Mata and coworkers have attempted to induce bone regeneration using microengineered scaffolds. Multilayer PDMS constructs were fabricated using replica molding, with porous films produced using dual-sided molding techniques. These layers were integrated using microfluidic connectors in order to produce a 3D bioreactor. This approach has been applied toward bone formation as well as to the generation of artificial cornea using corneal epithelial cells. In addition, stem cell bioreactors have been produced using these 3D PDMS scaffolding techniques, in which human bone marrow-derived connective tissue progenitor cells were cultured to promote osteoblast differentiation.

The field of wound healing is driven by clinical needs such as the increasing number of type II diabetics with ulcers of the foot and other locations, the

incidence of full-thickness burns in accident victims, and the need for treating soldiers suffering from burns and other injuries in the battlefield. The worldwide market for wound care products exceeds $10 billion annually, and most therapies focus on management of pain and infection but do not address the fundamental issues associated with nonhealing wounds. Advances in the understanding of wound healing from the biological perspective have been significant, and numerous tissue engineering products have been developed and commercialized in response to the clinical need. A recent trend toward the use of biologically active scaffolds, developed for skin tissue engineering applications, has emerged in the field of wound care as well. Such bioactive therapies entail the delivery of antibiotics, growth factors, and other compounds to the wound site.

In addition to bioactive materials, recent developments are aimed at the application of mechanically active scaffolds and devices toward wound care. One such product utilizing mechanical forces to promote wound healing is the vacuum-assisted closure (VAC) device (Kinetic Concepts Inc.), in which a dressing is applied to the wound site and a vacuum is applied, thereby applying mechanical forces across the wound bed and promoting healing. Pioneering work by Orgill, Ingber, and coworkers (Saxena *et al.* 2004) has led to the development of a model for the mechanism associated with wound healing via the VAC device. Micromechanical forces are believed to promote cell division and amplify the effects of growth factors, and cytoskeletal rearrangements in response to these forces are believed to play an important role as well. Fluid transport of nutrients and waste products through the wound site, driven by the mechanical forces or the vacuum pressure, is also believed to play a major role in the enhancement of wound healing.

New microfluidic concepts for promoting wound healing are emerging, based on the ability to photopattern biomaterials and to construct 3D microfluidic devices therefrom. The work of Stroock and coworkers (Cabodi *et al.* 2005b) has resulted in the demonstration of a novel biopolymer, hydroxyethyl methacrylate, in a microfluidic device that optimizes mass transport in order to promote nutrient and waste exchange and to enable the delivery of drugs *in situ*. Such microfluidic devices combine a porous matrix with a well-defined network of microchannels engineered to provide transport of biomolecules to promote the healing process. In addition to the enhancement of mass transport, the fluid exchange also applies shear stresses to the wound site, a second avenue for accelerating the healing process.

2.15.6.2 Neural Tissue Engineering

Brain development is the subject of intense efforts, and microsystems technologies are providing new avenues for exploration of the mechanisms involved. Chemical gradients, as described earlier, are a critical element in neuronal behavior and in axon guidance. In one pioneering study (Dertinger *et al.* 2002), neurons from the hippocampus were cultured in systems involving a microfluidic mixer controlling the formation of a chemical gradient. As described therein, neuronal development involves the formation of processes at each end followed by the rapid elongation of one end toward axon formation. In the absence of chemical gradients, this process cannot be reproduced and hippocampal neurons do not become polarized. Substrate interactions such as contact with laminin trigger axon formation and polarization, and therefore, the microfluidic gradient generator was used to create a gradient of laminin versus bovine serum albumin to attempt to reproduce the axonal development process *in vitro*. A nearly linear gradient of laminin across a 180-μm channel was generated, first within the bulk of the microfluidic channel and then on the surface of the channel. These gradients were shown to promote axonal specification but not axonal guidance, as had been seen in earlier studies.

Other approaches to neural tissue engineering have utilized nanoscale techniques to control the microenvironment within engineered scaffolds. These matrices, based on the nanostructured self-assembled oligopeptides described earlier (Holmes *et al.* 2000), comprise alternating sequences of amino acids known as sapeptides. Neuronal attachment and differentiation, leading to synapse generation, have been demonstrated in scaffolds constructed with these sapeptide matrices. One of the specific cell types used, PC12 rat cells, are a clonal cell line that differentiates in the presence of neural growth factor. Primary cells from the rat cerebellum and hippocampus were also used in culture. When exposed to nerve growth factor (NGF), the PC12 rat cells seeded in specific sapeptides were shown to exhibit significant neurite outgrowth. Similar results were seen in primary cerebellar and hippocampal cell culture studies. Synapse formation was also dramatically enhanced in these cell culture studies, demonstrating the importance of these nanostructured peptides in promoting neural engineered tissues.

2.15.6.3 Vital Organ Tissue Engineering

Progress in the field of tissue engineering has been greatest in applications such as skin, bone, cartilage, and tubular structures such as blood vessels and urologic tissues (Kojima *et al.* 2003). While these advances have provided lifesaving therapies for newborns with congenital defects, burn victims, and many other patients, the greatest potential of tissue engineering technology is in the replacement of vital organ function. Vital organs such as the liver, kidneys, and lungs contain extraordinarily complex structure and function that arises from precise architecture spanning length scales from submicron features up to several centimeters. Prior to the introduction of microsystems technologies to the development of engineered tissues, such structures could only be produced by the introduction of growth factors, ECM materials, and other biochemical components into cell-seeded scaffolds with no significant microscale organization. For instance, microvascular networks have been produced by the stepwise introduction of VEGF and PDGF into a porous scaffolding to coax the formation of self-assembled capillaries (Richardson *et al.* 2001). Other studies have introduced sphingosine to generate vascular structures (Lee *et al.* 1999). Organ-specific structures such as sinusoids and biliary structures in engineered liver tissue, as well as nerve-like elements, have been demonstrated in response to the use of novel 3D nanostructured ECM materials (Semino *et al.* 2003). However, in each of these cases, the extraordinary complexity of the organ cannot be approached through the use of biochemical signals alone, and therefore, the field of microsystems technology has been instrumental in establishing the mechanical, spatial, and topographic microenvironment that comprises vital organs. In Sections 2.15.6.3.1–2.15.6.3.4, recent advances in engineered liver, kidney, cardiac, and pulmonary tissues will be described in brief.

2.15.6.3.1 Liver

The liver represents one of the most important and difficult challenges in the field of tissue engineering, because of the urgent need for solutions for liver failure beyond cadaveric organ transplantation, and because of the numerous requirements related to the mechanical and biochemical microenvironment for the hepatocytes and other cells. In addition, engineered liver replacement therapies require a means for the delivery of oxygen that reaches down to the 100-μm scale, due to the high OCR of liver tissue and the poor diffusivity of oxygen within liver tissue. Liver tissue engineering applications range from the development of artificial liver devices for drug screening to acellular and cell-based liver assist devices. Within the field of microscale cell and tissue engineering, more emphasis has been placed on the liver than on any other tissue, and a larger number of microscale tools have been developed in investigations involving hepatocytes than any other cell type.

Hepatotoxicity represents one of the principal reasons why candidate drug therapies are withdrawn from the market or never reach the market due to negative results obtained in toxicity and toxicology studies by pharmaceutical companies. The economic costs of failed drug compounds approach 1 billion dollars per event, and an untold number of promising candidates never reach patients who desperately need them due to inaccurate toxicity assessments in early-stage safety studies. Therefore, one of the most significant contributions of the field of tissue engineering, in addition to direct production of replacement tissues and organs, will be the development of laboratory screening tools based on human cells cultured in engineered scaffolds. In these applications, the power of microfabrication technology in replicating the microenvironment for suitable hepatocyte function will be critical.

Numerous drugs have encountered safety issues following FDA approval, including several (Rezulin/Parke–Davis, Duract/Wyeth–Ayerst, and Serzone/Bristol–Meyers) for hepatotoxicity. Other drugs have encountered safety problems with cardiotoxicity, such as the appearance of Q-T prolongation and other types of cardiac or vascular injury. In each case, the toxicity might have been predicted by the existence of early-stage screening tools based on the culture of human cells in microarrays.

Numerous studies have demonstrated the successful culture of primary hepatocytes in microfabricated arrays. Powers *et al.* (2002) have reported the development of microstructured silicon devices in which hepatocytes are cultured; in these studies the 3D nature of the scaffold results in a more physiological behavior of the cells. Kane *et al.* (2006) have developed a microfluidic array for the coculture of primary rat hepatocytes along with 3T3 fibroblasts. Coculture has resulted in improved albumin synthesis, drug detoxification through the cytochrome *P*450 pathway, and urea production. Random coculture of hepatocytes and fibroblasts, as described by

Bhatia *et al.*, does not produce results equivalent to those seen in micropatterned coculture studies. In the work of Kane *et al.*, glass substrates micropatterned with surface adhesion molecules were used as the foundation for a microfluidic array with PDMS wells and microchannels. Albumin and urea synthesis were monitored over periods of up to 5 weeks, and differences between the perfused arrays and control devices were observed and potentially attributed to shear stresses or oxygen distribution. **Figure 16** illustrates the time course of the albumin synthesis in this microengineered bioreactor (Kane *et al.* 2006).

Numerous approaches toward the replacement of liver function have been developed, with early systems based on acellular devices similar to those used for hemodialysis in renal failure patients. However, the complex array of biological functions such as protein synthesis and drug metabolism cannot be replicated without hepatocytes, and therefore, a spectrum of cell-based therapeutic devices have been pursued. In a manner similar to that of renal dialysis, hollow fiber membrane devices loaded with hepatocytes have also been utilized for liver assist, with mixed results. As discussed in Section 2.15.4.1, the inability of mesoscale technologies such as hollow fiber bundles to simulate the microenvironment of the liver sinusoids ultimately limits the effectiveness of such devices in therapeutic applications. A number of modifications to the conventional hollow fiber design have been reported, including the use of microcarriers and multiple coaxial geometries. The membrane itself can be modified to more closely approximate the adhesive and immunological properties of the liver, but long-term hepatocyte function has been limited even in the presence of these advanced configurations. Flat-plate geometries with radial flow have been implemented in an effort to more closely approximate the liver physiology, thereby providing the appropriate spatial microenvironment. Chemical signals and substrate–matrix interactions are equally critical, as are the specific coculture interactions that have been described earlier.

Hepatocyte immobilization on scaffolds and subsequent transplantation of these scaffolds for liver assist or replacement represents a towering technical challenge that will have enormous benefits for patients suffering from end-stage liver failure, hepatitis, and other diseases. Scaffolding for tissue-engineered liver devices can be synthetic or natural; synthetic materials include bioresorbable materials such as PLGA as well as polysaccharides. Biological scaffolds such as collagen sandwiches or hyaluronic acid have also been tested. Hepatocyte encapsulation

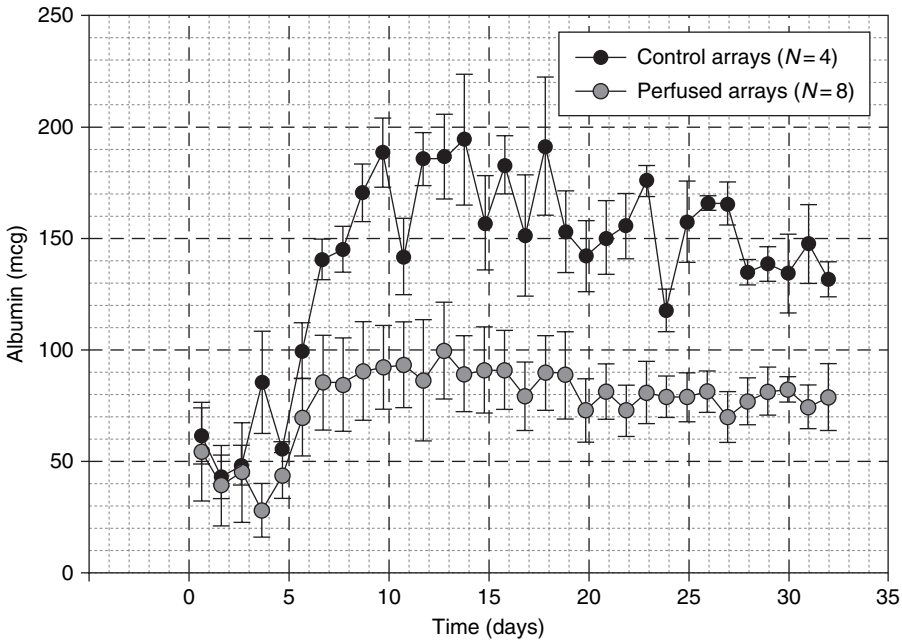

Figure 16 Albumin synthesis in a perfused microfabricated array compared with an open control device, using a coculture of primary rat hepatocytes and 3T3-J2 fibroblasts. (Source: Kane B J, Zinner M J, Yarmush M L, Toner M 2006 Liver-specific functional studies in a microfluidic array of primary mammalian hepatocytes. *Anal. Chem.* **78**, 4291–8.)

in alginate spheres has also been reported, and aggregates of hepatocytes and nonparenchymal cells have been studied as well. The high OCR of hepatocytes requires maintaining small distances between the hepatocytes and the oxygen source. Immune response and long-term viability and functionality of hepatocytes in these devices represent significant challenges, leading to developments such as the microvascular network technologies described earlier. Formation of a viable vasculature to provide oxygen to the highly metabolic liver tissue and development of a biliary network for excretion represent major challenges that need to be addressed in order to develop tissue-engineered liver devices.

2.15.6.3.2 Kidney

The kidney represents the first vital organ for which an artificial device was successfully used to replace function. Renal dialysis still represents the only long-term extracorporeal treatment for organ failure, despite huge efforts aimed at liver and lung augmentation. Kidney dialysis for patients with end-stage renal disease (ESRD) is a life-sustaining therapy but has many drawbacks including poor 5-year survival rates, high cost, severe impact on patient's quality of life, and poor temporal control over blood toxicity levels. The trend in the past decade has been toward slower, gentler dialysis, so that the levels of toxins such as urea and creatinine in the bloodstream do not reach the extreme high and low concentrations of typical hemodialysis. Home dialysis given each night reduces the excursions in toxin levels by replacing three 4-h dialysis treatments with seven 8-h treatments per week; wearable continuous dialysis would even more closely approximate the operation of healthy kidneys for ESRD patients. The goal of microsystems research in microfabricated dialysis devices is to approach the size, capacity, and reliability of a healthy kidney to enable wearable continuous dialysis for the 300 000 ESRD patients in the United States. One group has demonstrated improved clearance of urea and creatinine using a microfabricated device in which multiple layers of PDMS microchannels are stacked with intervening PES nanoporous membranes. In **Figure 17**, a 35-layer device containing a bonded stack of bilayers, each with a semipermeable PES membrane separating a vascular and dialysate chamber, is shown.

ARF represents another opportunity for microsystems technology to improve therapy for patients suffering from kidney disease. ARF can follow serious infections, poisonings and drug overdose, and numerous other causes, and currently the most prevalent therapy for ARF is supportive hospitalization to prevent complications such as sepsis while the kidney function regenerates. New technologies present the possibility for improved therapy for ARF, based on hollow fibers lined with renal proximal tubular cells. Improved glomerular filtration is achieved using silicon nanomachined membranes with slit pores to improve the permselectivity of solutes while maintaining physiological levels of hydraulic permeability.

Advanced membrane technology represents a tremendous opportunity for microfabrication and nanofabrication in the field of renal replacement. Traditional renal dialysis membranes utilized regenerated cellulose as the substrate material, because of its low cost and easy availability. These cellulose membranes were incorporated into various dialyzer configurations, including rotating drums, parallel plates, spirals, and hollow fiber-based systems. Biocompatibility concerns led to the modification of cellulose by vitamin E bonding and heparin bonding, and eventually to the replacement of cellulose by synthetic membranes such as PS and PES. Biocompatibility issues such as thrombogenicity and biofouling are only one aspect in hemodialysis; the efficiency (clearance) of ultrafiltration is another critical aspect of the technology. Diffusive transport governed the filtration process in early dialysis machines, separating small solutes from high-molecular-weight constituents and the solid fraction of the blood and removing them in an efficient manner. Convective transport has emerged as a means to remove middle molecules more efficiently and has accompanied the shift from cellulose to synthetic membranes such as PS and PES. These newer membranes have larger pore sizes in order to

Figure 17 Image of renal filtration device constructed by stacking 35 individual bilayers, each containing a vascular network and dialysate chamber separated by a nanoporous membrane. (Source: Borenstein, Weinberg, Kaazempur-Mofrad, Krebs, and Vacanti, unpublished.)

accommodate the clearance of materials such as $\beta 2$-microglobulin, a middle molecule with a molecular weight of roughly 10 kDa that is responsible for diseases such as amyloidosis in renal failure patients.

One of the most potentially significant advances in the field of organ assist and organ replacement technology based on MEMS fabrication techniques is the silicon nanopore membrane reported by Humes *et al.* (2006). Detailed investigations of the physiology of the glomerulus have shown that a slit-shaped pore with engineered spatial and electrical properties approaches physiological performance more closely than do conventional cylindrical or sponge-like pores. Analysis of the dependence of the hydraulic permeability on the pore geometry indicates that slit-shaped pores may provide improved control over the filtration process. In early studies, Humes' group has collaborated with the Cleveland Clinic to produce slit-shaped silicon nanopores in polysilicon membranes, using a sacrificial silicon dioxide layer that can be controlled to within ± 1 nm. Initial flow characterization of these silicon nanopores matches Hele–Shaw flow through slit-shaped tubes very closely.

2.15.6.3.3 Cardiovascular tissues

The development of cardiovascular tissues such as heart valves (Sodian and Hoerstrup 2000), pulmonary artery grafts (Shinoka *et al.* 1996), and large and small blood vessels represents the largest set of applications for tissue engineering because of the prevalence of heart disease in the United States. As in the case of the liver and other tissues, multiple cell types are required in order to construct replacement cardiovascular tissues, and the need for coculture as well as the requirement for a microvascular supply makes this set of applications an ideal target for microscale tissue engineering. Tissue engineering approaches involving cell-seeded rolled tubes (Shinoka and Ma 1996) have shown extraordinary success for arterial grafts in the clinic in early studies, but the goal of a vascular graft with suitable long-term mechanical and structural properties similar to natural vessels remains a challenge for the field. Topographic cues such as the micropatterning and nanopatterning techniques described earlier have been shown to produce appropriate morphology for the vascular SMCs that comprise the tunica media of blood vessels (Sarkar *et al.* 2005). These topographic cues can be integrated into a biodegradable scaffold (Sarkar *et al.* 2006) to generate the classic herringbone organization of cells present in the smooth muscle layer of native vessels.

Numerous studies have demonstrated the ability to imprint microscale features in biodegradable constructs such as PLGA and PGS (Bettinger *et al.* 2006b). In the blood vessel construct described earlier, PCL was selected because of its biocompatibility, mechanical properties, ease of processing, and the ability to modify the degradation times within a wide range. One drawback of PCL is its poor bulk oxygen and nutrient transport properties. In this instance, PLGA nanoparticles were used to generate an interconnected network of pores in the bulk PCL structure, and this particulate leaching was combined with the formation of microtopography as a cue for orienting the vascular SMCs. This application represents an excellent example of the merger of microfabrication technology and biomaterials modification in order to produce a physiological engineered construct.

2.15.6.3.4 Lung assist devices

The lung is yet another vital organ that is composed of a vast interconnected microfluidic network of channels proximate to an equally complex network of capillaries, in this case placing the blood vessels adjacent to the alveolar structures. Current therapies for pulmonary failure include ECMO, a cardiopulmonary assist device that oxygenates the blood automatically in the absence of normal lung function. Several microsystems-based technologies are currently under development for applications in lung assist and replacement devices. These devices include a microchannel network of blood vessels placed adjacent to a network of oxygenated vessels, with a semipermeable membrane placed in between.

Hollow fiber bioreactors similar to those used in renal and liver tissue engineering applications have been reported for a biohybrid lung by Polk *et al.* These fibers are chemically modified by the addition of adhesion proteins and by plasma processing and then endothelialized to confluence. Gas transfer studies are under way for the development of a mixing oxygenator for long-term patient applications.

The Federspiel group at Pittsburgh (Henchir *et al.* 2003) has reported the development of artificial alveolar capillary (AAC) modules for biohybrid artificial lungs, using a MEMS-based approach with numerous advantages over hollow fiber technology. These devices utilize PDMS microchannel networks generated by micromolding around thin metal wires, to increase the surface-to-volume ratio and enhance oxygen diffusivity. In order to reduce the incidence of thrombosis, these workers are endothelializing the constructs onto fibronectin-coated channels.

Researchers at Northwestern University are also pursuing an artificial lung technology based on microfabrication technology, with the current focus on analytical models for high-efficiency oxygenation. Another group is utilizing photocatalytic generation of oxygen to reduce the need for access to bulky oxygen sources for long-term operation of the artificial lung.

2.15.7 Future Directions

In response to the urgent need for therapeutic solutions for an increasing population of patients suffering from tissue loss and end-stage organ failure, the field of tissue engineering is undergoing explosive growth due to the convergence of advances in cell biology, novel biomaterials, and microscale and nanoscale fabrication techniques. These technologies are achieving success in applications as divergent as skin, bone, and nerve repair and liver, kidney, and lung assist and replacement devices. In each case, the power of the microfabrication technology lies in its ability to replicate the cellular microenvironment and the mechanical, spatial, topographic, and chemical cues that control cell behavior in these complex living systems. Before the introduction of microfabrication technologies to the field, the technological emphasis was principally on the development of biochemical environments in bioreactors that were capable of eliciting biologically based development of structure and function in these systems. While these biologically based approaches are still predominant in many applications, it is becoming clear that complex multiphenotype systems such as the liver and kidney will benefit substantially from the ability to provide microfabricated patterns and structures to drive cellular organization.

Scaffold preparation techniques, ranging from SFF to micromolding large-scale fluidic networks, represent a critical element of microfabricated constructs for tissue engineering. Each of the techniques described herein possesses advantages and disadvantages specific to each tissue engineering application, related to issues such as cost, biocompatibility, processing constraints, and manufacturability. The emergence of micromolding techniques with nanoscale resolution has resulted in rapid advances in vital organ tissue engineering. The use of lasers, ink-jet printers, and other tools developed for other applications has highlighted the vast opportunities for technologies developed for other industries to provide for rapid and precise construction of cell-based systems. Micropatterning of chemical cues on the surfaces of tissue engineering scaffolds has enabled the replication of complex coculture systems in the *in vitro* setting and has provided opportunities to merge these techniques so that cellular and biochemical deposition can be integrated with microfabrication of scaffolds to build complex systems to replace organ function.

The potential for advances in tissue engineering based on microscale and nanoscale systems and technologies can be further realized through the integration of MEMS and nanoelectromechanical systems (NEMS) active elements in the tissue engineering process. These advances are yet to be realized, and therefore, they have not been discussed here. However, control over the flows and concentrations of culture media, oxygen, nutrients, and other biochemical factors in bioreactors for tissue engineering can be enhanced through the use of MEMS sensors and actuators such as microvalves and micropumps, flow sensors, biosensors, and other microscale elements. Integration of these elements into extracorporeal devices seems to be a natural development that will improve control, lower the cost, and increase the reliability of organ assist devices, for instance. Integration of these types of devices into fully implantable systems, and ultimately into fully biodegradable systems, represents a future challenge.

Advances in tissue engineering depend on numerous factors beyond the scaffolding and microenvironment associated with microscale technologies. These include advances in biomaterials for scaffolding substrates as well as matrix components, integration of delivery vehicles into scaffolding, advances in basic cell biology, and cell sourcing. The opportunity for microsystems technology lies in the integration of these various elements, and therefore, an engineered tissue construct represents a classic example of a microsystem in the same manner as miniaturized sensing and actuation systems developed using MEMS technology. Much of the added complexity in these systems lies in the extraordinarily intricate functioning of biological elements such as cells that are far too complex to be modeled using the types of physical laws and analyses applied to most MEMS systems. Therefore, most of the advances here are still at a very early stage, and for the foreseeable future, most systems will be represented by an integration of microfabricated devices and cells, because cell functions will be too difficult to replicate in a fully artificial system. Future developments in tissue engineering are

expected to continue to leverage advances in microfabrication and nanofabrication technology in order to more closely replicate the physiological systems these devices are being developed to replace.

Acknowledgments

The author would like to acknowledge the extraordinary contributions of colleagues and collaborators too numerous to mention. Special thanks go to James Hsiao, Ernest Kim, Kim Bonner, Eleanor Pritchard, Mark Keegan, Chris Bettinger, Eli Weinberg, Ahmad Khalil, and John Aceti of Draper Laboratory for their contributions to the tissue engineering program there. The contributions of collaborators Joseph Vacanti, Cathryn Sundback, Craig Neville, Katherine Kulig, and Nicholas Krebs of Massachusetts General Hospital are also gratefully acknowledged, as are those of Mohammad Kaazempur-Mofrad of the University of California at Berkeley, Robert Langer, Ali Khademhosseini, Kevin King, and Roger Kamm of MIT, and David Kaplan of Tufts University. The support of Draper Laboratory and the Center for Integration of Medicine and Innovative Technology (CIMIT) US Army DAMD17-02-2-0006 in the preparation of this chapter is gratefully acknowledged.

Biography

Jeffrey Borenstein is currently Director of the Biomedical Engineering Center and is a Distinguished Member of the Technical Staff at the Charles Stark Draper Laboratory in Cambridge, Massachusetts. There he serves as the Technical Director for Draper's new biomedical engineering program, with projects in drug delivery, clinical diagnostics, regenerative medicine and biodefense. He is also a Program Leader and the Draper Laboratory Liason for the Center for the Integration of Medicine and Innovative Technology (CIMIT). Dr. Borenstein is Principal Investigator for several commercial and government programs in tissue engineering as well as an NIH Bioengineering Research Partnership in drug delivery. Dr. Borenstein has a Ph.D. in Physics from the University at Albany and 20 years of experience in microsystems technology and biomedical devices. Dr. Borenstein's current work is focused on the application of microsystems technologies towards organ assist and organ replacement for transplant medicine and drug discovery, diagnostics and sensing applications, and drug delivery. He has eight issued patents, as well as nine published patent applications, and drug delivery. He has eight issued patents, as well as nine published patent applications and over 80 peer-reviewed journal articles and conference proceedings.

3.01.1 Introduction

The definition of the micromirror may be the small-sized device including some new mechanisms as compared to bulk mirror devices, which usually use bulk motors for actuation. The micromirror requires a smaller amount of power for driving, and some integration in numbers or functions can be combined. At present (2006), Digital Micromirror Devices (DMD), a product from Texas Instruments, is a typical micromirror because of mass production and commercial success. Of course, there are many other variations and potential uses of micromirrors. The continuing growth in optical system applications (e.g., display technologies or optical-fiber telecommunication infrastructure) has stimulated the progress of miniaturized, reliable, inexpensive photonic devices for light beam manipulation. In integrated optics, mechanical moving elements are avoided, as they cause unreliability. Electro- or magneto-optic effects are preferred. Such devices, however, generally suffer from low contrast and usually operate at low efficiencies. Movable mechanical elements such as mirrors can realize optical beam manipulation more effectively. The devices can be manufactured inexpensively by using the microelectromechanical systems (MEMS) fabrication technique. Microfabrication offers high-volume capability and therefore low-cost products. In general applications, not only cost reduction but also power reduction or portability and shrinkage in size will promote the introduction of micromirrors when compared to present designs. The foreseen goal will be to integrate the micromirrors and electrical circuits for their controls.

3.01.2 History at the Beginning

Historically, significant improvements have been carried out introducing new ideas and technologies. The first published report of a micromirror is the mirror matrix tube for mechanical light modulation developed at Westinghouse Research Labs in 1975 (Guldberg *et al.* 1975, Thomas *et al.* 1975). The mirror array is electrostatically deflected to the substrate when charged by an electron beam. With the saturated irradiation of the electron beam with the surrounding bias voltage, the mirror gets a bias voltage. The micromirror consists of an SiO_2 membrane grown on epitaxial Si on sapphire on which Al electrodes are patterned. SiO_2 layers are released by undercutting of Si forming the deflectable mirror surfaces. **Figure 1** shows the image of the mirror having the four-leaf clover shape and its cross section.

When the bias voltage is applied between the mirror and the underlying electrodes, the segmented leafs of mirror deflect. The reflected light beam generates four spots corresponding to each mirror leaf area. The rectangular mirror generates the cross-type reflection pattern (described in Section 3.01.3.1.1). **Figure 2(a)** shows the diffraction pattern illuminated with a laser beam. When the cross-type light shield is inserted (illustrated by white lines in **Figure 2(a)**), the reflection beam can be on/off modulated. **Figure 2(b)** shows the reflected white light beams that have passed through the cross-type shield. **Figure 3** shows the demonstration of the devices as the projection display for airport information.

In 1977, Petersen (1977) at the IBM research laboratory reported SiO_2 cantilevers for light modulators fabricated by anisotropic Si etching. An individual cantilever can deflect attracted by the electrostatic force. A 16-element light modulator array was used for parallel light processing. A beam of He–Ne laser light was reflected by the cantilever, apertured, focused, and scanned by a galvanometer. In 1980, Petersen presented the scanning mirror with the torsion bar using single-crystalline silicon (c-Si). **Figure 4(a)** shows the mirror image. This shape of the micromirror is fundamentally the same as that of typical micromirrors in use currently. For a 2 mm $\times$ 2 mm size mirror, a scan angle of $\pm 1^\circ$ was

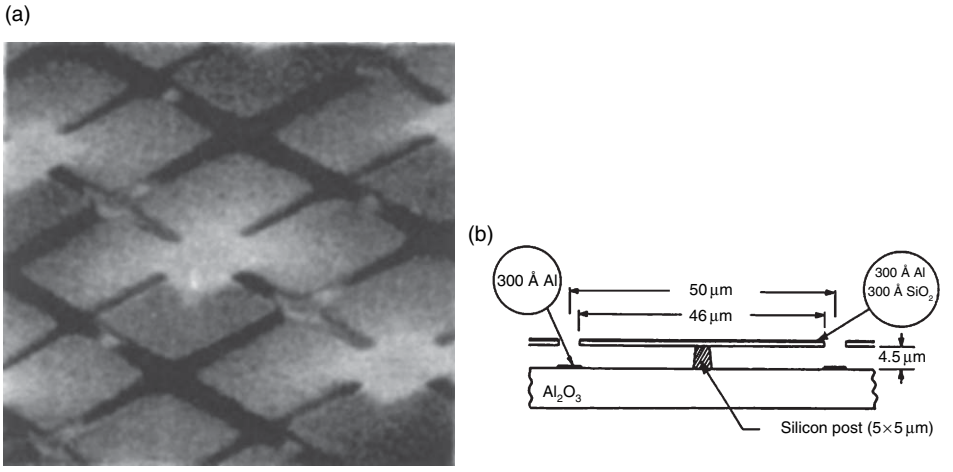

Figure 1 (a) Photographs of light valve elements and (b) cross-sectional view of a single element. (Source: Thomas R N, Guldberg J, Nathanson H C, Malmberg P R 1975 The mirror-matrix tube: A nonel light valve for projection displays. *IEEE Trans. On Electron Devices* **ED-22(9)**, 765–75.)

Figure 3 Photographs of projection display produced with the mirror matrix light valve. (Source: Thomas R N, Guldberg J, Nathanson H C, Malmberg P R 1975 The mirror-matrix tube: A nonel light valve for projection displays. *IEEE Trans. On Electron Devices* **ED-22(9)**, 765–75.)

demonstrated at the resonance frequency of 15 kHz. Figure 4(b) shows the cross section of the device. A glass substrate was etched to form a well into which the torsion plate could deflect. A support ridge is used to prevent it from being pulled down in parallel to the base of the well. A pair of driving electrodes was fabricated in the well. This idea is used in the recent micromirror device design (Yamamoto *et al.* 2003). Continuous operation of the devices for months ($\sim 10^{11}$ cycles) followed by dislocation-sensitive Si etching showed no damage exhibiting high fatigue strengths and high reliability (Petersen 1982). This highlights one of the important advantages of using single-crystal materials and of scaling down the device dimensions: fatigue mechanisms are not the same as those found in macroscopic materials due to the absence of grain boundaries.

3.01.3 Diffraction Characteristics of Micromirrors

3.01.3.1 Diffraction Image Obtained through Lens

The micromirror is usually used for making a spot far from the device. The spot can be treated as the (Fraunhofer) diffraction pattern of the micromirror

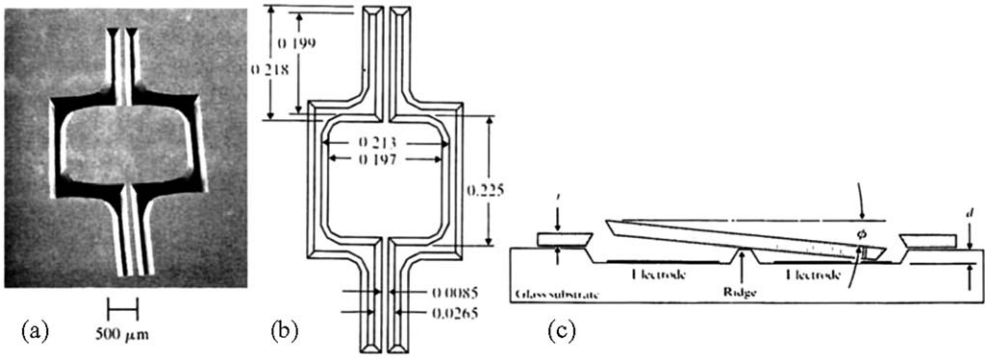

Figure 4 (a) Scanning electron microscope (SEM) image of typical torsion mirror. (b) Dimensions of 15-kHz resonating mirror (cm). (c) Cross section of mirror element. The depth of well is 12.5 μm. (Source: Petersen K E 1980 Silicon torsional scanning mirror. *IBM J. Res. Develop.* **24(5)**, 631–7.)

(Hecht 2002). **Figure 5** shows the optical setup. Q_0 is the point light source on the optical axis and Q is its image. The wavelength of the light emitted from Q_0 is λ. The folded orbit of the light beam reflecting at the mirror is straightened in this model. The reflection mirror is replaced with the screen aperture. The light, which has passed outside of the mirror, does not contribute to generating the spot image. The reflection mirror has the same function in the aperture. The following examples show the images of the micromirrors using the projection lens. When the imaging through the lens is ideal without aberration, the wave, which has passed through the aperture, will become a part of the spherical wave converging to its image. The emission pupil of the lens is considered as an aperture. The spherical surface Σ is defined to have the rim at the pupil. The center of Σ is point Q, and its radius f is the propagation distance from the aperture to the image. Huygen's principle states that the wave amplitude $u(x', y')$ on the image plane including point Q can be expressed as follows:

$$u(x', y') = C \iint \sum \exp\left\{ i \frac{2\pi}{\lambda} \frac{(\xi' x' + \eta' y')}{f} \right\} d\xi'\, d\varsigma' \quad [1]$$

where (x', y') is the coordinate near the image point Q. (ξ', ζ') is the coordinate for the plane of the emission pupil. Here, it is assumed that $\sqrt{\xi'^2 + \eta'^2} << f$. This assumption can be expressed as $(a/f)^2 << 1$, where a is the size of the emission pupil or the mirror. In the following case, the integral over the spherical surface Σ is replaced with the integral over the planar surface. This replacement is justified if observation is at a distant position.

3.01.3.1.1 Rectangular mirror

Consider a rectangular mirror having the side lengths of $2a$ and $2b$ along ξ' and ζ' directions, respectively. **Figure 6** shows the optical setup. From eqn [1], the following result is obtained:

$$I(x', y') = |u(x', y')|^2 = |C|^2 (2a \cdot 2b)^2 \left[\frac{(\sin(2\pi a/\lambda f))x'}{(2\pi a/\lambda f)x'} \right]^2 \left[\frac{(\sin(2\pi b/\lambda f))y'}{(2\pi b/\lambda f)y'} \right] \quad [2a]$$

At the center position $(x', y') = (0, 0)$, the intensity $I(x', y')$ becomes the maximum value $|C|^2 (2a \cdot 2b)^2$.

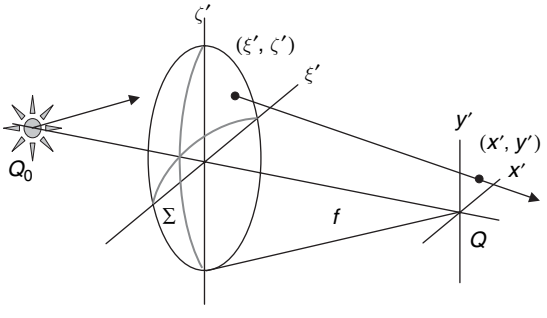

Figure 5 Optical setup for considering Fraunhofer diffraction through lens.

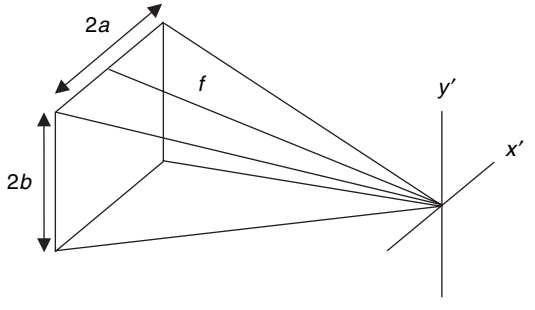

Figure 6 Diffraction from a rectangular mirror.

There is a proportional relation between the intensity and the square of the area. There are positions where the intensity $I(x', y')$ becomes minimum reaching a value 0 where dark nodes are generated. The position of dark nodes is decided by the numerator sine function in eqn [2a]. x' and y' will satisfy the following equation:

$$\frac{2\pi a}{\lambda f}x' = m\pi, \quad \frac{2\pi a}{\lambda f}y' = n\pi \quad (m, n = \pm 1, \pm 2, \pm 3, \ldots) \qquad [2b]$$

Figure 7(a) shows the intensity distribution obtained from eqn [2b]. **Figure 7(b)** shows the magnified image around the center. Beside the main center peak there are subpeaks. The magnitudes of the peak intensity are 4.7% (second peak), 1.7% (third peak), and 0.8% (fourth peak) of that of the center peak. **Figure 8** shows the calculated density plot of the diffraction pattern. The dark lines of the node are observed following eqn [2b]. The diffraction spots generate a ± shape pattern like the constellation. This is the reason why a cross-type shield is used in the mirror matrix tube (see **Figure 2**). When the four segmented leafs deflect, the center of the deflection pattern splits and shifts to the four corners in **Figure 2(b)**. The light passes through the shield realizing the light switching.

Consider the circular mirror shape having a radius a. **Figure 9** shows the optical setup. The coordinates (ξ', ζ') and (x', y') can be replaced by the polar coordinates. Calculating eqn [1], the following equation showing the symmetry against the origin can be obtained:

$$I(r') = |C|^2 (\pi a^2)^2 \left[\frac{2\mathcal{J}_1\left(\frac{2\pi a}{\lambda f}r'\right)}{\frac{2\pi a}{\lambda f}r'}\right]^2 \qquad [3]$$

where r' is the radius from the center of the spot image. $\mathcal{J}_1$ is the Bessel function of order 1. **Figure 10** shows the curve. $\mathcal{J}_1$ is a slowly decreasing oscillatory function. Its shape is similar to that of a sine function. The curve passes the origin showing the odd function.

Therefore, the main feature of eqn [3] is similar to that of eqn [2a] and [2b] and relates to the telescope image of the star, and was first derived by G B Airy (1801–1892), Astronomier Royal of England. When the twinkling due to the air flow can be ignored, the center brightness of the star is proportional to a to the power of 4 as can be seen from the factor $(\pi a^2)^2$. In this case, $2a$ is the aperture diameter of the lens of the telescope. This is the reason why the telescope uses the larger lens. In the case of a micromirror with a reduced size a, the larger diffraction effect appears, even though the almost light power is reflected using the mirror having the diameter larger than the size of the laser beam diameter.

Figure 11 shows the intensity distribution expressed by eqn [3]. **Figure 12** shows the calculated density plot of the diffraction pattern. This circular spot pattern is called an Airy disk. Around the center peak, there are circular rings having a radius r'_{m} for the black one and a radius r'_{M} for the bright one. The condition of these rings can be expressed by the following equations:

$$\mathcal{J}_1\left(\frac{2\pi a}{\lambda f}r'_{\mathrm{m}}\right) = 0 \qquad [4]$$

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[\frac{2\mathcal{J}_1\left(\frac{2\pi a}{\lambda f}r'_{\mathrm{M}}\right)}{\frac{2\pi a}{\lambda f}r'_{\mathrm{M}}}\right] = \mathcal{J}_2\left(\frac{2\pi a}{\lambda f}r'_{\mathrm{M}}\right) = 0 \qquad [5]$$

Table 1 lists the radius of bright (maximum intensity) and black (minimum intensity) rings and the relative intensity compared to the center value. The position of the first minimum ring is given by

$$\frac{2\pi a}{\lambda f}r'_{\mathrm{m}} = 1.22\pi, \quad r'_{\mathrm{m}} = 1.22\frac{\lambda f}{2a} \qquad [6]$$

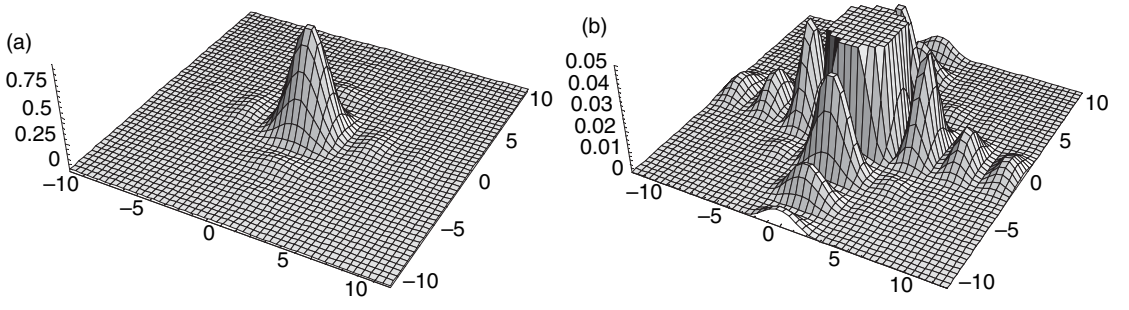

Figure 7 (a) Intensity pattern calculated from eqn [2]. (b) The magnified view is around the center peak. The coordinates in the figures are normalized by the equation $x = (2\pi a/\lambda f)x'$, $y = (2\pi b/\lambda f)y'$.

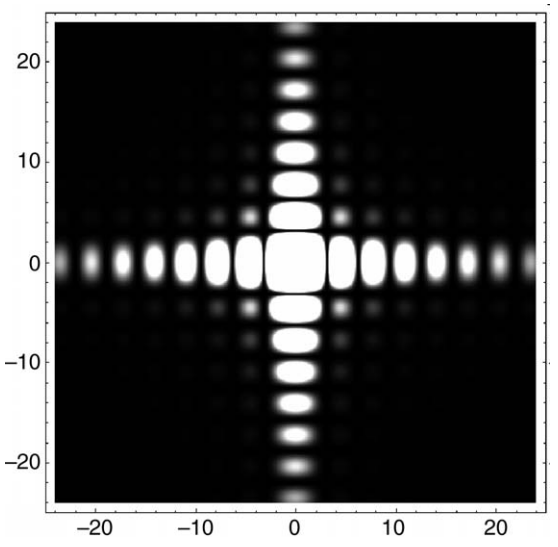

Figure 8 Calculated density plot of the diffraction pattern from a square aperture (or mirror).

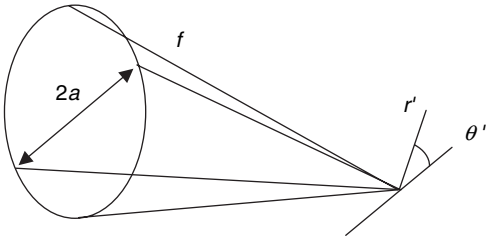

Figure 9 Diffraction from circular mirror.

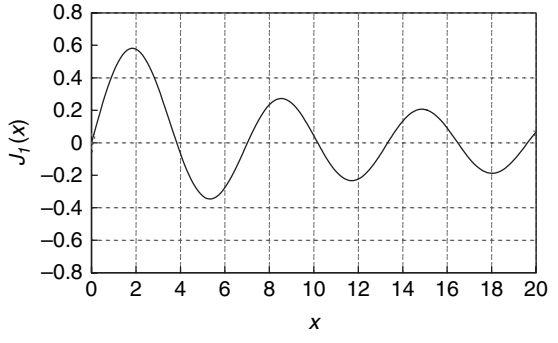

Figure 10 Shape of Bessel function of order 1 of $J_1(x)$.

Comparing to the condition in eqn [2a] and [2b], the difference is the factor 1.22. This larger value can be attributed to the smaller area of the circular aperture πa^2 (the area of the rectangular aperture is $4a^2$). The light intensity of the spot inside the first black ring is ~84% of the total light bundle that has passed through the circular emission pupil.

Figure 13 shows the normalized intensity distributions from rectangular and circular mirrors. The lateral axis is normalized multiplying the factor $2\pi a/\lambda f$ to r or x. The main difference is outside peaks. The inset of Figure 13 shows the magnified profile. The subpeaks of the circular mirror are smaller than those of the rectangular one. Compared to the circle area, the rectangle area includes a larger percentage of the side area far from the center. This will generate the larger contribution of the phase change in eqn [1].

3.01.3.2 Number of Resolvable Spots – Resolution

Setting integer m to be 1 in eqn [2b], the width of the center bright spot obtained from the rectangular mirror can be expressed as follows:

$$x' = \frac{\lambda f}{2a} \qquad [7]$$

This width means the limit of the optically resolvable size of the resolution. For making this peak width smaller, the factor f/a has to be small. The wavelength λ is usually fixed depending on the application. f is the parameter of the outside optics. The parameter of interest for the micromirror is a, and the mirror size $2a$ needs to be large. Figure 14 shows two diffraction profiles. The additional profile shown by the gray curve is set at the black node of the center profile. Here, the relative position shift is $\Delta x' = \lambda f/2a$. When the light sources are incoherent, the image profiles become simple summation of two profiles. The summed intensity profile expressed by the dotted curve is added showing the existence of two peaks. If two peaks further approach each other, these two spots will mix resulting in a single spot. One definition of the resolution that is usually used is the nearest black node $\Delta x' = \lambda f/2a$, which was proposed by Rayleigh. When this value is transformed to the angle, the resolvable diffraction angle $\theta_{\text{diffraction}}$ can be expressed by

$$\theta_{\text{diffraction}} \approx \tan^{-1}\frac{x'}{f} \approx \frac{\lambda}{2a} \qquad [8]$$

For making this result more general, the diverging angle can be expressed as follows:

$$\theta_{\text{diffraction}} = C\frac{\lambda}{2a} \qquad [9]$$

where C is the shape factor of the mirror ($C = 1$ for the rectangle, $C = 1.22$ for the circle). The resolvable

pixels of the image obtained by the laser display are discussed using this factor.

Now the resolution of the image obtained from the parallel electrostatic torsion mirror, as shown in Figure 15, can be discussed. The light modulator developed by Petersen (Figure 4) has this structure. The mirror is suspended in the air at a height h from the gap. The driving method is arbitary. The

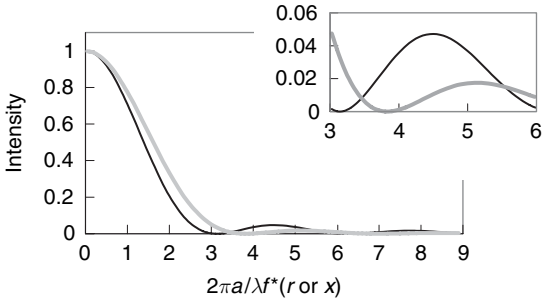

Figure 13 Intensity profiles from circular and rectangular mirrors.

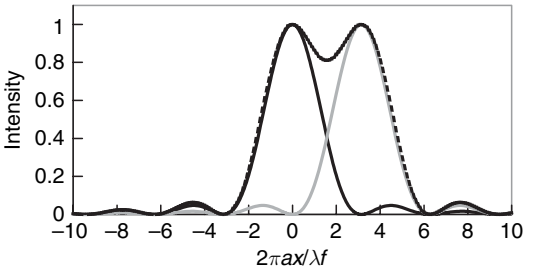

Figure 14 Overlapping point images for illustrating Rayleigh criteria.

maximum rotation angle of the mirror is decided by the geometry as shown by the dashed line.

$$\theta_{\max} = \sin^{-1}\left(\frac{b}{a}\right) \approx \frac{b}{a} \qquad [10]$$

For the center pivot mirrors, $\theta_{\max}a$ corresponds to the motion of the edge of the mirror. The optical scan angle is $2\theta_{\max}$ due to the light reflection.

The number of resolvable spots is obtained as follows:

$$N = \frac{2\theta_{\max}}{\theta_{\text{diffraction}}} \approx \frac{2b}{a}\frac{2a}{C\lambda} = \frac{4b}{C\lambda} \qquad [11]$$

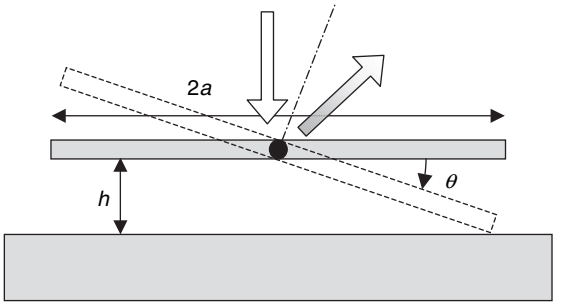

Figure 15 Simplified drawing of the micromirror for discussing the resolution.

To increase the number of resolvable spots, the air gap b has to be large. Supposing the values of $C=1$, $\lambda=0.5\,\mu m$, and $N=1000$ for the high-quality laser display, the height b has to be $125\,\mu m$. This vertical distance is large for micromirrors, requiring special techniques in microfabrication.

When the parallel plate electrostatic actuator is used for driving the mirror, the stable obtainable rotation angle decreases to $\sim 1/3$ of the maximum rotation due to the pull-in instability (Senturia 2001). With the larger height b, the decrease of the electrostatic force becomes the restrictive factor for the actuator design.

3.01.3.3 Static Flatness of Mirror

Let us consider the criterion for the static flatness of the mirror (Nee 2001). **Figure 16** is the illustration of the mirror. The mirror is considered to deform having a diameter D as a section of a sphere with radius r. The total amount of deviation from the flat line at the center of the mirror is assumed to be b. A collimated laser beam incident on a curved mirror will reflect at an angle ϕ and will conform to the following equations:

$$\sin\phi = \frac{D/2}{r} \quad [12]$$

$$\cos\phi = \frac{r-b}{r} \quad [13]$$

From the relation of $\sin^2\phi + \cos^2\phi = 1$, r can be expressed as follows:

$$r = \frac{D^2 + 4b^2}{8b} \quad [14]$$

Inserting this result into eqn [12] and assuming small angle yields:

$$\phi = \frac{4bD}{D^2 + 4b^2} \quad [15]$$

The mirror deformation that results in beam divergence equal to the diffraction Rayleigh limit gives the following relation:

$$b = \frac{\lambda}{4} \quad [16]$$

This is the criterion for static flatness of the mirror. A round trip of the reflecting light beam propagation corresponds to a delay of $\lambda/2$. For the mirror that can generate a diffraction-limited spot, the condition is as follows:

$$b << \frac{\lambda}{4} \quad [17]$$

The bulk mirror element usually satisfies the condition of $<\lambda/10$.

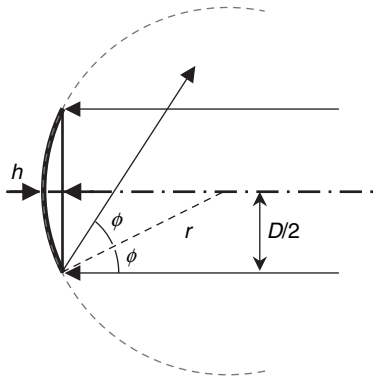

Figure 16 Sketch of relationship between beam divergence and nonplanar mirror surface approximated as part of a sphere.

3.01.3.4 Dynamic Flatness of Mirror

The dynamic deformation of the mirror can be the limiting factor for realizing the laser display, which requires low distortion of the image. The dynamic torque produces a surface distortion at the flyback position where the angular acceleration becomes maximum. This issue was discussed at an early stage (Petersen 1980). **Figure 17** illustrates the schematic drawing where the mirror no longer conforms to the original shape. The high acceleration forces during mechanical deflection of the mirror result in bending of the mirror. Dynamic deformation calculation does not take damping into account. The maximum acceleration is attained at the extremities of the scan, where the velocity is zero.

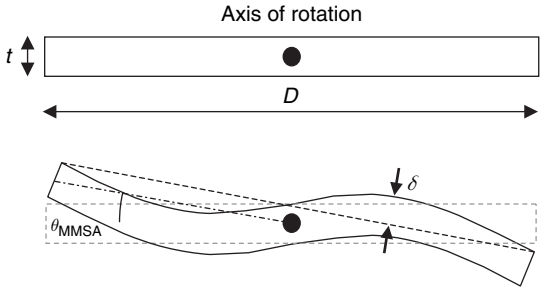

Figure 17 Schematic drawing of a dynamic mirror deformation.

Damping force is related to velocity; thus, the damping should have no effect in the calculation.

For rectangular mirrors, the following formulas can be used for calculating deformation, which is defined as the deviation from linear line shown in **Figure 17**. **Figure 18** shows the shape of the mirror surface as a function of u $(-1 < u < 1)$, which is the normalized mirror coordinate perpendicular to a rotation axis. The positions $u = \pm 1$ correspond to edges of the mirror, where the deformation δ is set to be 0, subtracting the effect of the slant angle.

$$\delta(u) = \frac{\delta_{\max}(u^5 - 10u^3 + 20|u| \cdot u - 11u)}{1.83} \quad [18]$$

$$\delta_{\max} = 0.217 \frac{\rho f^2 D^5 \theta_{\max}}{Et^2} \quad [19]$$

where ρ is the material density, E is the modulus of elasticity (Young's modulus), and f is the scanner frequency, and $\theta_{\max}$ is in radian. The large mirrors scanning at high speeds will have considerable dynamic deformation.

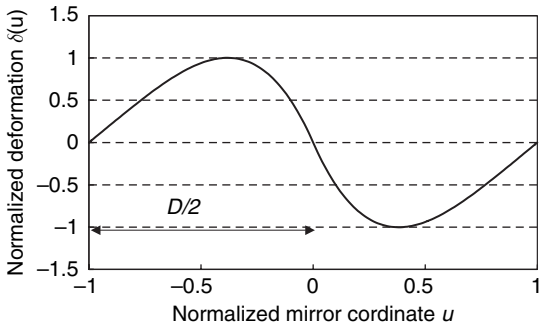

Figure 18 Surface profile as a result of deformation. Maximum deviation occurs at ~40% way from the center to the edge of the scanner.

3.01.4 Recent Progress after *c.* 1999

Around 1999, the technique of the surface micromachining using structural polysilicon (poly-Si) layers was mainly adopted for devices fabrication. This is because the multilayer structures give more design flexibility and are advantageous for realizing high fill factors with actuators and mechanical springs hidden underneath the mirrors (Bustillo *et al.* 1998). The micromirrors prepared by surface micromachining have narrow gaps between the moving element and the substrate at the initial state. As justified in Section 3.01.3, there were many efforts to increase this gap for obtaining larger rotation angles. **Figure 19(a)** shows an example lifting the frame for a 4×4 micromirror array (Su *et al.* 1999). The lifted height is 72 μm taking the balance with the disadvantage of the increase of the driving voltage.

Figure 19(b) shows another example developed in the MicroStar project at Lucent Technologies for realizing a large-scale optical switch (Aksyuk *et al.* 2000). The lifting height from the substrate is 50 μm. The parallel plate-type electrostatic actuator with the underlayered electrodes is adopted. The angular range needed for switching applications is about ±9°. A self-assembly mechanism powered by tailored residual stress in a separate metallized layer is developed.

The limitation of the parallel plate layout can be overcome taking another layout reported from the group of UC Berkeley (Kiang *et al.* 1998a, b, Muller and Lau 1998). **Figure 20** shows an example. Suspended by a frame that is connected to a hinged slider at its back, the micromirror is inclined at 70° to the substrate. The backspace of the mirror is open, and the mirror motion does not suffer from the geometrical limit. Amplification of the mirror motion at resonance is realizable. The linear comb-drive actuator on the substrate drives the mirror. The electrostatic comb drive consists of 100 interdigitated fingers on the shuttle comb and 101 fingers on the stationary comb. The comb fingers are 2 μm wide and 40 μm long, and the entire comb region extends 1 mm from side to side. The shuttle of the comb drive is connected to the bottom of the mirror. The maximum rotation angle $\theta_{\max}$ is decided by the stroke of the linear motion and the position of the rotational axis. In this example, the maximum displacement of the shuttle comb is ±15 μm. Using eqn [11], the number of resolvable spots can increase with the

maximum rotation angle and the mirror size and is expressed as follows:

$$N = 2\theta_{\max}\frac{2a}{C\lambda} \qquad [20]$$

This is the relation under the static condition. At resonance, $\theta_{\max}$ will be doubled taking the full stroke of the scanning motion. **Figure 21** shows the scanning electron microscope (SEM) image of another

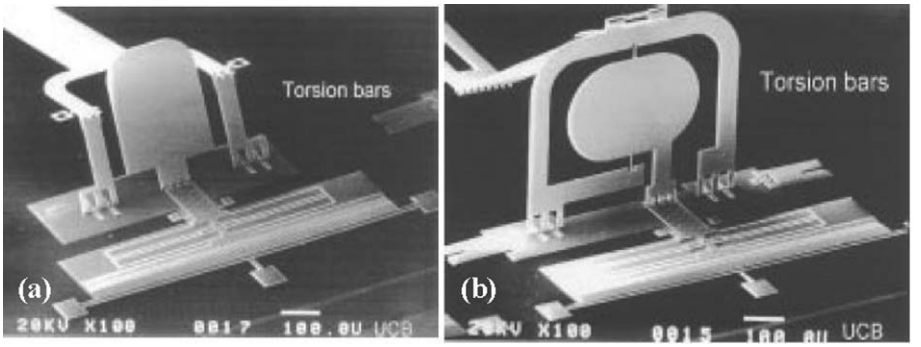

Figure 21 Scanning electron microscope (SEM) photographs of two prototype resonant scanners. (Source: Muller R S, Lau K Y 1998 Surface-micromachined microoptical elements and systems. *Proc. (b) A 440 × 300 μm scanning mirror that scans the beam in a direction parallel to the substrate.

microscanner constructed with a 300 μm × 400 μm and a 440 μm × 300 μm mirror. The mirror stands upright on the wafer and its rotational axis is normal to the substrate. The system has a resolution of 7 × 11 pixels (Kiang *et al.* 1998a, b).

Figure 22 shows a raster-scanning display using two scanners (Hagelin and Solgaard 1999). The incoming optical beam first reflects off the fast mirror and then strikes the slow mirror. The laser beam is modulated with an acousto-optic modulator that is synchronized to the mirror driving voltages for drawing some images. The fundamental structure of the microscanner is similar to that shown in **Figures 20** and **21**. The diameter of the scanning mirrors is increased to ∼500 μm having nearly circular shape. The maximum optical scanning angle is 15°. The resolution achieved is 102 × 119 pixels. The pixel size is observed to vary according to mirror angle. The smallest pixel size is at the center of the display with no voltage applied to the actuators.

The transition of the micromirror made of thin poly-Si layers to that made of a bulk c-Si layer using

deep reactive ion etching (DRIE) was tried by the group at Cornell University (Yeh *et al.* 1999). The process is a combination of surface micromachining and DRIE of bulk Si. **Figure 23(a)** shows the image of a micromirror. A torsional actuator consists of poly-Si fingers and bulk Si fingers. The suspended mirror is actuated by comb structures moving in the out-of-plane direction. The electrostatic force increases the overlapping capacitance of the electrode when the voltage is applied between the movable and fixed combs as shown in **Figure 23(b)**.

One of the hurdles of the surface micromachined mirror is the mirror curvature. The stress gradient appears in the film and its reduced thickness cannot prevent the mirror from bending. Although this static deformation is overcome using the stress control, the dynamic deformation remains. The dynamic mirror deformation is the deflection caused by the scanning motion of the mirror. The curved mirror surface affects the wavefront of the reflected light beam. The pixel size change is observed (Hagelin and Solgaard 1999). Satisfying the requirements of high resolution and high scan speed has been difficult. The dynamic mirror deformations limit the resolution to less than 20% of the diffraction-limited resolution.

In 2000, Conant *et al.*, reported a new type of micromirror. **Figure 24** shows the micromirror with the so-called staggered vertical comb drive

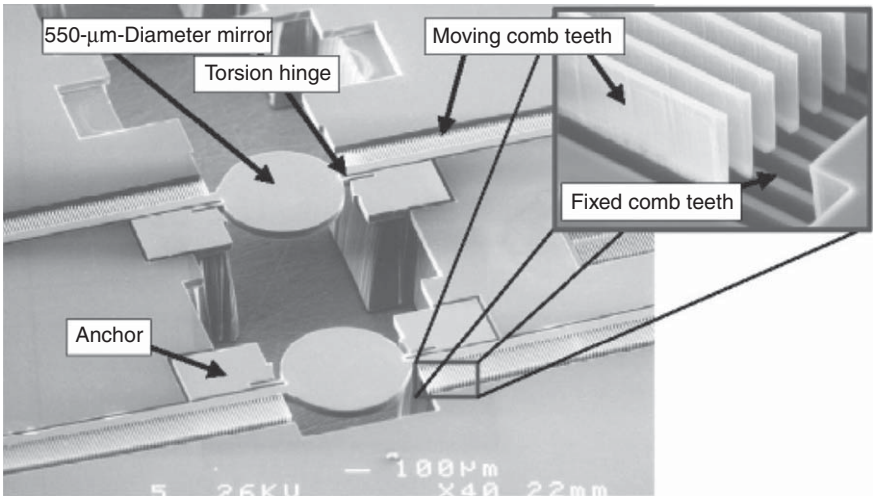

Figure 24 Scanning electron micrograph (SEM) of micromirrors with a staggered vertical comb drive. The inset shows a close-up view of the fixed and moving comb teeth. (Source: Conant R A, Nee J T, Lau K Y, Muller R S 2000 A flat high-frequency scanning micromirror. *Proc. Solid-State Sensor and Actuator Workshop*, Hilton Head Island, SC, USA, June 4–8, pp. 6–9.)

(SVC) for electrostatic driving, which is made from two layers of bulk c-Si separated by a 1.7-μm-thick SiO_2 layer. The mirror diameter is 550 μm and the resonant frequency is 42 kHz. The mirror, torsion hinge, and moving comb teeth are in the top Si layer. The fixed comb teeth are in the bottom Si layer. Applying the voltage between the top and the bottom layers, the moving comb teeth are attracted to the fixed comb teeth, exerting torque on the mirror generating the rotation. There are no hinges to couple the moving slider and the mirror as in the previous design, as shown in **Figures 20** and **21**. This vertical comb drive offers an advantage over gap-closing parallel plate-type actuators because the energy density in the comb drive is higher; moreover, parallel plate pull-in instability in the actuation is avoided.

The 50-μm-thick c-Si plate improves the rigidity of the mirror. This is valid for not only static but also dynamic deformation. Compared to the surface micromachined mirror, the mirror can be more than 10 times thicker. **Figure 25** shows the deformation of the micromirror where the dynamic deformation reaches its maximum. The total deformation is less than 30 nm.

The spot size and separation at eight different regions across the scan give the device performance. The optical resolution of 350 pixels is measured at the resonant frequency of 34 kHz with the scan angle of ±6.25°. The resolution of this 550-μm-diameter mirror with a 24.9° optical scan and 655-nm laser light is near the diffraction-limited resolution of 356 pixels based on eqn [20] by setting the value C to be 1.03.

Let us consider the dynamic deformation using eqn [19]. For a 550-μm-long rectangular c-Si mirror of 50 μm thickness, half-angle mechanical scan of 6.25°, and resonant frequency of 34 kHz, the estimated dynamic deformation is ~8 nm. This value is much lower than the Rayleigh limit of $\lambda/4$ for 655-nm light. For comparison, a 550-μm-long surface micromachined mirror of thickness 1.5 μm having the same resonant frequency will have the dynamic deformation ~9 μm. Because the dynamic deformation δ_{max} scales as the fifth power of the mirror length D, the small size of the mirror works advantageously. If the system performance is deformation limited, significant gains can be attained by slightly reducing the mirror size.

With greatly improved flatness, the micromirrors fabricated from the silicon-on-insulator (SOI) wafer are developed using a simplified process. The next main issue is increasing the rotation angle. Milanovic *et al.* showed a mirror design using the leverage. The inset of **Figure 26** shows a schematic drawing. By applying the lateral force F on the arm by either pushing or pulling on the arm, the lateral

force is transferred along linkages and applied below the axes of rotation of the mirror torsion bars, resulting in mirror rotation (Milanovic *et al.* 2003). The fabrication of the time-controlled multi-level DRIE of Si realizes types of beams providing the needed distance between axes and loads. The thickness of the device Si layer is 50 μm. **Figure 26** shows an example of a micromirror with three level structures, which experienced the largest mirror rotation angle in their designs. Lower beams are thinned to a height of 8-12 μm. **Figure 27** shows the demonstrated optical beam deflection. Applying the bias from 0 to 130 V, a static mirror rotation reached up to 22° optical (mirror rotation is half that value, i.e., 11°) in the pull mode, and 21° optical in push mode. The first resonant mode is >2 kHz.

After the invention of SVC, another category of actuator, the angular vertical comb drive (AVC) was developed. **Figure 28(a)** and **28(b)** shows the schematic drawing for explaining the difference between AVC and SVC, respectively. In an SVC, the moving fingers have the offset vertically from the fixed fingers. The AVC has the slant fingers, which require some new fabrication technique. Hah *et al.* (2004a) have demonstrated an AVC using reflow of photoresist. **Figure 28** shows the fabricated micromirror. After the release of the structures, the wafer was placed in deionized water at about 100°C to reflow the photoresist hinge. The inset is an enlarged view of the AVC. The moving fingers are patterned in the same layer as the fixed fingers and then tilted upward using the surface tension of the photoresist. The fingers are self-aligned. Compared to the SVC, AVC can generate a larger overlap capacitance between the moving and the fixed comb fingers. The maximum scan angle of the AVC increases up to 60% compared to that of the SVC for the same comb-finger dimensions with the enlarged stable region.

3.01.5 Classification of Micromirrors

3.01.5.1 Actuation Methods

Micromirrors using the electrostatic force have been described previously. A wide variety of actuation methods have been developed. Although the magnitude of the electrostatic force is generally small, electrostatic actuation seems to be adequate as light does not introduce any load. On the contrary, the other types of actuators can produce larger forces, and are suitable for performing external tasks (e.g., manipulation of objects). A comparison of actuation methods is important for satisfying the application requirements.

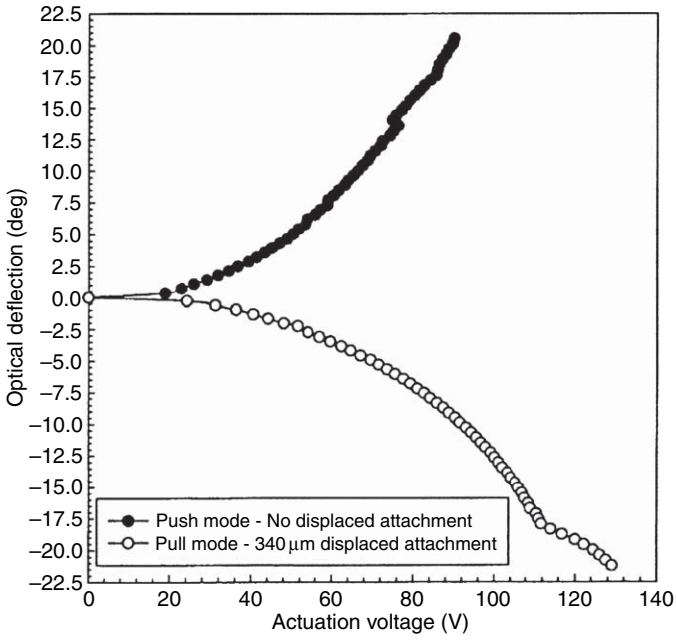

Figure 27 Demonstrated static optical deflection angle. (Source: Milanovic V, Last M, Pister K S J 2003 Laterally actuated torsional micromirrors for large static deflection. *IEEE Photonics Technol. Lett.* **15(2)**, 245–7.)

Electron.* **10(3)**, 505–13.)

The actuators mainly consist of four categories: electrostatic, piezoelectric, thermal, and magnetic driving (Bell *et al.* 2005). In the category of magnetic actuators, a magnetostrictive actuator is included. Piezoelectric and magnetostrictive materials have intrinsic actuation capabilities. Magnetostrictive materials produce enough force to build microactuators (Bourouina *et al.* 2002). Thermal expansion and phase transformations such as the shape–memory effect cause shape or volume changes. It is appropriate to conduct the assessment and comparison for these types of devices. In the following sections, examples of individual actuators are described.

3.01.5.1.1 Electrostatic actuators

The electrostatic actuator is rather preferred as the device can be completed within a chip, making integration easy. The actuator consumes little power. Heat dissipation is zero, in principle, as there are no steady-state currents caused by capacitive loads. The degradation in device reliability due to heat generation can be prevented. Here, different variations are described.

Figure 29 shows one of the sophisticated surface micromachined mirror devices for 2D optical switching developed by Lin *et al.* (1999) for the AT&T project. The free-rotating mirrors are monolithically integrated on a substrate. The collimated light beam is switched to the desired output port by rotating a mirror. **Figure 30** shows a schematic drawing showing the mechanism in a single micromirror. The mechanical linkage converts the linear displacement of the microactuators to the rotation of the mirror. The hinges anchor the mirror on the Si substrate. The mirror is connected to the translation stage by push rods. The translation stage is actuated by arrays of scratch-drive actuators (Akiyama *et al.* 1993, 1997).

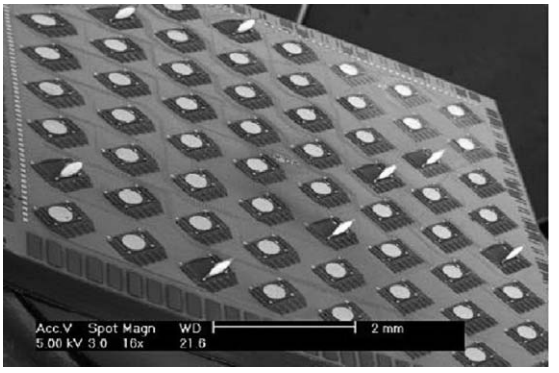

Figure 29 Two-dimensional optical cross-connect consists of mirrors, which can be flipped up from the substrate using the microactuators. (Photo courtesy: Lih Y. Lin.)

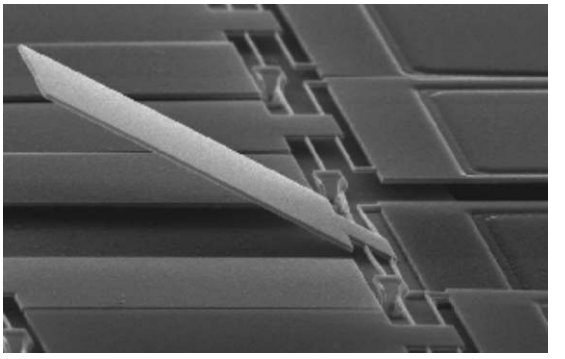

Figure 31 Scanning electron microscope (SEM) image of the double-hinged tilting mirror showing the snap down position of the actuator. (Photo courtesy: Alcatel-Lucent.)

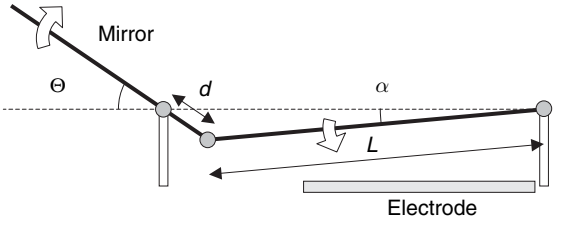

Figure 32 Schematic drawing of the double-hinged linkage for the angular amplification.

Some surface micromachined micromirrors are used to break the limitation of the rotation angle expressed by eqn [11]. **Figure 31** shows a 1D mirror array developed by Lucent Technologies (Lopez *et al.* 2002). The mirror size is $30\,\mu m \times 50\,\mu m$. The mirror is suspended at the side end, and the rotation toward the out-of-plane direction is generated with the neighboring actuator motion via the mechanical linkage. With the lever arm layout, the small downward displacement inside the actuator is transmitted as a large mirror rotation. The parallel plate-type electrostatic actuator shown at the right-hand side of **Figure 31** matches the structure. **Figure 32** shows a schematic drawing of the mechanism. The device consists of a double-hinged tilting mirror. One hinge anchors the mirror to the substrate and the other attaches the mirror to the moving plate electrostatically. When a driving voltage is applied, the moving plate is attracted downward, causing the mirror to pivot around the anchored hinge. This design has advantages. The micromirror is decoupled from the need for a large gap under the moving element. A double-hinged mechanism works as an angle amplification tool allowing large out-of-plane rotating mirror angles with small gap actuator designs. Neglecting sag and actuation plate deformation, the mirror rotates an angle θ given by:

$$\sin\theta = \frac{1}{d}\sin\alpha \qquad [21]$$

where α is the plate deflection angle, l is the length of the actuation arm, and d is the distance between the hinges. The larger rotation angle can be obtained with the amplification factor l/d. The maximum angle can be increased either by reducing the length d or by increasing the gap l. By separating the areas of actuators and mirrors, this mirror consists of a 1D array with a high fill factor. The larger area can be used for preparing micromirrors. **Figure 33** shows the voltage dependence of the angle θ. About 14° of the mirror angle is achieved at a voltage of <60 V with amplification factor of ~10. The inset shows a contour plot of an actuator element.

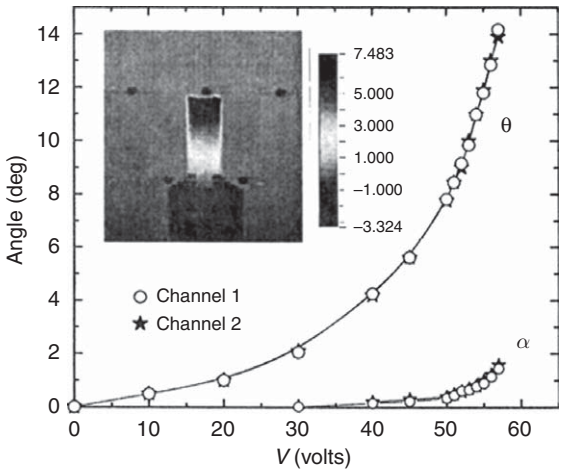

Figure 33 Rotation angle (θ) of two different mirrors and its respective actuator plate (α) as a function of the driving voltage. (Source: Lopez D, Simon M E, Pardo F, Aksyuk V, Klemens F, Cirelli R, Neilson D T, Shea H, Sorsch T, Ferry E, Nalamasu O, Gammel P L 2002 Monolithic MEMS optical switch with amplified out-of-plane angular motion. *Proc. IEEE/LEOS Int. Conf. Optical MEMS*, pp. 165–6.)

Figure 34 shows another design for realizing large mirror rotation (Greywall *et al.* 2003). The mirrors are made of c-Si and are covered with a thin layer of aluminum. The basic idea is to use thick poly-Si electrodes located on top of the SOI layer. The thick electrodes generate the offset geometry, generating a significant electrostatic interaction between the nearly horizontal mirror plate and the vertical sidewall via electrostatic fringing fields. **Figure 35** shows the mirror rotation as a function of the driving voltage. The maximum rotation of 9.2° is obtained at 175 V. The mirror is made from the c-Si device layer of the SOI substrate with a thickness of 1 mm. A 10-μm-thick *in situ* doped poly-Si layer is used to create the thick electrodes.

3.01.5.1.2 Piezoelectric actuators

Piezoelectric actuators are attractive because they can generate large stresses and high-energy density; they can be operated within a large bandwidth and potentially require lower operating voltages. The induced strain is proportional to the applied electric field. The same material can be used as the sensor based on the inverse effect measuring the piezoelectric voltage or the piezoelectric current charge when the separated electrodes are prepared. Disadvantages are the smaller displacement and the need for developing the delicate deposition process of the material. A thick film (1–100 μm) is necessary for the actuator. The deposition of piezoelectric material including the preparation of electrodes and the micromachining process are challenging. For skipping the deposition process, an external bulk piezoelectric actuator is sometimes assembled with passive micromachined structures (Yamada *et al.* 1998).

For amplifying the small displacement of the lead zirconate titanate (PZT) film and generating angular displacement of the mirror, the micromirrors are frequently combined with adapted mechanisms. **Figure 36** shows the schematic drawing for generating the larger rotation of a mirror using a pair of piezoelectric unimorph actuator beams. With the driving voltage, the right beam curves downward because of expansion of a PZT film, whereas the left beam bends upward as a result of film contraction with a reverse polarity. These bending motions are converted into a tilting motion of the torsion bar attached at the middle.

Figure 37 is an example of a 1D microscanner (Kobayashi *et al.* 2005b). The cantilever driven by the PZT film deforms the center hinge generating a steep angle at around the torsion bar. The scanner has Pt (0.2 μm)/Ti (0.05 μm)/PZT/Pt (0.2 μm)/Ti (0.05 μm)/SiO_2/Si as a multilayered structure. The PZT film is deposited by chemical solution deposition.

A commercially available solution (PZT-20, Kojundo Chemical Co., Japan) with a Pb:Zr:Ti ratio of 120:52:48 was used as the precursor solution. Coating, drying (120°C), pyrolysis (250°C), and rapid thermal annealing (630°C) were repeated more than 10 times to form a 1.1-μm-thick PZT film (Kobayashi *et al.* 2005a). A scanning angle of 25° at the driving voltage of 20 V is demonstrated at the resonant frequency.

Yasuda *et al.* (2006) report 2D optical scanners. The arc discharged reaction ion plating is developed for depositing a thick PZT film. **Figure 38** shows the image of a scanner. A double gimbal structure is used to tilt the ellipse mirror (1 mm × 2 mm) at the

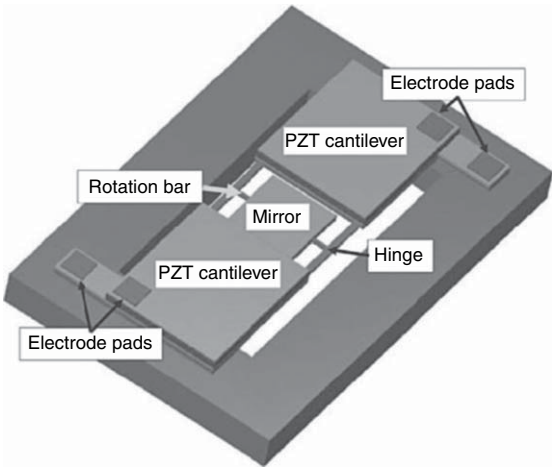

Figure 37 Schematic design of a 1D microscanner. The 50-μm-wide rotation bars, the hinges and the lead zirconate titanate (PZT) cantilevers (1.5-mm-long × 1.7-mm-wide) support the square mirror (1 mm × 1 mm). center two-dimensionally. The inner set of short torsion bars and small U-shaped unimorph actuators is used for the fast motion of the mirror around the *x*-axis. A slow scan around the *y*-axis is made using the outer set of long torsion bars and larger U-shaped actuators.

3.01.5.1.3 Thermal actuators

Although thermal actuators consume more power and have a lower bandwidth (determined by thermal time constants), they can generate a larger force. The fabrication is generally simple and their structure allows easy integration. **Figure 39** shows a well-designed micromirror with the cantilever beams (Schweizer *et al.* 1999). The mirror is attached to the end of two unimorph cantilever beams that are thermally actuated (Schweizer *et al.* 2000). **Figure 39** shows the state at the rest position. With the bending using the residual stress, the mirror is reversed as the initial condition. The unimorph cantilever consists of a metal film (Cr) and SiO_2 layers. The cantilever bends upward. The residual film stresses (the tensile stress in the metal layer and the compressive stress in the oxide) can control the rest position θ_{initial} setting the mirror at an out-of-plane position.

The freestanding cantilever can be resistively heated with an electric current through the conductive layer. The electrical current flows forth on one

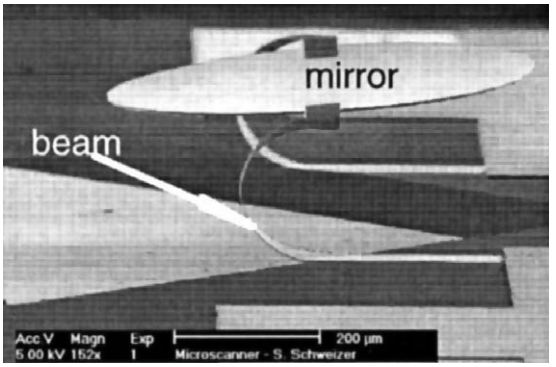

Figure 39 The image of the lateral fixed beams design: mirrors 600 μm × 600 μm, beam lengths 300 μm and thickness 5 μm, and resonance frequency 450 Hz. The mirror swings with the bending of the cantilever beams. (Source: Schweizer S, Calmes S, Laudon M, Renauld Ph 1999 Thermally actuated optical microscanner with large angle and low consumption. *Sens. Actuators* **76**, 470–7.)

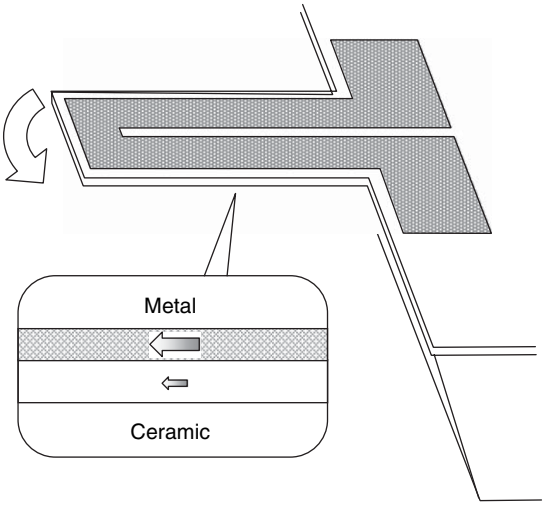

Figure 40 Schematic drawing for illustrating the unimorph cantilever with the thermal actuation. With the increase of the temperature, the cantilever bends downward due to the larger extension of the metal layer compare to the ceramic layer (e.g., oxide).

beam and back on the other. The temperature increase induces the thermal expansion.

$$\varepsilon = \alpha \cdot \Delta T \quad [22]$$

$$\sigma = E\varepsilon = E\alpha \cdot \Delta T \quad [23]$$

Because the stresses generated by thermal expansion are large, whereas the displacements are small, the mechanism amplifying the displacement is a good combination. Unimorph or bimorph structures are usually used. Figure 40 illustrates the situation inside the unimorph cantilever. The materials are selected for obtaining a large difference of α between two layers, as the difference of thermal expansion between the two layers generates the bending motion. The combination of a metal and a ceramic are popular (e.g., Si/Al, SiN/Al). Because the driving force is proportional to ΔT, the temperature control of the device is important for the accurate rotation angle.

Figure 41 shows the scan amplitude of the mirror as a function of the excitation frequency. The onset of thermal cutoff occurs at ~20 Hz and the resonance

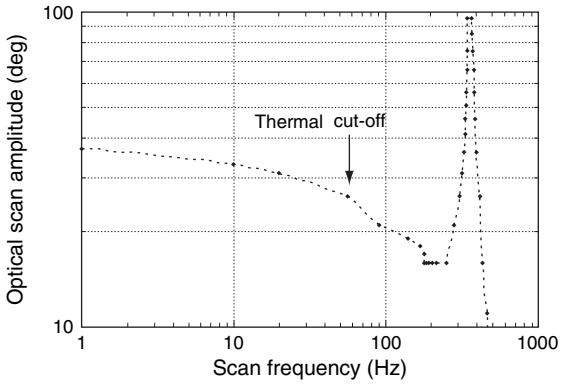

Figure 41 Frequency response of a 500 μm × 800 μm micromirror with a 300-μm-long beam. (Source: Schweizer S, Calmes S, Laudon M, Renauld Ph 1999 Thermally actuated optical microscanner with large angle and low consumption. *Sens. Actuators* **76**, 470–7.)

frequency is 30 Hz. Note that the device can be excited at its mechanical resonance frequency over the thermal bandwidth. The quality factor Q corresponding to the energy loss of the resonator was about 20–40 for various mirror designs.

Figure 42 shows another thermal actuator demonstrating the integration with the bulk 3D micro-optical bench (Sasaki and Yamaguchi 2003b). The V-shaped cantilever consists of doped poly-Si, SiN, and backside Al layers. The cantilever deflects upward with the temperature increase. A skew micromirror at the free end of the cantilever is scanned. The region on the left is the terrace and the laser diode (LD) chip mounted facing the scanning mirror. The region on the right is the thermal actuator. **Figure 42(a)** and **42(b)** shows the thermal actuator under resting and driving conditions, respectively. In **Figure 42(b)**, the bright spot of LD emission is observed on the scanning mirror.

3.01.5.1.4 Magnetic actuators

As described in Section 3.01.3, the mirror size has to be large for obtaining fine spots. The mirror size can be a few millimeters. The electromagnetic force becomes an attractive candidate for the actuation. The electromagnetic driving is adopted in some promising products as described later. Papers on the electromagnetic scanner can be found from 1991 onwards (Wagner *et al.* 1991). **Figure 43(a)** shows a schematic drawing for explaining torque generation. A one-axis mirror is shown for simplicity. The basic design consists of an integrated planar coil on a micromirror plate. **Figure 43(b)** is an example of a moving coil (Sasaki and Miura 2002). When placed in an external field of magnetic flux densities $\boldsymbol{B}$, applied in directions perpendicular to torsion bars, the current $\boldsymbol{I}$ in the driving coil generates paired Lorentz forces $\boldsymbol{F} = \boldsymbol{i} \times \boldsymbol{B}$. The paired forces are generated on the coil. The pure torque is obtained for driving the mirror. The rotation center is at the center axis of the coil. The electromagnetic force and the driving torque are proportional to the current $\boldsymbol{I}$. This linearity is advantageous for operation. After the mirror tilts, the restoring forces of the torsion bars are balanced with the corresponding rotational torques. Because the torsion bar restoring torque is nearly linear against the rotation angle, the system is stable. By controlling the magnitudes of the currents $\boldsymbol{I}$, the tilt angle control is stably obtained.

A series of micromirrors are commercially available from Nippon Signal Co. Ltd. **Figure 44** shows a photograph of a 2D micromirror. **Table 2** shows the performance of the micromirror. The tilt angle is in the ±10° range and the resonance frequency is a few kilohertz. The mirror size strongly relates to the performance of the scanner (the details are described later). The mirror is processed from single c-Si, as the energy loss can be suppressed.

3.01.5.2 Mirror Motions

3.01.5.2.1 Rotation – one and two axes

Ever since the development of the micromirror by Petersen (1980), a mirror plate tilting around the torsional support is the standard design for a micromirror. The mirror with a two-axis rotation is the extension of the design shown in **Figures 19** and **38**. In addition to the simple mirror rotation, various movements can be obtained in the micromirror device. Here, the micromirrors are classified from the viewpoint of mirror motion. The mirror motion is closely related to the performance and the function of the optical system.

3.01.5.2.2 Linear motion

The linear mirror movement can realize the crossbar 2×2 optical switch (Marxer *et al.* 1997). **Figure 45** is an illustration for explaining the mirror motion. Two paired optical fibers with sharpened ends (20 μm in diameter) are placed face to face (separation between fiber ends is 50 μm). Because the propagating beam has a small diameter, the linear displacement of ~24 μm (estimated from the image) changes the optical propagation condition dramatically. **Figure 45(a)** is the bar state, and **Figure 45(b)** is the cross state. **Figure 46** shows a device image. The micromirror is at the end of the moving part of the lateral comb-drive actuator. Compared to the devices using waveguides, the switching function does not depend on the wavelength, which is the common feature of the mechanical principle. This device uses the etched sidewall as the reflecting mirror. The thickness of the device Si layer is 75 μm. The core height of the standard single-mode fiber is nearl the top region ($\sim 62.5 \pm 5$ μm) of the sidewall. The gold is deposited for a proper reflectivity of the mirror.

This device opened the new area called SOI-MEMS demonstrated by the group from the University of Neuchatel in *c.* 1997 (before the development of SVC). This 2×2 optical switch was later commercialized by Sercalo Microtechnology Ltd., a

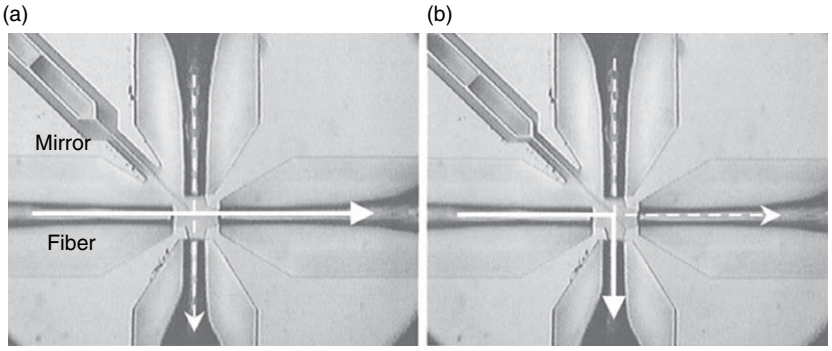

Figure 45 Linear motion of the shutter realizing 2 × 2 optical switch: (a) bar state and (b) cross state. venture company (Noell *et al.* 2002). The fabrication process is simplified to a single patterning and one etching step. The critical process step is the DRIE that determines the structure itself and surface roughness of the sidewalls. Four optical fibers are attached to the device. The mechanical guiding structure of U-grooves and the leaf springs to hold the fiber are integrated to guarantee alignment accuracy. To enhance optical performance and minimize loss, all the optical components are completely surrounded by a refractive index matching fluid. The index step between the fiber end faces and the ambient is decreased, and the divergence of the freely propagating light in the ambient and hence the beam diameter is decreased. The coupling efficiency between the fibers is increased. The performance of the devices shown in the homepage of Sercalo Microtechnology Ltd. includes repeatability of <0.01 dB, a response time of <1 ms, a cycling rate of >500 Hz, an insertion loss of <0.9 dB (0.3–0.5 dB in the paper), and the crosstalk of <50 dB (−70 dB in the paper) (Noell *et al.* 2002).

For using the etched sidewall as the mirror, the surface roughness determines the optical performance. Even a small degree of roughness produces measurable light scatter. For a gently sloped surface with a Gaussian distribution of the surface height, the amount of scattered light is estimated from the rms surface roughness σ using the relationship

$$\frac{P_{\text{scat}}}{P_{\text{tot}}} = 1 - \exp\left(-\left(\frac{4\pi\sigma\cos\theta_{\text{i}}}{\lambda}\right)^2\right) \qquad [24]$$

where P_{scat} is the flux of light scattered away from the specific direction, P_{tot} is the total reflected flux, and θ_{i} is the incidence angle.

Figure 47 shows the sidewall surface reported (Marxer *et al.* 1997). The surface quality is found to be best from the top surface to an etched depth of 30 μm. Between the 30- and 45-μm etch depth, vertical notches are visible; finally, between the 45- and 75-μm etch depth, the surface quality is degraded with a surface roughness of up to 1000 nm. The area for light reflection is selected to be the top region. The above features depend on the nature of the plasma etching and the performance of the etching system. The repeated pattern in the side profile is called scalloping. This is the trace of the cyclic etching and deposition steps (Bosch process).

There are researches for smoothening this scalloping. Decreasing the period of this etching/deposition is one method for decreasing the surface roughness of this scalloping (Johnson *et al.* 2005). The

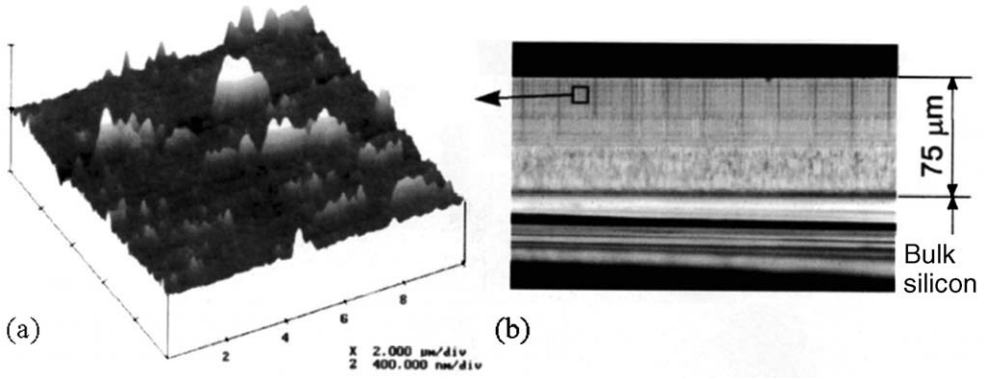

Figure 47 Surface profile of (a) magnified and (b) large area of etched sidewall used as the mirror. (Source: Marxer C, Thio C, Gretillat M-A, de Rooij N F, Battig R, Anthamatten O, Valk B, Vogel P 1997 Vertical mirrors fabricated by deep reactive ion etching for fiber-optic switching applications. *J. Microelectromech. Syst.* **6(3)**, 277–85.)

switching time is usually limited by the time constant of the mass flow controller. The bypass or exhaust gas lines in the etching system can overcome this limit maintaining the pressure of the gas. When the sidewall can fit to a specific crystal orientation (e.g., {110} or {111} surfaces), combining anisotropic wet etching is effective for smoothening the surface. Etchants such as ethylene diamine pyrocatechol (EDP) or KOH have been tried (Ezoe *et al.* 2006, Sasaki *et al.* 2003a). For the arbitrary surfaces, hydrogen annealing can be applied to smoothen or round the surface by facilitating the migration of Si atoms (Lee *et al.* 2005).

Another linear motion consists in lifting the micromirror. **Figure 48** is a device for generating the large piston motion (Jain *et al.* 2005). Its application is the optical coherence tomography (OCT). OCT is a nondestructive imaging that produces high-resolution cross-sectional images of biological tissue. The core of this OCT system is a Michelson interferometer in which a broadband light beam is split into a reference arm and a measuring arm. The light beams from the reference mirror and the sample interfere with each other. The interference, which occurs only when the optical path difference is within the coherence length of the light source, is picked up by the photodetector. The coherence length determines the axial resolution. The axial linear motion range of the reference mirror generates cross-sectional images. An imaging depth of ~2 mm in tissue samples is typically required, so the optical delay line in the reference arm must perform axial scanning by a few millimeters.

Figure 48 shows a mirror design. The mirror plate is attached to a rigid frame supported by Al/

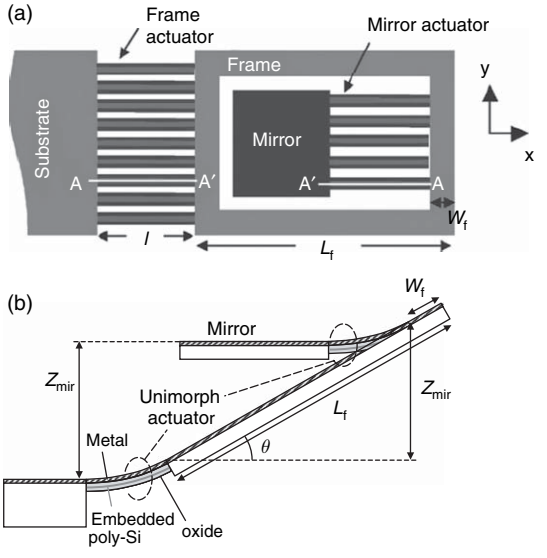

Figure 48 Schematic design of the micromirror generating a large vertical displacement: (a) top view and (b) cross-sectional schematic view of the device. (Source: Jain A, Qu H, Todd S, Xie H 2005 A thermal bimorph micromirror with large bi-directional and vertical actuation. *Sens. Actuators A Phys* **122**, 9–15.)

SiO_2 unimorph beams on the right side, where the thermal actuator is embedded. The rigid frame is connected to the substrate by another set of unimorph beams on the right side. This second set of unimorph beams actuates the frame. The mirror is actuated with two sets of unimorph actuators having an identical design. After the mirror is released, the bimorph beams curl up due to the tensile stress in the upper Al layer and the compressive stress in the lower SiO_2 layer, as illustrated in **Figure 48**. With the curls of the two sets of actuators, the tilt motions

compensate each other resulting in a zero tilt. At the initial state, the mirror plate elevates by Z_{mir}, which can be expressed by

$$Z_{mir} = (L_f - W_f)\sin\theta$$

where L_f and W_f are the length and beam width of the frame, respectively, and θ is the initial tilt angle of the frame. Because the frame dimensions are $L_f = 0.5$ mm, $W_f = 40\,\mu$m, and $\theta = 17°$, Z_{mir} is 135 μm. Because of thermal actuation, the mirror moves downward. The mirror moves vertically keeping its angular direction canceling the tilting motion of the two sets of actuator. The demonstrated piston motion is 200 μm.

3.01.5.2.3 Compound motions

Combining the rotation and the vertical movements of the mirror enables adjustment of the phase of the reflected light, which will be effective in an arrayed mirror like a grating (Krishnamoorthy *et al.* 2002). **Figure 49** shows another mirror device image (Lee *et al.* 2004). **Figure 50** is the schematic cross section illustrating the driving method and the mirror movement. Electrode 5 (the movable comb) is connected to the ground. Bidirectional rotation is achieved by applying a driving voltage on electrodes 1 and 4 or 2 and 3. Pure piston motion is achieved by applying the same voltage on electrodes 1 and 2. The static mirror demonstrates rotation of ±4.6° with 155 V driving voltage. The maximum static vertical movement is −7.8 μm with 110 V.

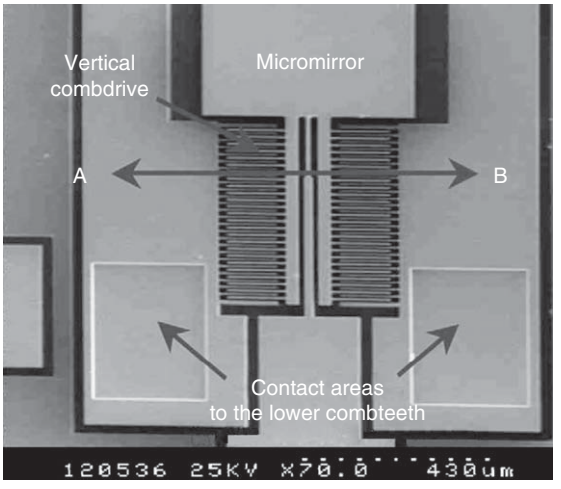

Figure 49 Image of the micromirror that can realize piston motion and rotation. (Source: Lee D, Krishnamoorthy U, Yu K, Solgaard O 2004 Single-crystalline silicon micrometers actuated by self-aligned vertical electrostatic combdrives with piston-motion and rotation capability. *Sensors and Actuators* **A114**, 423–8.)

When the accurate movement of the piston and the tilting motion of the micromirror can be realized as a large number of mirror arrays, the mirror array can work as a phase-shift mask. When the relative displacement between the neighboring mirrors is $\lambda/4$, the reflected lights interfere, canceling each other and thereby generating the dark field. This generates the higher resolution of the pattern. The maskless lithography with the high-end performance can be considered as an application (Martinsson *et al.* (2005) . The motivation for using optical maskless lithography is to decrease the mask cost, as the photomask set is prohibitively expensive for low-volume integrated circuit applications. The array of micromirrors is used as a reticle. The phase of the reflected light is controlled by shifting or tilting of the mirror. The function of the phase-shift mask is realized (Ljungblad *et al.* 2005). The reflected image from the micromirrors is projected and demagnified onto the wafer. The movement accuracy and the mirror-to-mirror uniformity are tightly required. Calibration and correction are carried out at present in the SIGMA7300 commercialized mask writer (Micronic Laser Systems AB).

The application of the tunable external cavity diode lasers requires a different mirror motion. This device will be useful in spectroscopy and especially in optical networks. Continuous wavelength tuning is important for wavelength-division-multiplexed (WDM) systems. Widely tunable lasers can be used as the sparing transponders in WDM systems. The ultimate goal is replacing fixed wavelength-distributed feedback (DFB) lasers with tunable ones (Bruce and Riezenman 2002). DFB lasers are stable but difficult to tune over a wide range. Valuable features like wavelength routing or dynamic provisioning to be incorporated into long-haul or metro-optical networks can be realized (Park *et al.* 2003). The continuous tuning of the wavelength is important, as mode hops mean the existence of an unusable wavelength. Among many tuning methods, the external cavity diode lasers (ECLs) offer advantages such as wide tuning range, high output power, and narrow line width. Although there have been tunable lasers using the bulk mechanism (Lazar *et al.* 2004), telecommunication needs small lasers with high yield. The micromirror is attractive because of its smaller size, larger shock resistance, lower power consumption, and potentially lower cost.

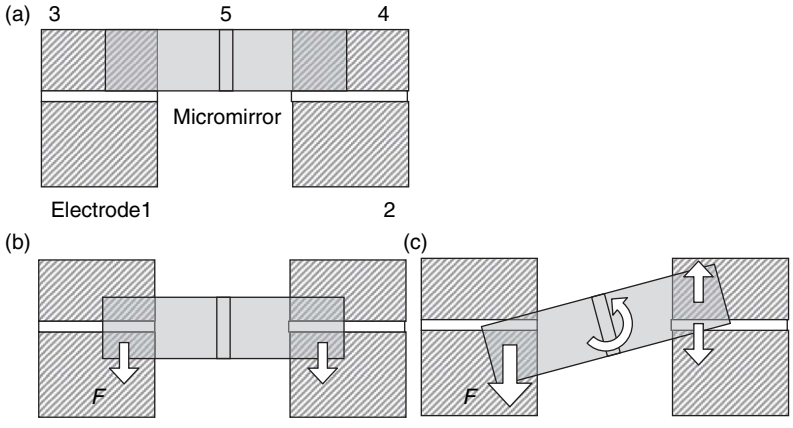

Figure 50 (a) Schematic cross section along AB (in **Figure 49**) without actuation; (b) pure piston motion is achieved by applying the same voltage to electrodes 1 and 2; and (c) electrodes 3 and 4 add actuation control in the adjustments of tilt and piston motion.

Figure 51(a) shows the schematic setup of ECL developed in Iolon Inc., which was acquired by Coherent Inc. in November 2005 (Anthon *et al.* 2002, Jerman *et al.* 2002). The Littman configuration has a folded resonator with a grating placed between the semiconductor amplifier and the resonator end mirrors. The grating is fixed and the mirror is moved. The first-order diffraction beam is incident on the resonator end mirror. The diffracted beam having the wavelength corresponding with the angle normal to the mirror is reflected back to the grating and to the amplifier. The grating provides a wavelength filter that selects a resonator mode whose exact frequency is determined by the cavity length. The zero-order reflection beam from the grating or the emission from the other end of the semiconductor amplifier become the output. The gain medium of the semiconductor amplifier is based on a high-power, 1.55-μm InGaAsP/InP multiple quantum well LD. The gain bandwidth is >80 nm, while the external cavity mode spacing is only 0.16 nm. A large number of external cavity modes are supported by the diode gain medium.

In addition to controlling the diffraction angle for the grating wavelength filter, it is necessary that the phase of the light in the cavity (the longitudinal modes of the cavity relating to the cavity length) be controlled for eliminating mode hops. For realizing wide continuous tuning, the pivot point is usually set at the specific point (near to the semiconductor amplifier). The mirror angle and cavity length are changed simultaneously so that an equal integer number of waves are included in the cavity.

Figure 51(b) shows the perspective view. The laser is tuned by applying voltage to the comb elements of the electrostatic actuator to produce an electrostatic force that rotates the mirror around a virtual pivot. The suspensions and comb fingers are not parallel to each other and have arch shapes. The angular range of the actuator is up to ±2.8° at ∼150 V, for tuning over a wavelength range of up to 42 nm. As shown in the inset photograph, the resonator end mirror is mounted on the microactuator. This mirror is prepared individually. The process for the mirror with high reflectivity can be optimized without the process restriction for combining the fabrication with the actuator. In addition to the part for mounting a mirror, there is another moving part. Two counter-rotating parts coupled by linkages through a flexural pivot give a zero-moment actuation.

Ishimori *et al.* (2007) reported another mirror design for controlling the virtual pivot position electrically. The mirror device has two parallel rotation axes for achieving mirror rotations and linear translation. **Figure 52** shows a schematic diagram of the external cavity diode laser using the mirror with two parallel rotation axes. The movable frame is suspended by torsion bars parallel to those of the mirror. To generate the translation, the micromirror is driven to the opposite rotational direction at a same angle around the two rotational axes. **Figure 53** shows the fabricated mirror. Two pairs of comb-drive actuators are included to enable an independent excitation of the actuators.

3.01.5.2.4 Mirror deformation

The deformable mirror is useful for controlling the wavefront. The dynamic focus control will realize the functions of field flattening or fine focus

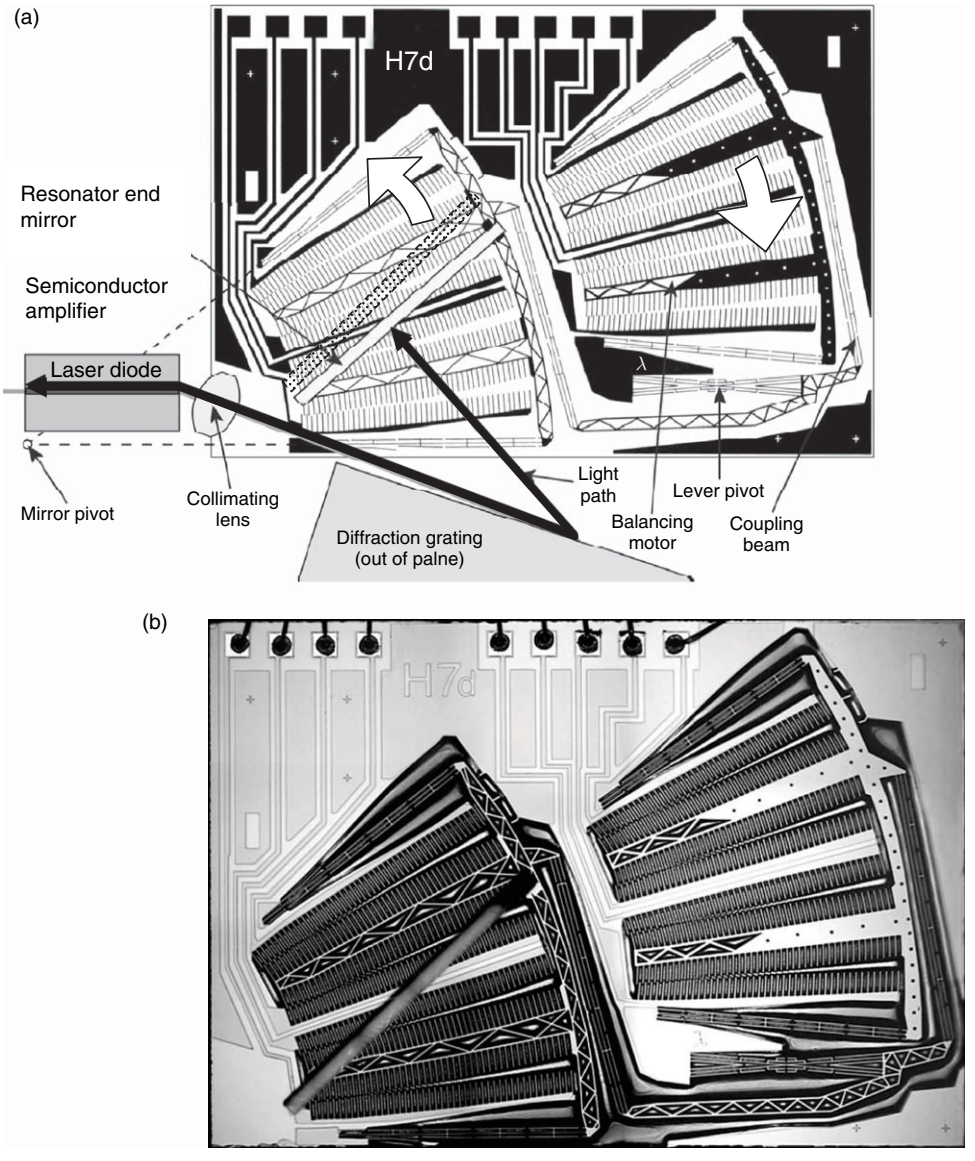

Figure 51 (a) Schematic drawing of external cavity laser diode with a balanced virtual pivot actuator. (b) Simplified perspective view with the inset photograph of actuator die after the attachment of the externally fabricated mirror. control. **Figure 54** shows an example with variable focus membrane mirrors (Shao *et al.* 2004) integrated with a two-axis mirror. **Figure 54(a)** shows the cross-sectional view. A deformable SiN membrane is supported on a gimbal structure. **Figure 54(b)** shows the whole view of a mirror. The thickness of the center mirror is 0.9 μm. The low-stress low-pressure chemical vapor density (LPCVD) nitride membrane is used. A 100-nm chrome–gold layer on top of the membrane serves as the mirror surface.

Figure 55 shows the line profiles of the deformable membrane that realizes the flat surface. With no applied actuation voltage, the maximum surface fluctuation is <90 nm peak to peak across the membrane. The solid lines are the measured surface profile and the dotted lines are the parabolic curve fits. The depth of the air gap between the membrane and the Si substrate is ~12 μm. The center displacement is 3.5 μm at 240 V. The effective focal length f_{mir} of the mirror is given by

$$f_{mir} = D^2/16\delta \qquad [25]$$

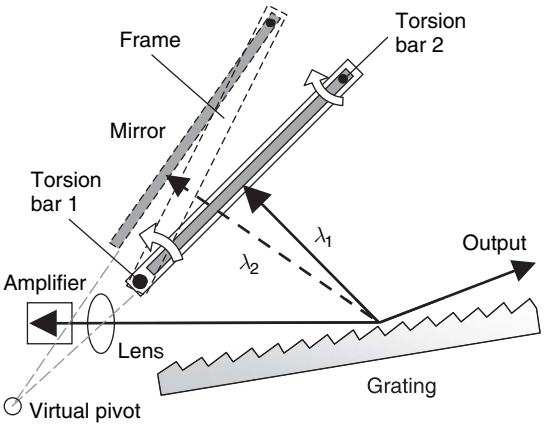

Figure 52 Illustration of the external cavity diode laser having Littman configuration and the micromirror movement.

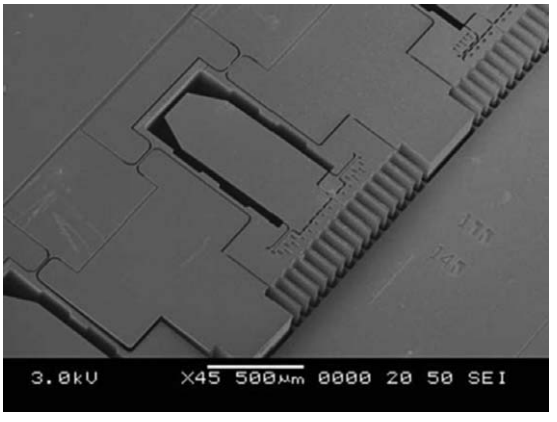

Figure 53 Fabricated micromirror with parallel two rotational axes.

where D (=700 µm) is the diameter of the mirror and δ is the center displacement. The demonstrated range of the focal lengths is from $f_{mir} = \infty$ with no displacement to $f_{mir} = 8.8$ mm with $\delta = 3.5$ µm.

The region of adaptive optics deals with the control of the further complicated wavefront. The final purpose is to increase the resolution of optical systems and to enhance fuzzy images by active compensation of phase aberrations. Aberrations are caused by imperfections of elements (e.g., mirrors deformed by mechanical or thermal stresses) and external conditions (e.g., turbulence of the ambient media). The active compensation of aberrations becomes important for large-aperture high-resolution systems, and for laser systems sensitive to energy losses. The principles of resolution enhancement have been applied successfully to large-aperture ground-based telescope systems, where the high cost of deformable mirror can be allowed. Passing through the atmosphere, the light wave is affected by fluctuations in density of the atmosphere due to turbulence, distorting the front of the wave. A blurred image is produced. To compensate for this distortion, the wavefront sensor and the deformable mirror are introduced. One inhibiting factor is the expense of conventionally manufactured deformable mirrors, which typically cost about $1000 per actuator (Xinetics Inc., according to Doble *et al.* 2002). Microfabrication can increase the number of actuators, decreasing the cost per actuator. Many applications (e.g., retinal imaging in ophthalmology, confocal microscopy, ultrashort laser pulse shaping (Bartels *et al.* 2000), and machine vision) can be realistic.

A group from Boston University (Bifano *et al.* 1997, Mali *et al.* 1997) reported a single compliant poly-Si membrane supported by multiple attachments to an

underlying array of electrostatic actuators as shown in Figure 56. The micromirror based on the surface micromachining is now manufactured by Boston Micromachines Corporation. The mirror consists of 10×10 arrays of electrostatic actuators with the spacing of 300 μm supporting a thin-film continuous or semicontinuous mirror membrane via posts. Two types of deformable mirrors are reported. Figure 56(a) is a continuous membrane mirror with a fill factor of 99.7%. Figure 56(b) shows a continuous membrane with interpost cuts introduced into the mirror surface in order to relieve stress in the mirror membrane. The fill factor is 98.6%.

A group from Delft University reported a deformable mirror display consisting of a 10 mm × 10 mm SiN membrane fixed on another wafer with a 2D array of electrodes (Vdovin and Middelhoek 1995, Vdovin and Sarro 1994). OKO Technologies now produces membrane mirrors. The membrane is covered by Al and electrostatically deflected at the location of individual pixels. Figure 57 shows the schematic drawing. The membrane is thin (0.5–10 μm thick) and can have diameters of up to 50 mm. Voltages applied between the membrane and the individual electrode result in the deformation of the membrane. Combinations of voltages applied to different electrodes can form specific shapes on the membrane surface. Microfabrication realizes many electrodes with high density. The number of electrodes and its area are balanced with the amplitude of response of a single individual electrode. The feature of zero-hysteresis actuation enables the feed-forward control after preliminary calibration. Figure 58 shows a typical view of the deformable mirror.

An application of retinal imaging is introduced here. The micromirror designed by Boston Micromachines is applied for the human eye (Doble *et al.* 2002). The wavefront is corrected by modifying the optical phase profile. A wavefront sensor is coupled with the deformable mirror in a feedback loop. The wavefront is flattened with the conjugated phase profile controlling the optical path difference controlled by the mirror deformation. A 6.8-mm pupil is corrected for retinal imaging, and the central 6-mm pupil is used for retinal imaging. This eliminates edge effects that might disturb the wavefront. Figure 59 shows the retinal mosaic images before and after the correction, taken at 1° eccentricity. The field of view is 0.25°, corresponding to 75 μm on the retina. On examining the image power spectra, there was a fourfold increase in the relative power at the cone spatial frequency.

3.01.6 Applications and Specifications

Here, some products are overviewed, analyzing specifications and showing chosen technical solutions. This section aims in clarifying the advantages as well as the disadvantages of the micromirrors to

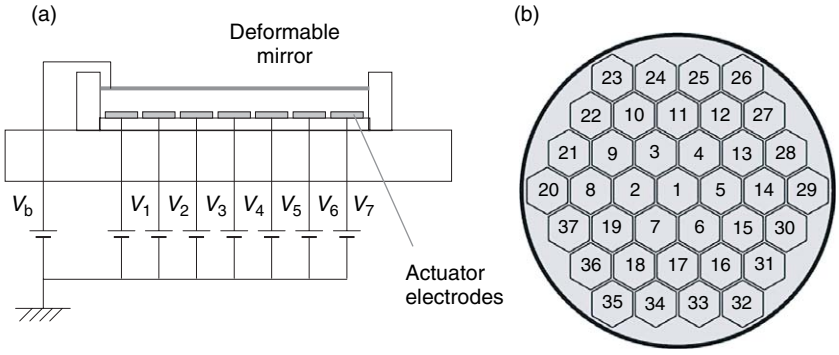

Figure 57 (a) Schematic drawing of deformable mirror and (b) the layout of driving electrodes. (Photo courtesy: Flexible Optical B.V. (aka OKO Technologies).)

reach specifications. At first, the bulk mirror devices will be discussed as reference.

3.01.6.1 Bulk Mirror Devices

3.01.6.1.1 Polygon mirror

Figure 60 shows the typical polygon mirror. Applications include printer, facsimile, and copying. Table 3 lists the specifications of Sanyo LS7230 or LS3440. The actuator is the brushless motor driving at 24 V for example. The rotating motion of the motor stabilizes the scanning speed. Let us assume that for a hexagonal prism, the optical scan is six times of the motor rotation speed. Optical rotation speed can reach several thousand revolutions per second. The frequency corresponds to 2–4 kHz. Because one side of the surface of the hexagon generates a rotation of 60°, the optical scan angle of 120° is the maximum value. Compared to the polygon mirrors, the micromirror gives the reflecting surface

placed at the same level with the rotation axis, allowing a steady reflecting point in geometry. The resonant frequency on the order of a few kilohertz is achievable. The scanning angle of the micromirror is relatively smaller.

3.01.6.1.2 Galvanometric mirror

Figure 61 shows galvanometric mirrors of another popular bulk mirror. These mirrors have the axis of rotation lying on the plane of the reflecting surface. The applications are, for example, optical processing (like rapid prototyping), machining of laser ablation or welding, laser marking or patterning, and optical metrology. For creating 2D scanning, two galvanometric mirrors are usually used. The biaxial micromirror can reduce the size simplifying the system. Table 4 lists typical specifications. The scanning frequency is relatively low. The settling time is ~1 ms. The rotation angle is about ±10. The mirror is exchangeable, and its size is on the order of 10 mm having a thickness of 3–7 mm. The tilt platforms are equipped with rotary encoder, capacitance, or strain gauge sensors. The rotation angle of the mirror is measured enabling the closed-loop control generating high-accuracy and repeatability scans. The resolution is, for example, 0.33 μrad, and the repeating accuracy is 10 μrad (0.0006°).

3.01.6.2 Scanning Performance of Micromirror

Consider the micromirror having a typical gimbal design as shown in Figure 62. Independent of the driving method, the resonant frequency is decided by the balance between the spring constant of the torsion bars and the moment of inertia of the micromirror. The rotational spring constant k_θ of two torsion bars having a rectangular cross section is expressed as follows:

$$k_\theta \approx 2\frac{Gwt^3}{3l}\left\{1-\frac{192}{\pi^5}\frac{t}{w}\tanh\left(\frac{\pi w}{2t}\right)\right\} \qquad [26]$$

where G is the shear modulus of the torsion bar, l is the length of the torsion bar, and w and t are the width and the thickness of torsion bars, respectively, supposing the relation $t < w$. The moment of inertia of the micromirror can be expressed as follows. Here, the inertia of the torsion bar is neglected as the torsion bar is usually small compared to the mirror.

$$I \approx 2\int_0^L \rho x^2 wtW\,\mathrm{d}x = \frac{2}{3}\rho wtWL^3$$

where ρ is the density of the mirror material and W and L are the width and half-length of the mirror. The mirror is supposed to be filled with uniform material. Using these relations, the resonant frequency f_r can be expressed as follows:

$$f_r \approx \frac{1}{2\pi}\sqrt{\frac{k_\theta}{I}} = \frac{1}{2\pi}\sqrt{\frac{Gwt^2}{\rho WlL^3}}\sqrt{1-\frac{192}{\pi^5}\frac{t}{w}\tanh\left(\frac{\pi w}{2t}\right)} \qquad [27]$$

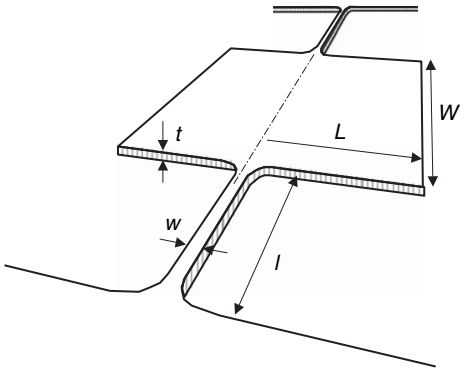

Figure 62 Schematic drawing of the typical micromirror for discussion.

Because the material used is usually Si, the resonant frequency is decided by the sizes of the torsion bar and the mirror. For increasing the resonant frequency, the larger spring constant k_θ and the smaller inertia I are necessary.

According to eqn [7], $x' = (\lambda f/2a)$, the spot diameter is $2x'$. The mirror diameter is necessary for obtaining the smaller spot. If $f = 10$ cm, $\lambda = 500$ nm, and the aiming spot size is 50 μm (corresponding to 508 dpi spot size), the mirror diameter has to be >1 mm. The larger resonant frequency for faster scanning has the trade-off relation with higher resolution due to the increase of inertia (Urey *et al.* 1999a).

3.01.6.3 Confocal Microscope

Olympus Corp. uses two scanners in their confocal microscope, which illuminates the specimen with a small optical spot. The image is obtained by scanning a spot two-dimensionally. **Figure 63** shows the optical setup. One micromirror is for vertical and the

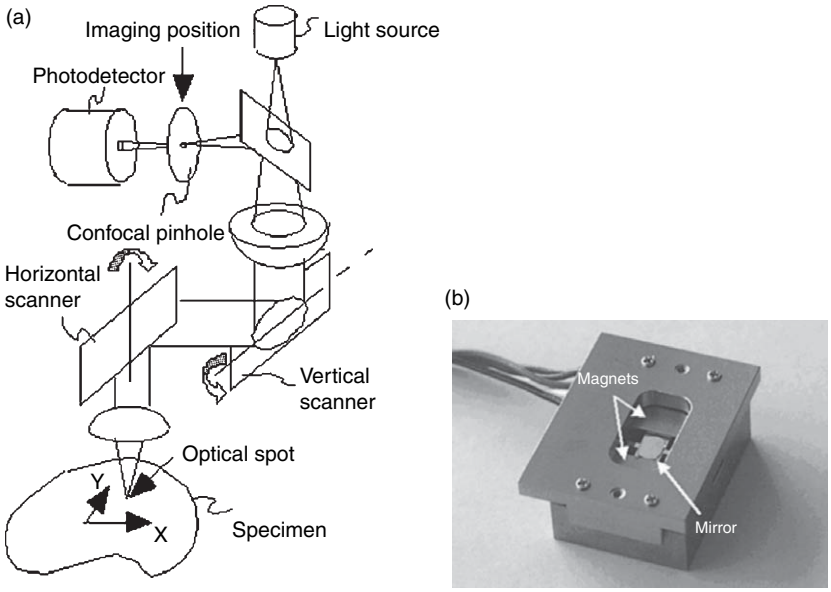

Figure 63 (a) Optical setup of confocal microscope and (b) photograph of the assembled scanner using micromirror. (Source: Miyajima H, Murakami K, Katashiro M 2004 MEMS optical scanners for microscopes. *IEEE J. Selected Topics in Quantum Electronics*, **10(3)**, 514–27.)

other is for horizontal scanning. The horizontal scanning is the fast scan. The micromirror is designed so that it can be installed into the existing product. **Table 5** shows the requirements for the horizontal scanner. The mirror size is >4.2 mm × 3.0 mm because the millimeter order optical beam size is used in the conventional microscope. The scan angle should be interchangeable between 2.1° and 16° to cover one to six times the optical zoom. Although higher resonant frequency is better for fast image acquisition, the scanning speed of ~4 kHz is still a moderate task.

A mirror thickness of 300 μm is required for maintaining its flatness against the residual stress of the coil films (7-μm-thick Cu-electroplated driving coil) on the mirror plate and dynamic deformation (described later). The development of a horizontal scanner (fast scanning) starts from the electromagnetic scanner using polyimide hingers (Miyajima *et al.* 2001). Later, the polyimide hinge is replaced by the c-Si hinge (Miyajima *et al.* 2003). The trade-off of the higher resonant frequency and sufficient scan angle (inversely proportional to the hinge stiffness k_θ in eqn [27]) is solved with the higher Q factor obtained by the c-Si hinge. The energy loss can be reduced. The scanner is equipped in the confocal microscope OLS1200 (renamed from OLS1100 as the micromirror is installed).

Table 5 Specifications of horizontal scanner for the confocal microscope

Mirror size (mm)	>4.2 × 3.0
Resonant frequency (Hz)	3900–4100
Scan angle (deg)	2.1–16 (changeable)
Scan angle fluctuation (%)	<0.1
Mirror flatness (nm peak-to-valley)	<244
Mirror reflectivity (%)	>85 ($\lambda = 488-633$ nm)

3.01.6.4 Laser Display

The laser display is a natural idea as an application of the micromirror and has been researched widely. The bright light spot is two-dimensionally scanned on a screen to create an image. Raster scanning systems combined with a modulating light source generates a 2D image. The advantages of this architecture include the absence of pixel boundaries, the ability to synchronize the system to a wide ratio of video input signals, and the ability to reformat image aspect ratios. **Table 6** lists the requirements for various video formats. The horizontal line rate is for fast scan. This value somewhat depends on the optical system supposed (Urey 2004). The vertical mirror motion (slow scan) is required to function as a linear ramp. The vertical drive must provide a sufficient torque to allow nonresonant actuation. Note that the resolution of SVC micromirror developed by Conant *et al.* is still 356 pixels, satisfying only the quarter video graphics array (QVGA) format. High-quality extended graphics array (XGA) or high-definition television (HDTV) displays require a higher resolution. The resolution and higher line rate are related to the trade-off. The resolution can be increased only by increasing the size of the mirror (assuming flat mirror surface). As seen from eqn [27], the resonant frequency f_r is proportional to $L^{-3/2}$. θ_{max} is the maximum mechanical scan angle amplitude (from center to peak).

The number of resolvable spots limited by diffraction depends on the relation $\theta_{max}D$, which is the product of scan angle and mirror size. The mirror size D is for overall size (e.g., diameter). This is a defining parameter for resolution in scanning displays. Eqn [20] can be rewritten as follows:

$$\theta_{max} 2a = \frac{NC\lambda}{2} \qquad [28]$$

This is the static relation. For the dynamic operation, the overall scanning angle can be used increasing the number of resolution by double (Urey 1999).

$$N = \frac{4\theta_{max} D}{C\lambda} \qquad [29]$$

Table 6 Requirements to scanners for realizing various display formats

Display format	*QVGA*	*VGA*	*SVGA*	*XGA*	*SXGA*	*UXGA*	*HDTV*

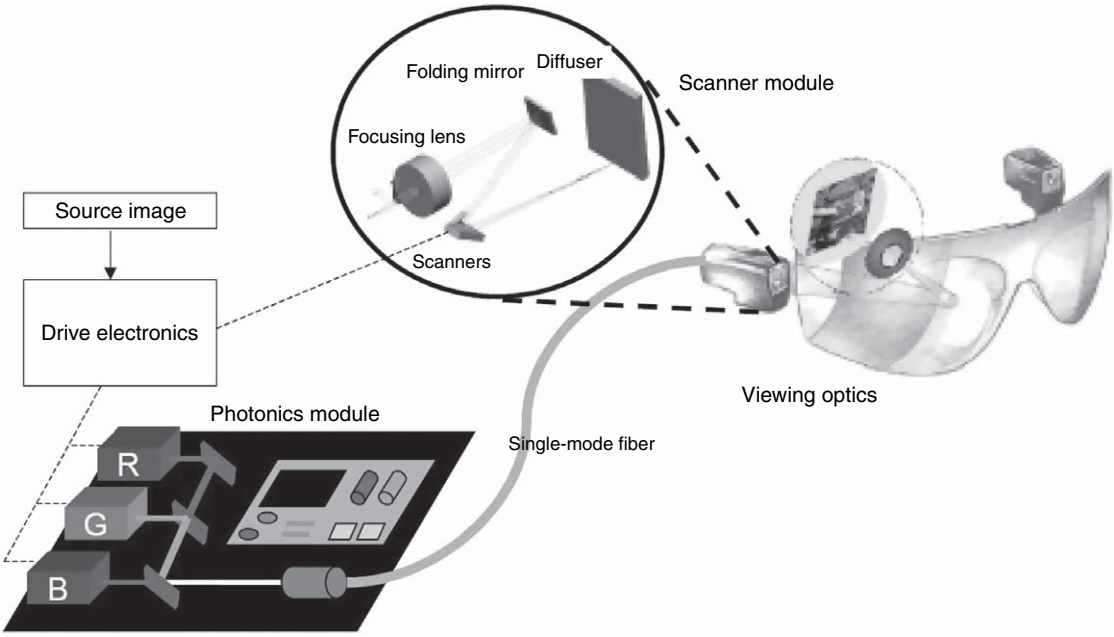

Figure 64 Conceptual drawing of a head-worn display. (Source: Urey H, Nestorovic N, Ng B, Gross A 1999b Optics designs and system MTF for laser scanning displays. *Proc. SPIE* **3689**, 238–48.)

The microscanner is considered to have the potential of opening new markets with regard to some new systems, where the miniaturization advantage matches with the application. An example is a head-worn display where the light beams are scanned directly over the viewer's vision. **Figure 64** shows the conceptual drawing. The beam from the light source is focused onto an intermediate image plane. The position of this focus point is determined by the angle of the scanning mirror, which is placed between the collection optics and the intermediate image plane. Scanning the mirror two-dimensionally, an image is created onto the intermediate image plane. This image is relayed onto the viewer's eye using a set of relay optics. The lens of the eye then focuses the image onto the retina. The net result is that the light from the light source is focused onto the retina of the viewer's eye.

Such virtual retinal display has been explored at the human interface technology laboratory of the University of Washington and Microvision Inc. is currentlyattempting to commercialize it by eliminating the bulky power-hungry panel monitor. The system suits the low-power requirements of mobile applications. One or two micromirrors are required to produce the entire image. Tiny semiconductor lasers for RGB (red, green, and blue) colors are used mixing colors. The display hardware is miniaturized and fits onto an eyeglass frame. This approach has a see-through capability, i.e., the displayed image can be superimposed on a bright external scene. This is advantageous for cockpit displays and in industrial and medical applications. According to Microvision's report, the systems are moving into several industries, including automotive service, to help service technicians keep track of the huge and ever-changing reams of repair data and display it precisely where and when they need it – in the service bay, while they are working on a car. This first-generation system was introduced to auto dealers in early 2004. Technicians may perform repair procedures in less time. The system is built around a lightweight display mounted on a baseball cap or visor. In the current version, a wireless computer with a touch pad control is worn on the belt.

Figure 65 shows the 2005 version of the biaxial microscanner with a mechanical layout (Sprague *et al.* 2005). The electromagnetic driving is adopted. The biaxial scanner architecture eliminates the need for a second scanner and makes the device more compact. The center mirror does not have a coil for escaping the stress, which degrades the mirror flatness.

The biaxial operation is based on superimposing the drive torques for the two scanning directions and apply this torque at 45° relative to the two scan axes, as shown in **Figure 66**. It is possible to excite both scan axes with only one applied drive mechanism. The

Figure 65 The biaxial microscanner. (Photo courtesy: Microvision Inc. http://www.microvision.com.)

scanner mechanism acts as a mechanical filter, separating the superimposed drive torque into its component parts. The frequency response characteristics of the mirror separate the torque components into their respective modal motions. The resonant response modes used are shown in **Figure 67**. Mode 1 is the vertical resonant mode (**Figure 67(a)**) and mode 6 is the horizontal mirror resonant mode (**Figure 67(b)**). Mode 6 includes a counterrotation of the gimbal ring with respect to the mirror. The high Q of mode 6 amplifies the 20-kHz motion to produce high angular deflection. This mode does not respond significantly to the low-frequency components for the vertical scan, so the resulting scan motion is pure sinusoidal motion at the resonant frequency. The frequency components of the applied torque are selected to excite the horizontal mirror resonance (20 kHz). The vertical axis is driven nonresonantly in a sawtooth pattern at the desired display frame rate (e.g., 60 Hz).

3.01.6.5 Digital Micromirror Devices

DMD was invented in 1987 by Dr. L Hornbeck of Texas Instruments (Van Kesel *et al.* 1998). Compared to the scanner driving a single mirror, DMD adopts the method using a large number of micromirrors (integration in number). The number of resolvable spots is decided by the number of mirrors in the array. The factor, which decides the resolution, is different from the case of the laser display. **Figure 68(a)** shows the schematic drawing for explaining image formation. One reflective mirror corresponds to one pixel. Each image of the mirror is projected on the screen using the lens. **Figure 68(b)** shows the case of the laser display. By preparing mirrors that are as many as the number of pixels for the image, the task of each mirror decreases.

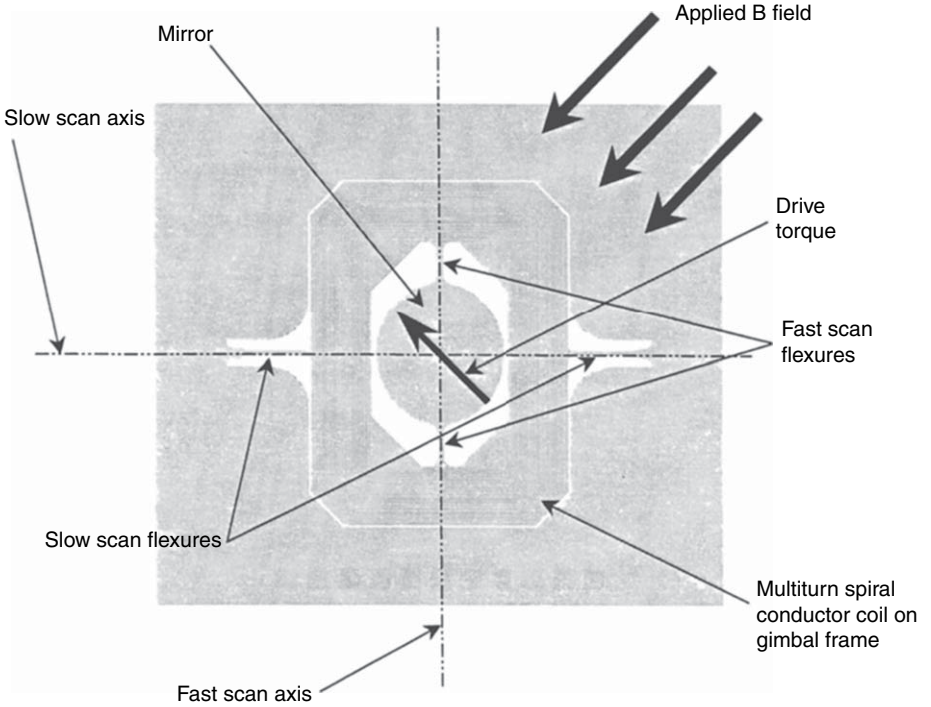

Figure 66 Schematic drawing for explaining the bi-axial operation based on superimposing drive torques for the two scanning directions. (Source: Sprague R, Montague T, Brown D 2005 Bi-axial magnetic drive for scanned beam display mirrors. *Proc. SPIE* **5721**, 1–13.)

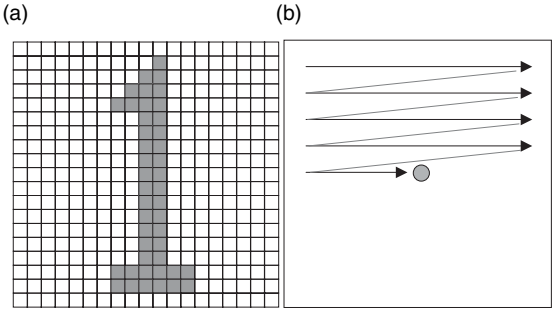

Figure 68 Schematic drawing for illustrating two methods of image generation on a screen using (a) pixel array and (b) raster scanning of the mirror.

The image generation proceeds in parallel. In 1996, 0.7SVGA 800 × 600 mirror array started to be shipped. 0.9SXGA 1280 × 1024, SXGA+ 1400 × 1050, and 1080p 1920 × 1080 mirror arrays were shipped in 2001, 2004, and 2005, respectively.

Figure 69 shows the schematic view of DMD illustrating the two mirrors (Rai-Choudhury 2000). The pitch of the micromirror array is 17 μm (decreased to 13.8 μm in early 2000). Micromirrors are mounted on the static random access memory (SRAM) circuits. This results in the integration of an optical element of the mirror and the electrical circuit of SRAM. The fabrication process is based on that for the established standard complementary metal oxide semiconductor (CMOS) circuit. The change of the process is minimized. A1 structural layers are deposited over organic sacrificial layers. The lower layer of CMOS electronics produces the electrostatic field, which acts on the yoke of the middle mechanical layer. The mirror can tilt along the hinge in the diagonal direction, through electrostatic attraction produced at the air gap under the mirror and on top of the CMOS. The driving method uses the

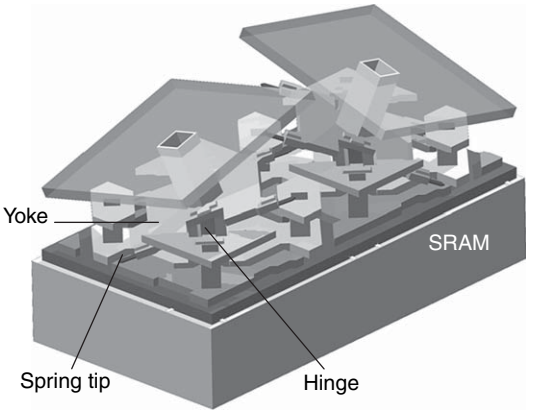

Figure 69 Cutaway view of Digital Micromirror Devices (DMD) showing two mirrors in opposite tilt states. (Photo courtesy: Texas Instruments.)

bounding from the touchdown situation. Mirrors are independently adjustable and can deflect through a tristable range of motion (fundamentally ±10° for the optical function and 0° for the reliability).

The on/off digital operation is the unique characteristic of this device. The use of this operation closely relates to the accuracy of the mirror rotation angle. **Figure 70** shows the optical setup for projecting the image. The illumination light is incident from the right side at around ∼20° against the normal axis of the device. The reflection light from the mirror is on/off controlled by the angle of the mirror. The mirror modulates the light by deflecting the beam in and out of the entrance pupil of the projection lens. Each individual mirror is used in a digital on/off mode. When the mirror is tilted clockwise (in **Figure 70**), the light is in the on state. The reflected light passes through a lens. The mirror image is projected on a screen. When the mirror is in the off state tilted counterclockwise, the light goes into a beam dump. The small mirror size contributes to the fast response decreasing the inertia. This enables time division multiplexing for generating the gray scale of the color. The digital light pulse becomes the analog mixing signal, as the human eye cannot detect the change faster than ∼60 Hz modulation. The response time of the micromirror is <5 μs (>200 kHz). Controlling the duty ratio of the on/off stages, gray scales can be created digitally. The accuracy of the mirror angle does not become an issue.

The color image is accomplished either by rotating the color wheel with one DMD chip (e.g., the

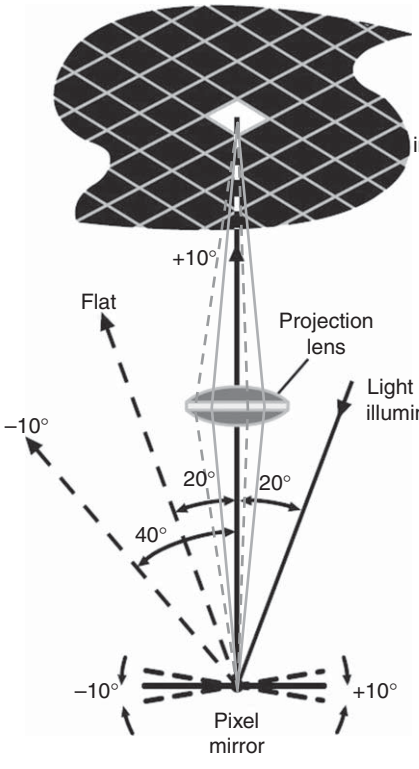

Figure 70 Schematic drawing for illustrating on/off switching action of the mirror. (Source: Van Kesel P F, Hornbeck L J, Meier. R E, Douglass M R 1998 A MEMS-based projection display. *Proc. IEEE* **86(8)**, 1687–704.)

portable system as shown in **Figure 71**) or by using dichroic mirrors and combining the prisms with three DMD chips for the RGB colors. Incoming video signals are turned into a digital code of binary (0 or 1) signals. DMD mirrors tilt accordingly. By passing the accurately modulated light through the projection lens with digital signal processing, a full color image is projected on to the screen. This time division multiplexing for each pixel permits digital creation of color images. The accuracy of the rotation angle of the mirror is greatly relaxed when compared to the analog operation.

In the literature of Texas Instruments, there are detailed discussions on hinge memory (Douglass 2003). **Figure 72** shows the image of micromirrors with hinge memory. Each mirror shows the minute different tilt angle. The first row at the bottom of the image is in the normal flat unbiased state. The device shown in **Figure 72** is still available and used normally. For decreasing hinge memory, a 0° (resting) position is required during the operation. The accuracy of the rotation angle is not guaranteed in each micromirror. Although the exact value of the accuracy of the tilt angle is not found from the documents, the fluctuation of the mirror angle will be a significant percentage of the total mirror rotation ($\pm 10°$ or $\pm 12°$). The tolerance for the accuracy can be balanced between the outside optical setup. When the total flux of the reflected light passes the lens, the intensity of the pixel image is the same and is independent of the rotational angle of the mirror. The dashed gray line in **Figure 70** shows the light path reflected from the mirror with small fluctuation of the image brightness. Unless the pupil clips the light, the image brightness is maintained. **Figure 73** illustrates the conceptual margin until the destruction. The optical setup can give the margin to the mirror rotation angle. Taking the advantage of digital processing, the mirror is open-controlled without monitoring the mirror rotation or the image intensity.

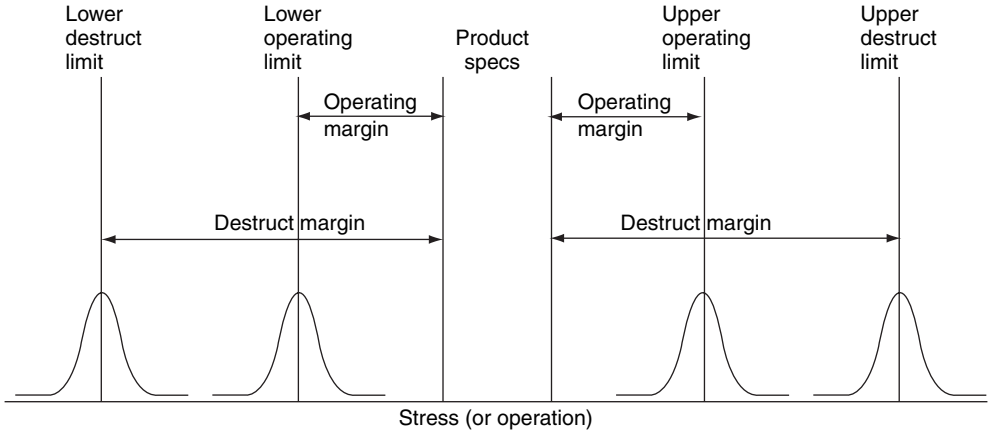

Figure 73 Illustration for explaining the stress (or operation) margin until the destruction. The operation margin relates to the allowable fluctuation of the mirror rotation angle. (Source: Douglass M R 2003 DMD reliability: A MEMS success story. *Proc. SPIE* **4980**, 1–11.)

Time division multiplexing contrast with the continuous additive color mixing adopted in the liquid crystal (LC) panel, which is the competitor in the projector market. A typical LC panel had a response time of 5–8 ms in 2006. Due to this relatively slow time response, LCs have to use the continuous additive color mixing method for generating color (spatial superposition). The preparation of the three RGB coloring segments for each image pixel becomes necessary. DMD can prepare one pixel using a single mirror.

Due to mechanical light modulation, the contrast can be larger than 1:1000. The LC display is under improvement for realizing the contrast 1:1000, but there is a trade-off between the response times. **Figure 74** shows the optical setups of the projector.

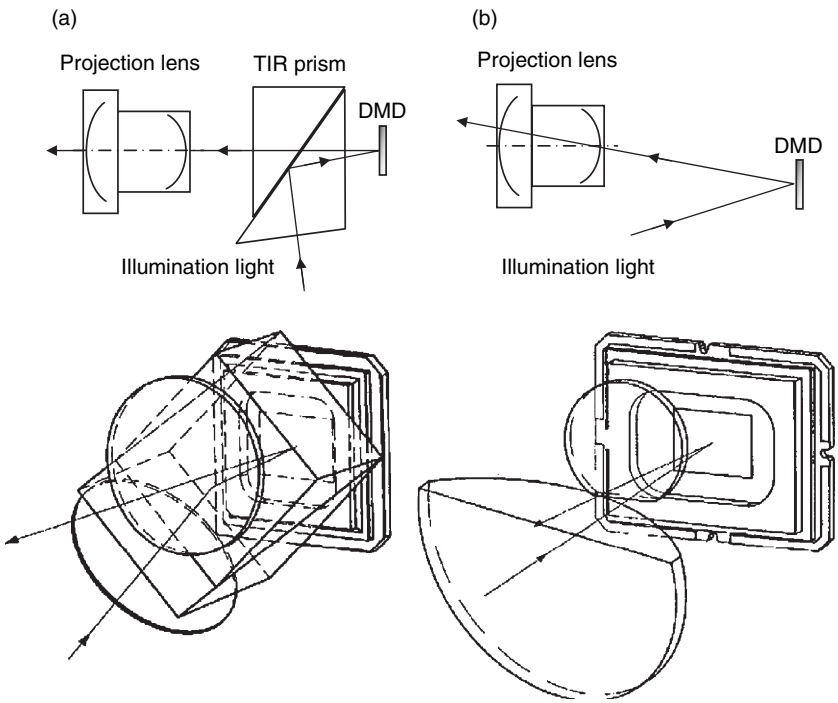

Figure 74 Schematic and perspective optical setup using (a) total internal reflection (TIR) and (b) off-axis illuminations to Digital Micromirror Devices (DMD) chip. (Image courtesy: Texas Instruments.)

The interface reflection has to be at least <0.1% for obtaining the contrast of 1:1000. The number of the optical elements is minimized for reducing the reflection at interfaces. The reflection stray light can be decreased. The biggest market is the lightweight portable projector and ~95% of projectors in the market fall within this category. Currently, the mainstream projection technology is the one-chip setup using the off-axis setup (as shown in **Figure 74(b)**). The space over the DMD element is crowded. When the lenses become larger, the projection lens cannot be set at the front of the DMD. This means that the surface plane of DMD cannot be set at the exact imaging plane of the projection lens. Using a total internal reflection (TIR) prism can be the solution (as shown in **Figure 74(a)**). However, the contrast has to be maintained by adopting high-quality antireflection coating. The theater system requiring high brightness uses this setup with three chips for high-end quality.

3.01.6.6 Grating Light Valve

The small and lightweight moving element is advantageous for increasing the resonant frequency as seen in the case of DMD. Grating light valve (GLV) takes further advantage of miniaturization. In this device, the moving element is a part of the mirror, decreasing the size. Around 1991, Professor D Bloom (Stanford University) considered the basic idea. The first paper appeared in 1992 (Solgaard *et al.* 1992). He started the venture company of Echelle in 1994. This company changed its name to Silicon Light Machine Inc. in 1996. GLV device has been considered to be a part of the display market.

GLV is a device that acts as a dynamic, tunable grating for varying the amount of laser light that is diffracted or reflected. **Figure 75** illustrates the principle showing the cross-sectional view. One reflecting mirror is divided into some ribbons, which is the basic element. The alternative ribbons can deflect down over small distances by controlling the magnitude of the electrostatic force between the ribbon and the electrode underneath. When ribbons do not deflect, being at the same height as shown in **Figure 75(a)**, the incident light reflects back. When the ribbons move up and down alternatively as shown in **Figure 75(b)**, the incident light diffracts. With the displacement of the ribbon, the diffraction angle is constant but the light intensity varies. Especially when the ribbon displacement is $\lambda/4$, the normal reflection beam is canceled due to the phase difference of $\lambda/2$ generated by the round trip propagation.

Figure 76 shows the schematic view. The GLV consists of a series of ribbons. The region corresponding to one image pixel is 25 μm in length with six ribbons. For the SXGA (1280 × 1024) display as an example, the linear diffraction grating array becomes 25.6 mm in the overall length.

Figure 77 shows the optical setup of the laser projection system using GLV chips (Perry 2004). Light beams of three-color (RGB) lasers are partially diffracted by GLVs. A Fourier (offner-type) filter distinguishes the diffracted light from the reflected light. The laser beams are combined to make up colors of pixels in the video image, for example 1080 pixels (corresponding to HDTV) at a time. The display system contains an external bulk optical scanning mirror (a bulk galvanometric scanner). A 1D linear array of GLV modulates pixel colors for a single column. Once an image is in a frame, this vertical line image is scanned across the screen to produce a complete image. **Figure 78** shows the schematic drawing illustrating the image formation. This is the combination of a 1D

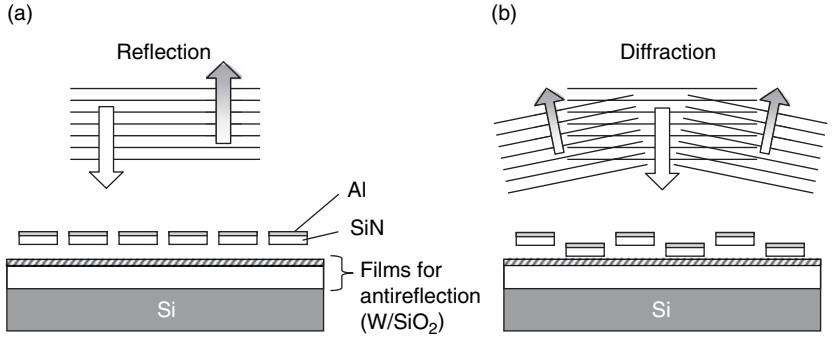

Figure 75 Grating light valve (GLV) ribbons at undeflect and deflected conditions for creating reflection and diffraction beams.

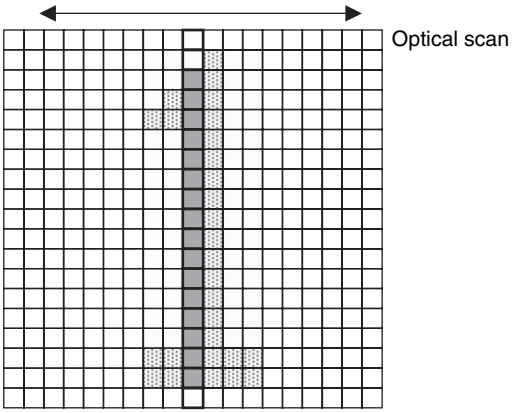

Figure 78 Schematic drawing for illustrating a scanning grating light valve (GLV) array architecture for creating an image.

discrete-pixel array and a 1D scanning system. This is the medium concept shown in **Figure 68(a)** and **(b)** for explaining DMD and laser display, respectively.

Figure 79 shows the schematic of the GLV element, which corresponds to a single image pixel. The fundamental element is the dual-supported parallel ribbon formed with SiN, coated with a reflective top metal layer. The metal layer is used also as an electrical conductor to realize electrostatic attraction to the bottom common electrode. The switching speed will be fastest in the optical MEMS devices. The first paper in 1992 mentions a 20-ns response, which may use the pull-in transition of the electrostatic actuator. The recent documents report a resonant frequency in the megahertz range (the exact value is tuned depending on the design). Before *c.* 1996, the ribbon was designed to contact the underneath electrode, as shown in **Figure 79(a)**. The reason could be for obtaining an accurate $\lambda/4$ displacement over a longer ribbon region. The contacting mechanism will involve the problem of charge up of the insulating material (SiN in this case) or the reliability issue. Now ribbons are designed to operate without contact as shown in **Figure 79(b)** (Senturia 2001). The incident light is focused slightly at around the center of the ribbon, where the displacement is considered to be equal. Current GLV devices are said to have diffraction efficiency near the theoretical maximum for square-well diffraction grating of 81% (into the ±first orders), fill factor of 95%, and top layer reflectivity of 91%, with an overall device efficiency of about 70%. This optical efficiency corresponds to an insertion loss of ~1.5 dB.

The diffraction pattern from GLV can be analyzed using the diffraction theory. Consider the array of rectangular slits (width c, length is not considered for the simplicity) having the pitch d as shown in **Figure 80**. The number of slits is N. The wave amplitude $u(x)$ is obtained as follows starting from eqn [1]. Because the shape of the slit is

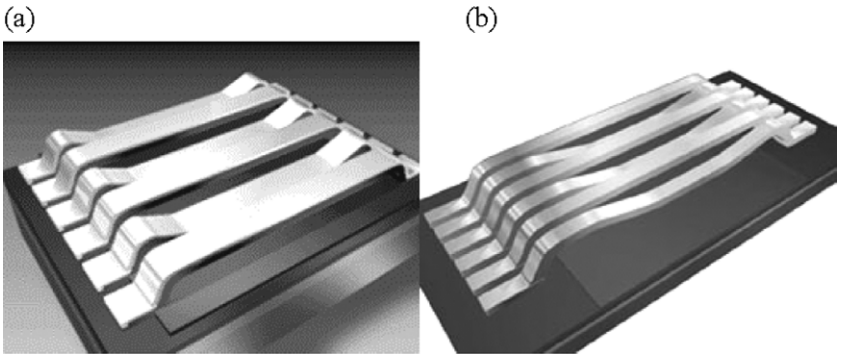

Figure 79 Grating light valve (GLV) ribbons corresponding a single-image pixel using (a) contact. (Source: Trisnadi J I, Carlisle C B, Monteverde R 2004 Overview and applications of grating-light-valve-based optical write engines for high-speed digital imaging. *Proc. SPIE* **5348**, 52–64.) and (b) noncontact scheme. (Source: Payne A, DeGroot W, Monteverde R, Amm D 2004 Enabling high-data-rate imaging applications with grating light valve technology. *Proc. SPIE* **5348**, 76–88.

the same, each slit generates the integration $C\int_{-c/2}^{c/2}\exp[\mathrm{i}\{(2\pi/\lambda)(\xi x/f)\}]\mathrm{d}\xi$. The difference is the relative phase depending on the position of the slit, which is multiplied to the integration. The total light intensity can be obtained as summation as follows:

$$u(x) = [1+\exp[\mathrm{i}\{(2\pi/\lambda)(dx/f)\}]+\exp[\mathrm{i}\{(4\pi/\lambda)(dx/f)\}]+\cdots+\exp[\mathrm{i}(N-1)\{(2\pi/\lambda)(dx/f)\}]]\,C\int_{-c/2}^{c/2}\exp[\mathrm{i}\{(2\pi/\lambda)(\xi x/f)\}]\,\mathrm{d}\xi$$
$$= \frac{-\exp[\mathrm{i}N\{(2\pi/\lambda)(dx/2f)\}](\exp[\mathrm{i}N\{(2\pi/\lambda)(dx/2f)\}]-\exp[\mathrm{i}N\{(2\pi/\lambda)(dx/2f)\}])}{-\exp[\mathrm{i}\{(2\pi/\lambda)(dx/2f)\}](\exp[\mathrm{i}\{(2\pi/\lambda)(dx/f)\}]-\exp[-\mathrm{i}\{(2\pi/\lambda)(dx/f)\}])}\,C\frac{\exp[\mathrm{i}\{(2\pi/\lambda)(cx/2f)\}]-\exp[-\mathrm{i}\{(2\pi/\lambda)(cx/2f)\}]}{\mathrm{i}\{(2\pi/\lambda)(x/f)\}} \quad [30]$$

The intensity from the slit array can be expressed as follows:

$$I(x) = N^2 I_0\left[\frac{\sin N\frac{2\pi}{\lambda}\frac{dx}{2f}}{N\sin\frac{2\pi}{\lambda}\frac{dx}{2f}}\right]^2\left[\frac{\sin\frac{2\pi}{\lambda}\frac{cx}{2f}}{\frac{2\pi}{\lambda}\frac{cx}{2f}}\right]^2 \quad [31]$$

where I_0 is the intensity at the center of the diffraction pattern from a single slit having width c. There is the factor having the shape of the sinc function:

$$\left[\frac{\sin\frac{2\pi}{\lambda}\frac{cx}{2f}}{\frac{2\pi}{\lambda}\frac{cx}{2f}}\right]^2$$

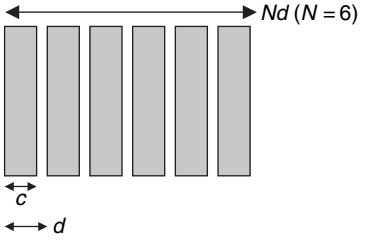

Figure 80 Schematic drawing for illustrating the grating light valve (GLV) ribbons that will interfere with the laser beam.

This is the same factor shown in eqn [2] obtained as the diffraction pattern from the single rectangular mirror. The grating pattern is considered as the superposition of the diffraction pattern of a single slit and the factor

$$\left[\frac{\sin N\frac{2\pi}{\lambda}\frac{dx}{2f}}{N\sin\frac{2\pi}{\lambda}\frac{dx}{2f}}\right]^2$$

which comes from the array.

Figure 81 shows the diffraction pattern expressed by eqn [31]. The ribbon condition $d=3c$ is maintained. Three patterns are shown changing $N=4$, 6, and 12. As for the display device, the ribbon number for one image pixel is first designed to be 4, and later increased to 6. The illuminated region is the center of the ribbon focusing the laser beam slightly. There are peaks at the condition of the numerator corresponding to $\sin N((2\pi/\lambda)(dx/2f))=\pm 1$. Fundamentally, this generates small peaks named subsidiary maxima. With them, there are large peaks named principal maxima. The position of the principal maxima is independent of N but decided by the condition of the denominator

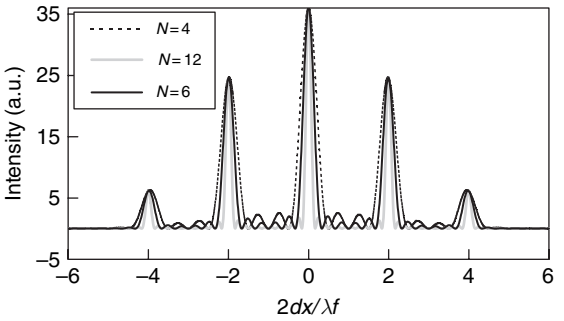

Figure 81 Diffraction pattern from the grating. The grating ribbons are supposed to have the relation of $d = 3c$. Three curves correspond to $N = 4$, 6, and 12.

$\sin((2\pi/\lambda)(dx/2f)) = 0$. The position is given by the following equation:

$$x_m = \frac{m\lambda}{d} f \quad (m = 0,\ 1,\ 2,\ 3, \cdots) \qquad [32]$$

The number of subsidiary maxima between the principal maxima is $N-2$. The peak height of the subsidiary maxima decreases with the increase of N. Because the principal maxima (especially $\pm$ first order) are used, some loss of contrast is incurred due to the existence of the subsidiary maxima at the same position. This loss can be decreased with the increase of the number N of ribbons for each image pixel. There is a trade-off between increasing the number of image pixels and obtaining the higher contrast, because the increase of N means preparing more GLV ribbons.

With the increase of N, the full-width at half-maximum of the principal maxima decreases. The width defined by the length Δx from the peak center to the neighboring 0 position is expressed as follows from eqn [31].

$$\Delta x = \frac{\lambda f}{Nd} \qquad [33]$$

The denominator Nd corresponds with the width of the reflecting area. The wider the reflecting area Nd, the sharper the diffraction spot. This is fundamentally the same as expressed by eqn [7] showing the diffraction limit. As can be seen in **Figure 81**, the gaps between ribbons do not appear inside the peak spot. This characteristic is unique compared to the standard micromirrors. The peak intensity changes depending on the fill factor of the reflective area. This factor is included in I_0 in eqn [31]. The basic diffraction pattern does not change.

Figure 82 shows the illustration for explaining two different ribbon heights. With the displacement of the

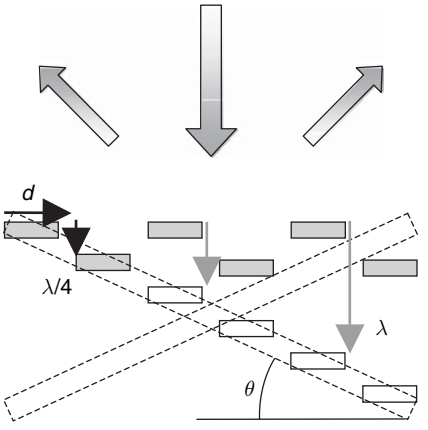

Figure 82 Schematic drawing for illustrating the role of grating light valve (GLV) ribbons.

ribbons, the relative phase of the wave reflected from the neighboring ribbon changes. When the GLV ribbons deflect downward exactly by $\lambda/4$ of the incident light, the diffraction spot intensity becomes maximum. In this case, the mathematical model becomes as follows. The phase difference between neighboring ribbons becomes $\lambda/2$ or π. As the phase 2π can be added without disturbing the phase condition, the series of integration can be expressed as follows instead of expressing it in terms of eqn [30]:

$$\begin{aligned} u(x) = 1 &+ \exp[\mathrm{i}\{(2\pi/\lambda)(\mathrm{d}x/f) + \pi\}] \\ &+ \exp[\mathrm{i}2\{(2\pi/\lambda)(\mathrm{d}x/f)\} + \pi] + \cdots \\ &+ \exp[\mathrm{i}(N-1)\{(2\pi/\lambda)(\mathrm{d}x/f) \\ &+ \pi\}]\, C \int_{-c/2}^{c/2} \times \exp[\mathrm{i}\{(2\pi/\lambda)(\xi x/f)\}]\ \mathrm{d}\xi \end{aligned} \qquad [34]$$

$$I(x) = N^2 I_0 \left[\frac{\sin N\left(\frac{2\pi}{\lambda}\frac{dx}{2f} + \frac{\pi}{2}\right)}{N \sin\left(\frac{2\pi}{\lambda}\frac{dx}{2f} + \frac{\pi}{2}\right)}\right]^2 \left[\frac{\sin \frac{2\pi}{\lambda}\frac{cx}{2f}}{\frac{2\pi}{\lambda}\frac{cx}{2f}}\right]^2 \qquad [35]$$

Figure 83 compares the diffraction patterns calculated from eqn [35] (gray curve) and eqn [31] (black curve). The black curve is when the ribbons are at the

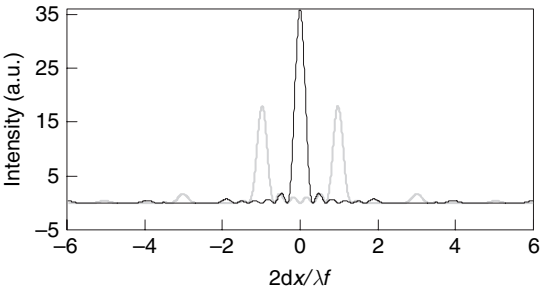

Figure 83 Calculated diffraction pattern from grating light valve (GLV) based on eqn [35].

same height. The ribbon pitch d is 4.17 μm (25 μm element size according to the actual device). The number of ribbons N is 6. I_0 is supposed to be 1. The ribbon gap that is supposed to be 10% of d setting is 0.417 μm. Due to the narrow gap, the diffraction peak that should appear at $2dx/\lambda f = \pm 2$ is small. The parallel ribbons can be considered as a single mirror. When the ribbon deflects downward by $\lambda/4$, the diffraction pattern will change to the gray curve. The center peak disappears by the destructive interference. Instead, the constructive interferences occur at the condition where the denominator becomes zero, i.e., $\sin((2\pi/\lambda)(cx/2f)+(\pi/2)) = 0$. Due to the phase offset $\pi/2$, the peak position shifts. As the result, the center principal peak is mainly divided to two peaks at the position expressed as follows:

$$\frac{x}{f} = \pm\frac{\lambda}{2d} \qquad [36]$$

This is the modulation of the light beam generated by the small displacement of ribbons.

Consider the condition when the ribbon deflects by $\lambda/4$. As the phase difference of λ (as a total of round trip) is same with the phase 0 for the light, the ribbon array can be considered as a single inclined mirror plane as shown by the dotted rectangles. The two inclining directions can be assigned due to the arbitrary nature of the phase. This inclined angle can be expressed as follows:

$$\tan\theta = \pm\frac{\lambda}{4d} \qquad [37]$$

Remembering that the optical reflection angle becomes double compared to the mirror rotation angle, this equation becomes equivalent to eqn [36]. The principal spots from GLV can be considered as the reflection from the equivalent tilt mirrors. In this meaning, GLV can be considered as a kind of micromirror.

The light powers carried by the zeroth and ± first orders are dominant and nearly complementary as seen from **Figure 83**. There are two possible optical setups using GLV (Trisnadi *et al.* 2004). One uses the reflected beam (zeroth order) as shown in **Figure 84(a)**. The other uses diffracted beams (± first orders) as shown in **Figure 84(b)**. The location where the orders are optimally separated is at the Fourier transform plane. The spatial filter is placed and discriminates reflected and diffracted beams. This Fourier filter is analogous to the Schlieren filter. Because a slit that path zeroth-order beams has a finite width, some diffracted peaks (corresponding to two subsidiary maxima under the zeroth-order principal maximum in **Figure 83**) cannot be filtered out. From the theoretical curve, the contrast becomes about 30 for the six ribbons (Tamaki *et al.* 2004). Use of more ribbon pairs generates less diffracted energy in the vicinity of the zeroth-order beam, thus giving higher contrast as seen from **Figure 81**. The computer-to-plate (CTP) system modulating the high-power laser beam uses the reflected beam (Tamaki *et al.* 2004). Twelve ribbons are used for one image pixel. The contrast is ~130. The laser beams are used to write images onto plates for the offset printing based on the thermal reaction activated by the high energy. The display application uses the optical setup shown in **Figure 84(b)**. A contrast larger than 1000:1 has been reported. The light scattering is also necessary to be minimized. The real device may include the technique of the profile control of the ribbon (like blazing).

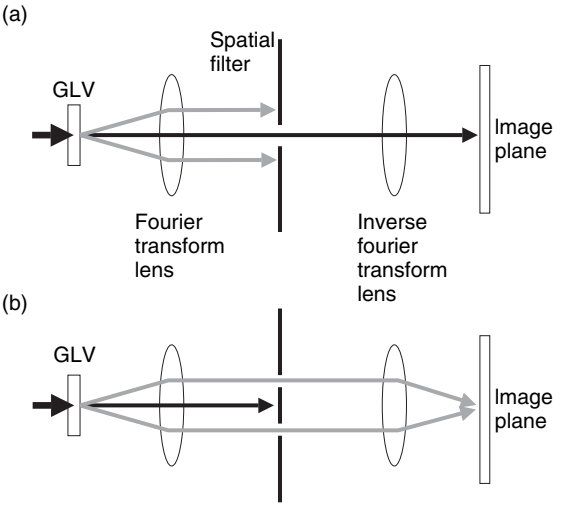

Figure 84 Imaging optics using the zeroth- and first-order beams.

Although both GLV and DMD are well-known devices as spatial light modulators, their features are contrasting. GLV works with a laser beam having a single wavelength λ. DMD works with white light. When the laser beam is used with DMD, the diffractions or the speckles will disturb the image. The photocurrent can disturb the SRAM operation. GLV can handle relatively high-power density because of the absence of IC underneath the ribbons. GLV is controlled in analog, so the displacement accuracy will be stricter than that of DMD using the digital on/off control.

3.01.6.7 Variable Optical Attenuator

The micromirror is applied to the telecommunication network. From the initial stage of the optic-fiber network, the device having the fixed attenuation value is used. With the progress of the WDM system (from *c.* 1996), the device that can control the attenuation (or insertion loss) according to the electrical control signal is required. This is the variable optical attenuator (VOA). A large number of VOAs become necessary because transmission powers of multiple channels of different wavelengths are individually controlled at the wavelength multiplexing and demultiplexing nodes. Many kinds of principles have been considered including the mechanical (conventionally the assembly of a prism or a mirror driven by a solenoid coil or a motor), electromechanically operated Fabry–Perot interferometers, and the magneto-optical methods. VOA is basically the device to be included in the larger systems, and a smaller size is required.

There are two main uses of VOAs. One is leveling the light intensity having different signal wavelengths, and another is leveling the output signals for amplifying the intensity of many photonic signals in erbium-doped fiber amplifier (EDFA) setting a constant amplifying ratio, even when the number of signals or the intensity changes. This need is because the telecommunication system performance becomes lower when the amplifying ratio changes. When optical add drop multiplexing (OADX) and optical cross connect (OXC) are introduced in the optical network, the optical signal intensity can change depending on its route. This nonuniform signal intensity has to be leveled. For using VOAs for each wavelength in WDM system, the arrayed VOA is preferred.

The specification to VOA is somewhat different depending on the system to be applied. The main specifications are

(1) insersion loss (<2 dB),
(2) dynamic range (>15 dB),
(3) polarization-dependent loss (<0.2 dB),
(4) wavelength dependence of attenuation,
(5) reflection (<−45 dB),
(6) driving speed,
(7) resolution of attenuation,
(8) hysteresis, and
(9) power consumption.

Specifications (3) and (4) become important when the VOA deals with many wavelength signals. The mechanical method using the micromirror can realize the little dependence on the wavelength. Specification (6) becomes important when the VOA is required to follow the transient response of EDFA.

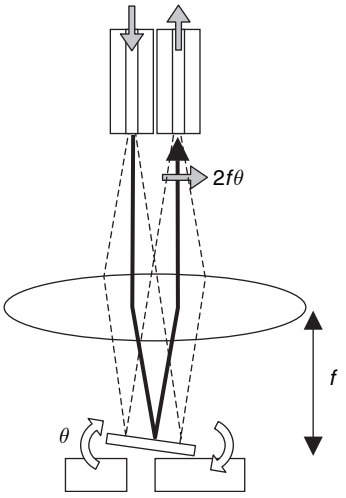

Figure 85 Schematic drawing of optical setup of a variable optical attenuator (VOA) using the micromirror adopted in the Santec Corporation.

Figure 85 shows a schematic drawing of the optical setup of VOA using the micromirror adopted in the Santec corporation (Isamoto *et al.* 2004). The setup is symmetrical to the center axis of the lens. Because the output fiber is at the symmetric position and the mirror is at the focus position, the output light beam is normally incident on the output fiber end with the same beam condition at the input fiber end. The mirror rotation generates the shift of the beam spot, which is the main reason of the attenuation. The large focus length f increases the displacement. When the mirror rotation angle is 0.3° and the focus length is 1.8 mm, the shift displacement is 9.4 μm. Because the core diameter of the fiber is ∼10 μm, the attenuation or the coupling ratio is highly sensitive to the minute displacement of the beam spot.

The attenuation can be calculated based on the coupling of the Gaussian beam with the output optical fiber. When the incident beam profile exactly matches with the mode of the output fiber, the attenuation η can be expressed as follows:

$$\eta = \kappa \exp\left[-\kappa \frac{x_0^2}{\omega^2}\right] \qquad [38]$$

where κ is set to 1 assuming the exact matching of the mode profile, ω is the radius of the Gaussian beam set to 5.5 μm, and x_0 is the shift having the relation of $2f\theta$

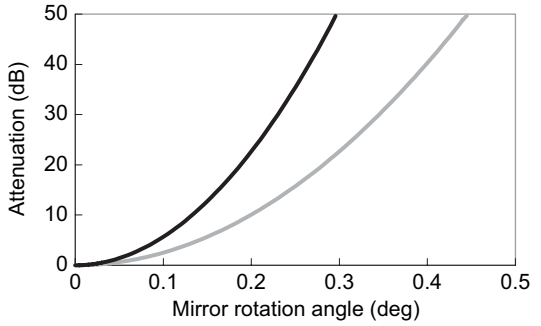

Figure 86 Calculated optical attenuation as a function of the mirror rotation angle.

with the focus length f and the mirror rotation angle θ. **Figure 86** shows the relation expressed by eqn [38]. Black and gray curves are for the focus lengths f of 1.8 and 1.2 mm. f is reported to be 1.8 mm. The mirror angle is controlled up to 0.4°.

With the outside optical setup, a large attenuation can be obtained with a small mirror rotation angle. Therefore, the parallel plate electrostatic torsion mirror can be used. Because the VOA does not need full-time scanning, dynamic deformation is not a problem. **Figure 87** shows the attenuation curve as a function of the driving voltage. A low-voltage operation (DC 5 V or less) is realized. **Figure 88** shows the schematic view of the mirror. A circular mirror with electrostatic parallel plates is suspended

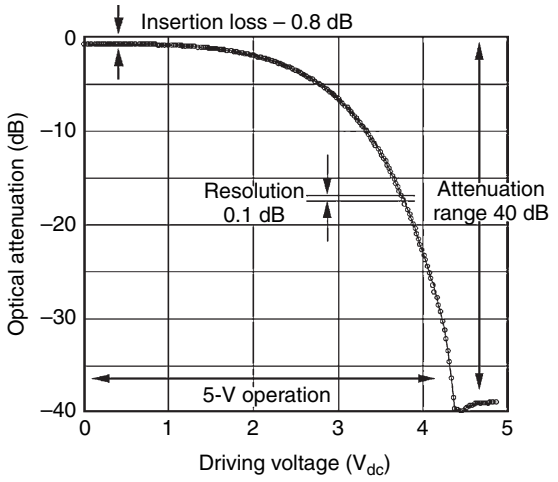

Figure 87 Typical attenuation curve as a function of the driving DC voltage of the micromirror. (Source: Isamoto K, Kato K, Morosawa A, Chong C, Fujita H, Toshiyoshi H 2004 A 5-V operated MEMS variable optical attenuator by SOI bulk micromachining. *IEEE J. Sel. Top. Quant. Electron.* **10(3)**, 570–8.)

with torsion bars. The structure is made of a SOI wafer. The right-side wing of the suspended mirror and the underlying substrate are electrodes of the gap-closing electrostatic actuator. The suspended mirror is biased. The underlying substrate is grounded a 2-μm air gap. The electrostatic attraction torque rotates the actuator plates with a small angle. There is a large through-hole under the mirror to prevent the mirror from contacting the underlying substrate. **Table 7** lists the performance. Because the incident angle to the micromirror is nearly normal even when the mirror is rotated, there is little polarization dependence.

Because shifting of the lens or mirror after packaging becomes the main cause for the degradation in performance, the positions of fibers or lens have to be highly stable. Hence, glue cannot be used for the assembly. The minute angular fluctuation caused by the outside force and the temperature change have to be avoided. A smaller lens holder and a metal package are adopted. **Figure 89** shows the micromirror mounted on the package base. The package size is 5.6 mm in diameter and 2.3 mm in length. The standard for the passive telecom device of Telcordia GR-1221-CORE requires testing with high acceleration. This standard does not take into account moveable elements like micromirror. The requirement for the mechanical shock is, for example, 500 G in 1 ms, five times per direction for six directions. Protecting the package with the suspensions or cushions is difficult, because the VOA device is required to be small. The shock resistance is satisfied by the technology of the metal packaging as well as the micromirror design.

3.01.6.8 Optical Switch

Some devices that have already been described (e.g., **Figures 19(b)** and **29**) are for optical switching. Around 2000, special attention was given to telecommunication applications. The large-scale OXC may be a representative application. **Table 8** shows the list of required specifications for the optical switch. Depending on the applications, the required port size and insertion loss are different. The optical route can be changed directly without conversion from optical to electrical signals. This switching method does not depend on the protocol, signal bit rates, and also wavelength. OXC can be used without disturbing the change of the above specifications. The main challenge of OXC is the realization of low loss in the large-scale system. The 2D switch setup as shown

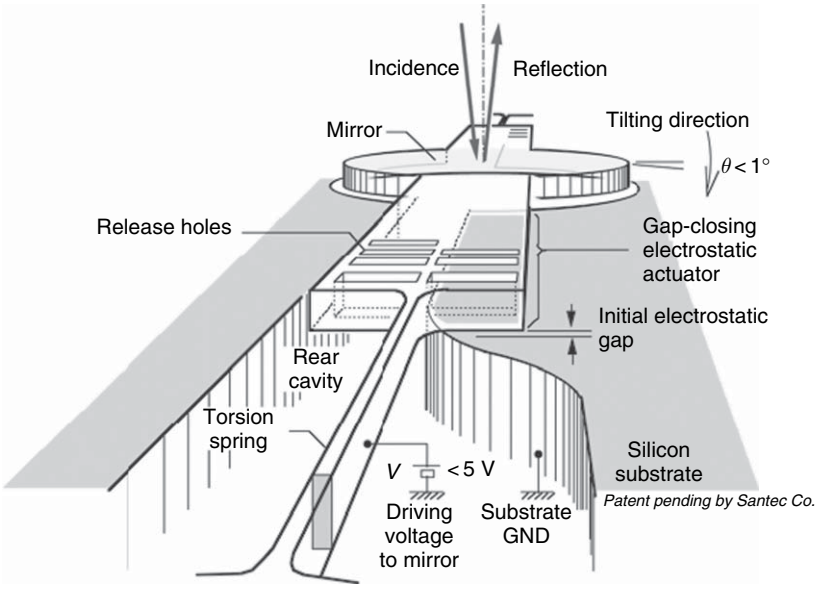

Figure 88 Schematic drawing of the micromirror used in the variable optical attenuator (VOA). in Figure 29 requires N^2 micromirrors for realizing $N \times N$ OXC. It is said that $\sim 32 \times 32$ scale will be the practical limit. Generally, a higher number of reflections increases the insertion loss. The free-space-type 3D MEMS beam-steering architecture is considered as the most promising candidate. The necessary number of micromirrors is $2N$ for realizing an $N \times N$ OXC.

Figure 90 illustrates the progress in the research on large-port-count OXC. To manage the flow of diverse optical signals, which was accelerated by the explosion of Internet data transport, petabit per second class optical switching capabilities were needed

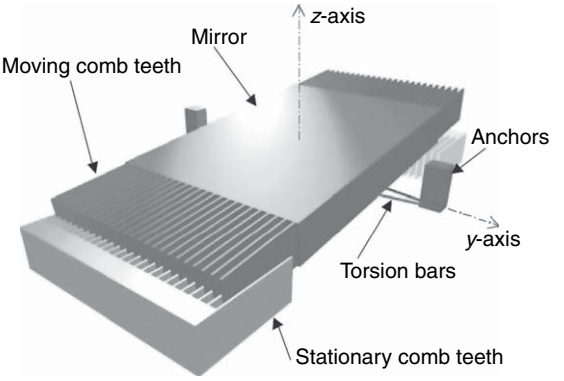

Figure 91 Schematic of single-axis type comb-driven micromirror developed at Fujitsu Laboratories Ltd. (Source: Tsuboi O, Mizuno Y, Koma N, Soneda H, Okuda H, Ueda S, Sawaki I, Yamagishi F 2002 A rotational comb-driven micromirror with a large deflection angle and low drive voltage. *Proc. 15th IEEE Int. Conf. on Micro Electro Mechanical Systems*, Las Vegas, Nevada, USA, pp. 532–5.

in the core optical networks. The large-port-count OXC of classes exceeding 4000 × 4000 were considered. Later, system concerns shifted to metropolitan area networks, because new network services have rapidly proliferated (especially those involving mobile access applications) and data traffic congestion in such regions is a growing problem. OXC of 100 × 100 class are being developed. In 2005, Calient Networks and Fujitsu Laboratories Ltd. were competing. In deployed optical networks, the acceptable full cross connect time among all ports is <5 ms for OXC at each network node, taking into account the permitted overall system failure time of 50 ms.

Figure 91 shows a schematic drawing of the micromirror developed at Fujitsu Laboratories Ltd. (Yano *et al.* 2005). The single-axis version is shown for simplicity. The vertical comb-drive actuator has a high aspect structure with thin comb teeth and a narrow air gap for generating a large electrostatic force. **Figure 92** shows images of the device. The comb-teeth pitch is 20 μm, the thickness is 5 μm, and the air gap is 5 μm. A 100-μm-thick Si layer on an SOI substrate is processed. The micromirror has two pairs of torsion bars realizing the rotation along the two axes. The mirror diameter is 650 μm. The torsion bar used is 5 μm thick and 3 μm wide. These narrow gaps require the torsion bars to provide stable tilt motions. A V-shaped torsion bar as shown in **Figure 91** is adopted. The V-shaped torsion bars have larger stiffness against the imbalanced forces causing the pull-in instability. Taking this advantage, the thick vertical combs can generate a larger driving force enabling both larger rotational angles and faster mirror motion.

Solid-State Sensors and Actuators*, pp. 1298–301.)

The optical setup is the symmetric confocal optics. Through the lens in front of the fiber bundles, the beam waists coincide at the center of the optical setup. This compensates the optical divergence. The centrally located beam waist can minimize the mirror and the lens size. **Figure 93(a)** shows a rectangular frame used in conventional housing. The optical beam is reflected twice by the micromirrors. The optical path is Z-shaped. Fujitsu adopted a cubic frame as shown in **Figure 93(b)**. The mechanical stiffness increases and the mirror chips can be set parallel to the base plane. This is advantageous for the assembly. Notice that the p-polarized beam at the micromirrors is incident on the roof-type mirrors as the s-polarized beam. The polarization dependence is averaged. The optical condition is almost the same within the small rotation angle of $\sim 5°$.

Figure 94 shows the optical setup for explaining the characteristics using flat and roof-type mirrors. In case of the flat mirror, the maximum angle required for the micromirror can be expressed as follows:

$$\theta_{\max 1} \approx \frac{D}{l_1} \qquad [39]$$

where D is the total length of the mirror array chip and will be $\sim$11 mm for a 10×10 matrix if the spacing between micromirrors is 1.1 mm. l_1 is the distance between the device and the mirror. This maximum angle is decided by the condition for steering the beam connecting corner-to-corner mirrors. In case of the roof-type mirror, the maximum angle can be expressed as follows:

$$\theta_{\max 1} \approx \frac{D}{\sqrt{2}s + 2l_2} \qquad [40]$$

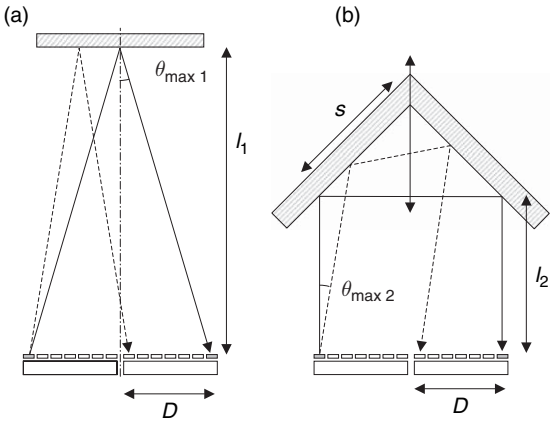

Figure 94 Schematic drawing of the optical configuration using (a) rectangular frame and (b) roof-type mirror for illustrating the parallel shift effect of the roof-type mirror.

The distances l_2 between the device and the mirror are relatively dominant. By the factor 2, the mirror rotation angle can be decreased or the shorter optical path length can be allowed, realizing a more compact switch fabric. This basically occurs from the parallel shift effect of the roof-type mirror. The normal beam incidence on the micromirror is allowed at the rest condition. The flat mirror requires the mirror rotation of $\theta_{\max 1}/2$ for connecting to the opposite corner. The reported total path length $(\sqrt{2}s + 2l_2)$ is $\sim$110 mm.

Figure 95 shows another example of an optical setup for a 238×238 OXC (named LambdaRouter) researched at Lucent Technologies (Aksyuk *et al.* 2003). The basic setup is a rectangular frame. At the center, a Fourier lens is placed for setting the beam waist at each micromirror. Two micromirror arrays (shown in **Figure 19(b)**) are placed at the left and right sides. Due to the function of the Fourier lens,

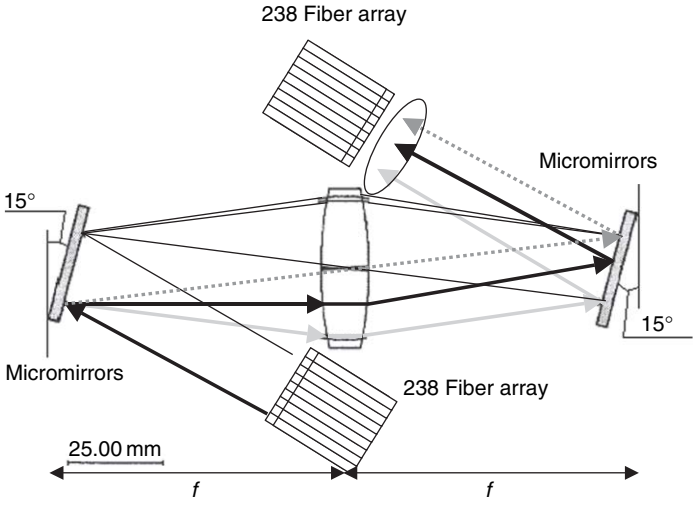

Figure 95 Optical configuration of the optical cross connect (OXC) using the Fourier lens. Beam paths are shown.

the reflection beam from the micromirror at the rest position will focus on the center mirror in the second micromirror array placed at the right side. The black curve shows the beam path. The required task of mirror rotation angle becomes the same for the arrayed mirrors. When the mirror rotates in the ± direction, the reflection beam shifts to the ± direction from the center as shown by gray curves. The Fourier lens can minimize the task of the micromirrors. It should be noted that the spot size of the beam is 372 μm on the micromirror, and that the mirror size is 600 μm. The additional size of the mirror can be the margin for the risk of clipping of the beam. The difficulty of the assembling can be alleviated.

3.01.7 Researches for Higher Performances

The micromirrors share some of the fundamental requirements. In this section, researches for higher performances of the micromirror are discussed.

3.01.7.1 Large Rotation Angle with Low-Voltage Driving

One research effort is realizing the larger rotation angle with the lower-voltage driving especially for the electrostatic actuator. The established system usually works with 5, 12, or 24 V DC sources. The higher driving voltage requires the additional power source and the driving circuit with the higher resistance. Fundamentally, there are two methods for decreasing the driving voltage. One is increasing the driving force, and another is decreasing the spring constant. Adopting both the methods, Hah *et al.* (2004b) report the poly-Si micromirror fabricated by surface micromachining (Sandia's ultraplanar multilevel MEMS technology-V, SUMMiT-V). **Figure 96** shows the schematic structure and the device image. The vertical comb-drive actuators and torsion springs are placed underneath the mirror (137 μm × 120 μm). **Figure 97** shows the mirror rotation angle. For the device with 0.5-μm finger spacing, a scan angle of 5.9° is obtained at 6 V bias. The finger length is 30 μm. The spring is 1 μm in width and thickness and 55 μm in length on each side. Considering the design enabling the plus and minus angles, the mirror rotation angle is 11.8° as the total. The maximum angle is limited by vertical pull-in instability due to the residual parallel plate capacitance between the mirror and the fixed fingers. As the finger gap spacing increases, the maximum continuous angle decreases because of the earlier occurrence of pull-in. The resonant frequency of the mirror ranges from 3.4 to 8.1 kHz.

In general, the torsion bar is frequently designed as the serpentine spring. The folded bar will be softer not only for rotation, but also for vertical and in-plane displacement and rotation. The resultant mirror motion depends on the balance of the spring constants for many modes of the mirror motion. The spring constant for the mirror rotation should be minimized while maintaining the rigidity in other motions. The serpentine spring helps the design, but often does not completely solve the problem.

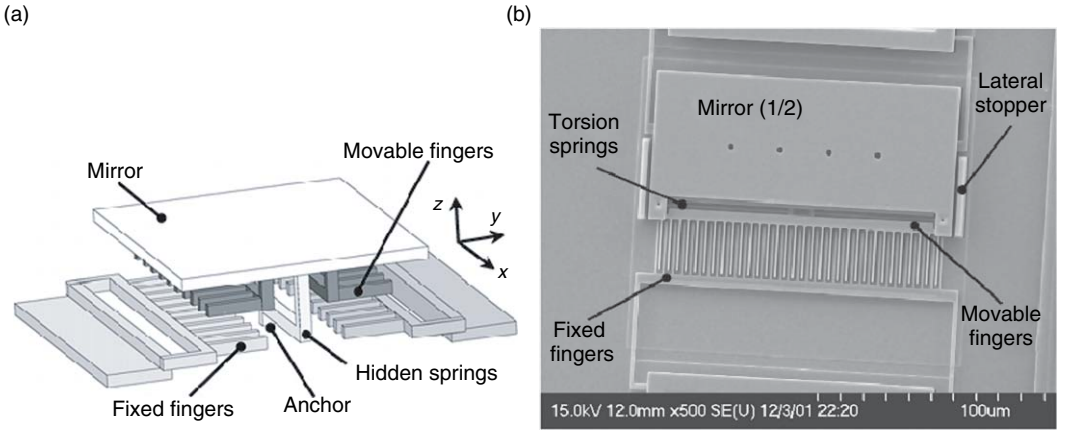

Figure 96 (a) Schematic view and (b) scanning electron microscope (SEM) image of the micromirror with hidden vertical comb drives and springs. The lower half of the micromirror was removed to reveal the underlying comb structures. (Source: Hah D, Huang S T, Tsai J, Toshiyoshi H, Wu M C 2004b Low-voltage, large-scan angle MEMS analog micromirror arrays with hidden vertical comb-drive actuators. *J. Microelectromech. Syst.* **13**, 279–89.)

The thin-film torsion bar is proposed for decreasing the rotational spring constant (Sasaki *et al.* 2006b). The tension is included inside for increasing the rigidity against the unwanted mirror motion, which will be the limiting factor of the maximum rotation angle. The torsional spring constant k_θ is expressed by eqn [26]. Remember the supposed relation of $w > t$. When thin films are considered, t is the thickness. The factor t^3 shows that decreasing the value t is effective for decreasing k_θ. Considering the deposited thin film as the structural material, the thickness of a few hundreds of nanometers can be obtained. Based on eqn [26], the spring constant is 1.4×10^{-11} N m rad^{-1} by setting the values of G, l, w, and t as 80 GPa, 200, 4, and 0.3 μm, respectively.

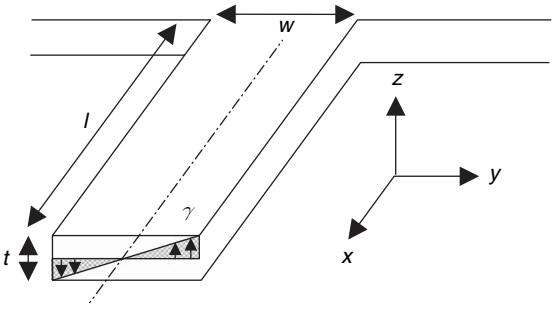
Consider the effect of tension included in the torsion bar. The tensile stress σ_0 inside the SiN film grown by low-pressure chemical vapor deposition can be 760 MPa, the tension $T = \sigma_0 wt$ is 910 μN for a 4 μm × 0.3 μm cross section. This value is large compared to the electrostatic driving force in normal cases. Because the thin-film torsion bar is the softest in the vertical direction, the vertical spring constant k_z is most important for the stability of the mirror motion. k_z is expressed as follows (Senturia 2001):

$$k_z \approx \frac{1}{\sum_{n=1,\ \text{odd}}^{\infty} \frac{1}{l} \frac{2}{\frac{Ewt^3}{12} k_n^4 + \sigma_0 wt k_n^2}}, \quad k_n = \frac{n\pi}{l} \quad (n = 1,\ 3,\ 5 \cdots) \qquad [41]$$

The first and the second terms correspond to the factors due to the elasticity E (290 GPa) and the stress σ_0. k_z are estimated to be 0.016 and 19 N m^{-1} when σ_0 is 0 and 760 MPa, respectively. The tension is dominant for deciding the spring constant. This large spring constant suppresses the vertical displacement of the mirror. The increase of the torsional spring constant $\Delta k_{\theta\ \text{stretch}}$ generated by the beam stretching can be estimated as follows:

$$\Delta k_{\theta\ \text{stretch}} \approx \frac{1}{8l} \left\{ \frac{\sigma_0 (w^3 t + wt^3)}{3} + \frac{E}{2l^2} \left(\frac{w^5 t}{10} + \frac{w^3 t^3}{9} + \frac{wt^5}{10} \right) \theta^2 \right\} \qquad [42]$$

The first term corresponds to stretching against the stress σ_0. The second nonlinear part corresponds to the elastic stretching. The dominant part is the first term having the value of $3.1 \times 10^{-12}\,\mathrm{Nm\,rad^{-1}}$ when the mirror rotation is not large (<6.6 rad). This is 22% of the spring constant estimated from eqn [26]. The tension is fundamentally perpendicular to the rotational displacement of the material inside the torsion bar. The increase of the spring constant is minimized.



Deduction of eqn [42] of $\Delta k_{\theta\ \mathrm{stretch}}$ using energy method: The transverse displacement $\omega(x, y, z)$ of any point generated by the mirror rotation inside the torsion bar can be expressed as follows:

$$\omega \approx \frac{\theta x}{l}\sqrt{y^2 + z^2} \qquad [43]$$

where θ is the rotation of the torsion bar in radian. With the help of the calculation mentioned in Senturia (2001, Chapter 10), the axial strain ε_x can be obtained.

$$\varepsilon_x = \frac{1}{2}\left(\frac{d\omega}{dx}\right)^2 = \frac{\theta^2}{2l^2}\left(y^2 + z^2\right) \qquad [44]$$

The strain energy can be found as follows:

$$\begin{aligned} W &= \frac{1}{2}\int \sigma_x \varepsilon_x \,\mathrm{d}V = \frac{1}{2}\int (\sigma_0 + E\varepsilon_x)\varepsilon_x \,\mathrm{d}V \\ &= \frac{1}{2}\left(\sigma_0 \frac{\theta^2}{24l}\left(w^3 t + w t^3\right)\right. \\ &\quad \left. + E\frac{\theta^4}{32l^3}\left(\frac{w^5 t}{10} + \frac{w^3 t^3}{9} + \frac{w t^5}{10}\right)\right) \end{aligned} \qquad [45]$$

The work done by the external load is $T\theta$, where T is the torque. The total potential energy is

$$U = W - T\theta \qquad [46]$$

Taking the derivative with respect to θ and setting to zero yields T.

$$T = T\frac{1}{2}\left(\frac{\sigma_0\left(w^3 t + w t^3\right)}{12l}\theta + \frac{E}{8l^3}\left(\frac{w^5 t}{10} + \frac{w^3 t^3}{9} + \frac{w t^5}{10}\right)\theta^3\right) \qquad [47]$$

From this relation, eqn [42] is obtained.

Figure 98 shows a fabricated micromirror. The structures of the thin-film torsion bar and the vertical comb-drive actuator are realized by combining isotropic and anisotropic Si plasma etching. The magnified image shows the torsion bar and the vertical comb. The vertical comb is generated by the downward deflection of the cantilever generated by the compress stress in an SiO_2 film.

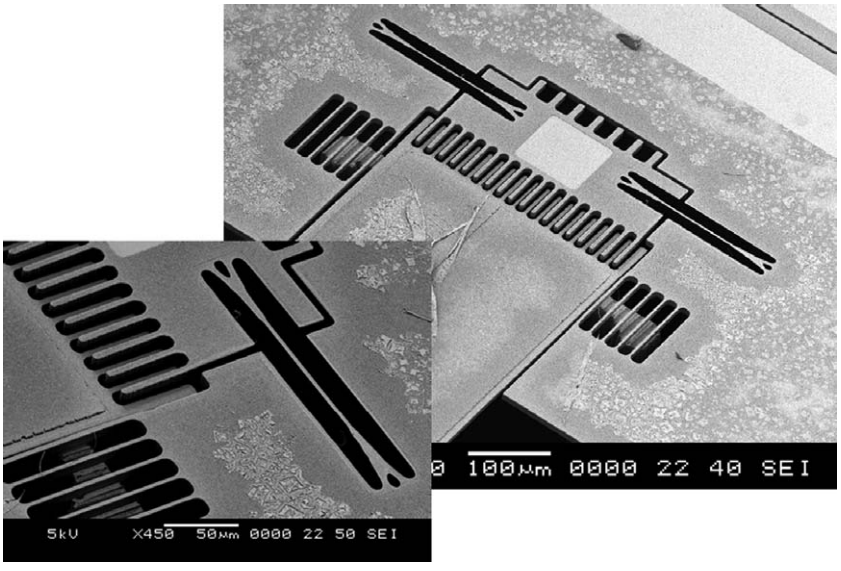


Figure 98 Fabricated micromirror and the magnified image of the torsion bar and the vertical comb.

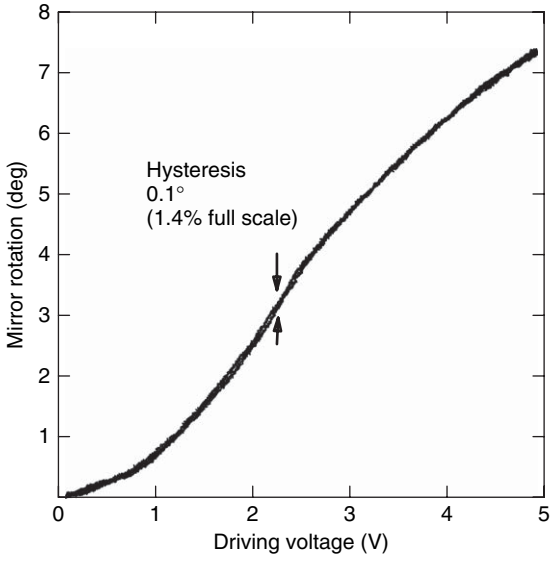

Figure 99 Mirror rotation as a function of the driving voltage.

Figure 99 shows the mirror rotation angle as a function of the driving voltage. The curves change from the concave up to down with increasing driving voltage. The thickness of the comb finger is 10 μm. The rotation angle reaches 7.3° at 5 V. The comb gap is 4 μm in the lateral direction. The curve is smooth showing a nearly linear relation. Data are for a round trip. The hysteresis (defined by the maximum difference of the rotation angle at the same driving voltage in the round trip motion) is 0.1°. This corresponds to 1.4% of the full scale. The resonance frequency of the mirror is about 670 Hz. The stress values are monitored using a strain gauge. Assuming the Young's modulus E of an SiN film to be 290 GPa, the estimated stress is 780 MPa.

3.01.7.2 Accurate Rotation Angle Control

In general, the applications require the mirror rotation angle, and the servo control becomes indispensable. As described, the galvanometric scanner realizes the high accuracy of the mirror rotation angle by combining with the rotation angle sensor. Consider a simple example of the laser printer of 600 dpi supposing the optical arm of 10 cm, the neighboring dot will be generated by the 0.012° mirror rotation. The accuracy will be on the order of 0.001°. The simple open-loop control of the miromirror cannot guarantee accuracy at this level. Remember that some microactuators have hysteresis in their motion (e.g., piezoelectric actuation). The feedback control of the rotation angle based on a sensor is desired. OXC uses the feedback control monitoring the light intensity signal, coupled with the output fiber. With the port switching, the combinations between the output port and the controlling mirrors change. The system becomes complex because the combination of the signal and the feedback loop changes from time to time. Since the driving circuits have a minute difference in their performance, the controlling method becomes complicated. Integrating the sensor inside the micromirror device is attractive for making the system simple and reliable. The same sensor signal and the same driving circuit can be used for controlling the same micromirror.

When the micromirror uses the electromagnetic actuator for full-time scanning application, open voltage based on the inverse electromagnetic effect can be used for sensing the rotation angle. Figure 100 shows the earlier version of the scanner developed at Olympus Corp. The sensing coil is prepared with the driving coil (Miyajima *et al.* 2001). Even when the micromirror does not have a sensing coil, the time division method can be used for detecting the open voltage. In a short period, the coil on the micromirror is driven with enough power, and then switched to monitor the current in another period for detecting the scanning amplitude. Sensing rotation angle using

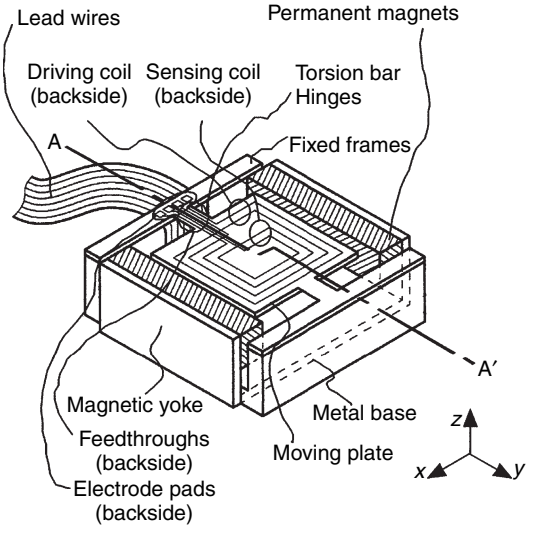

Figure 100 Schematic drawing of electromagnetic scanner with sensing coil. (Source: Miyajima H, Asaoka N, Arima M, Minamoto Y, Murakami K, Tokuda K, Matsumoto K 2001 A durable, shock-resistant electromagnetic optical scanner with polyimide-based hinges. *J. Microelectromech. Syst.* **10(3)**, 418–24.)

electromagnetic coupling at a high-frequency signal between the driving coil and detecting coil has been tried from an early stage. The detecting coil is prepared on the glass basement (Asada *et al.* 1994). A high-frequency (1 MHz) current is superimposed on the driving current, so that this does not disturb the mirror motion. Via the mutual inductance between the driving coil and the detection coil, a open voltage is measured at the fixed detection coil placed underneath. This signal has a linear relation to the rotation angle of the mirror.

There are some patents. Onix Microsystems Inc. proposes detecting the capacitance between electrodes, which will change with the mirror motion (Behrang and Satinderpall 2001). Texas instruments Inc. proposes assembling the lasers and photodetectors at the backside of the micromirrors inside the device package (Orcutt *et al.* 2001). The tails of the reflected beam profile are monitored. By comparing the signal magnitudes, the mirror rotation angle can be measured. Assembling elements with high accuracy will be necessary.

Kallweit and Zappe (2006) propose the use of a part of the incident light beam for sensing the mirror rotation. A transmission grating (period: 2 μm) is prepared in a small part of the micromirror. On the backside of the micromirror, a position-sensitive detector (PSD) is assembled for detecting the transmitted light beam through the grating. **Figure 101** shows the setup. The device is composed of three layers: a Si mirror layer on the top, then a Pyrex contact layer using indium–tin oxide electrodes, and a PSD at the bottom. The major part of the light power is reflected at the mirror. A small part of the incident light is transmitted through the grating. This light beam generates a tilt-angle-dependent diffraction pattern on a PSD.

Considering the case where the incident laser beam is orthogonal to the initial position of the mirror and the grating, the diffraction angle γ has the following relation with the mirror rotation angle β:

$$\gamma(\beta) = \sin^{-1}\left(\frac{m\lambda}{\Lambda} - \sin\beta\right) \pm \beta \qquad [48]$$

where Λ is the grating pitch and $m\ (= \pm 1, \pm 2, \cdots)$ is the diffraction order. The zeroth-order beam stays at the center. Knowing the wavelength of the laser light λ, the period of the grating Λ and the distance between the mirror and the PSD allows the determination of the mirror tilt angle β by measuring the position of the incident light on the PSD (related to γ). **Figure 102** shows the relation setting the value $\lambda = 650$ nm and $\Lambda = 2$ μm. The positive and negative diffraction maxima do not shift symmetrically upon the mirror rotation angle. The demonstrated resolution of the angular sensing is ~0.03° (confirmed angular resolution of 0.066° with the reference error of 0.04°) for a wavelength of 650 nm and a spacing of 7.90 mm between the mirror and the underlying PSD.

Another sensing principle is the piezoresistive method (Yalcinkaya *et al* 2006). The strain introduced in c-Si changes the conduction and valence band structures. The resultant carrier density or mobility change is observed as a bulk resistivity change. Bourouina *et al.* (2002) reported a magnetostrictive actuator integrated with a piezoresistive sensor. Taking advantage of the simplicity of the magnetostrictive microactuator, two Wheastone bridges are incorporated near the clamping

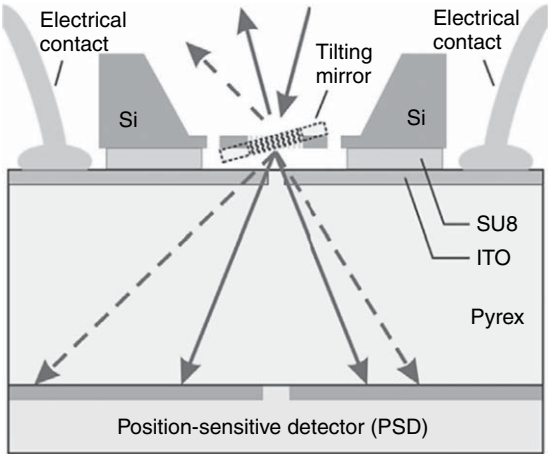

Figure 101 Schematic of the optical tilt sensing mechanism using the mirror with transmission-type grating. (Source: Kallweit D, Zappe H 2006 Fabrication of bulk-Si micromirrors with an integrated tilt sensing mechanism. *J. Micromech. Microeng*. **16**, 463–9.)

base of the cantilever for sensing bending and twisting motions of the mirror corresponding to the two-axis scanning. This scanner uses the normal gauge. The resistance change is generated by the longitudinal piezoresistance effect under normal stress.

Another micromirror integrated with a piezoresistive rotation angle sensor uses the shear piezoresistance effect (Sasaki *et al.* 2006a). The shear gauge measures the transverse voltage generated by the shear piezoresistance effect. The mirror rotation generates shear stress inside the torsion bar. Figure 103 shows the basic structure of the sensor. The sensor consists of an element and two pairs of terminals. One pair is for flowing the sensing current I_s. The other is for detecting the signal of the transverse voltage. The signal V_{out} is expressed as follows:

$$V_{out} = \frac{fW\pi_S\tau}{L} V_S \quad [49]$$

where f is a geometric factor that depends on the shape of the gauge. W and L are the width and length of the sensing element, respectively. τ is the shear stress, which is proportional to the mirror rotation angle. V_s is the voltage for supplying the sensing current I_s. π_s is the shear piezoresistance coefficient. This value depends on the doping type, conductivity, and orientation of c-Si. The sensor is prepared from p-type Si. In the device Si layer, a pn junction is prepared. The top surface is the p-type region, inside which the sensing current is confined. The inset of Figure 103 illustrates the considerable distribution of shear stress inside the torsion bar. The shear stress will be maximum at the top surface.

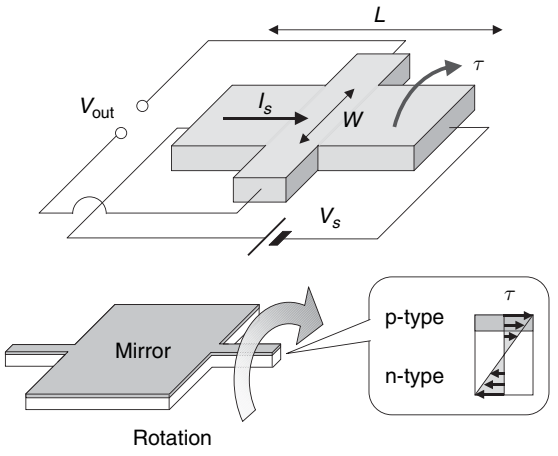

Figure 103 Basic structure of transverse voltage-type gauge for detecting shear stress inside torsion bar for supporting rotating mirror. The inset shows the distribution of the shear stress inside the torsion bar.

Figure 104 shows an embodiment of the combination of a micromirror with a rotation angle sensor. The mirror has through holes, as the study focuses on a proof-of-principle demonstration of the rotation angle sensor simplifying the process. Two sensor structures are included in the left and right torsion bars. The sensing current I_s flows along the torsion bar. The sensor voltage signal is measured through the meandering Si structures without using the metal wiring. These meandering structures have a rotational spring constant that is ~1/10 of that of the torsion bar. The piezoresistance coefficient is known to depend on the crystal orientation. The maximum sensitivity is obtained by aligning the torsion bar along the <100> direction.

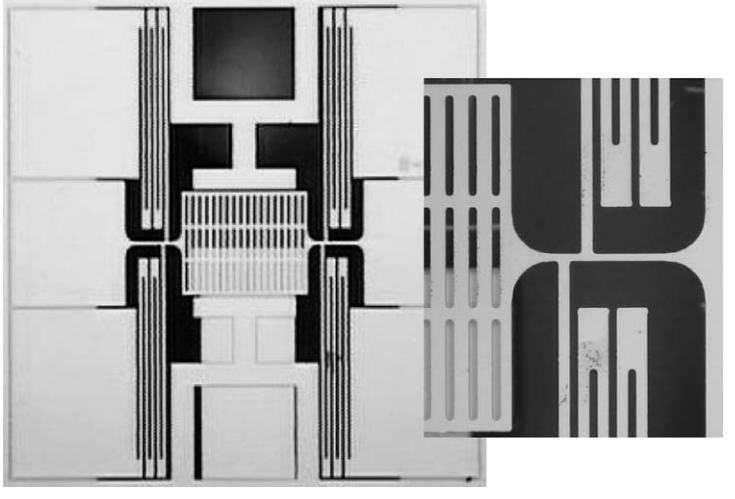

Figure 104 One of fabricated mirror devices. The enlarged image shows the sensor in the torsion bar.

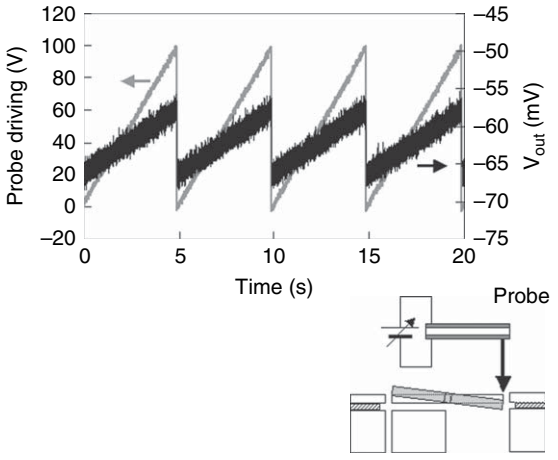

Figure 105 Sensor signal (black) obtained from sensor along <100> direction when mirror is rotated while being pushed by piezoelectric actuator driven by sawtooth wave (gray). The inset shows the experimental setup.

Figure 105 shows a typical signal. The DC sensor signal V_{out} is directly measured using an oscilloscope (input impedance: 1 MΩ) without signal amplification. To increase the sensor signal, a relatively large rotation angle is mechanically introduced by pushing the mirror side using the probe driven by the unimorph piezoelectric actuator, as shown in the inset. The mirror is rotated following the sawtooth wave shown by the gray color. The peak-to-valley of the driving voltage corresponds to 10.2° mirror rotation. The black curve is the sensor signal showing an amplitude of about 10 mV. This signal shows the same sawtooth waveform indicating the linear relation with the mirror rotation angle. Taking advantage of the orientation dependence of the piezoelectric coefficent, the torsion bar along the <100> direction can be sensitive to the mirror rotation but insensitive to the shift motion.

3.01.7.3 Lightweight Flat Mirror

The base micromirror structure can be prepared from the Si structure. The Si layer has little stress (it is known to have slight compress stress) in the SOI wafer. As for the poly-Si film used in surface micromachining, the film stress is known to decrease to nearly zero when poly-Si film (on the Si substrate) is annealed at high temperature (e.g., >1100°C, 30 min) (Guckel *et al.* 1988). However, the micromirror usually needs the metal coating for high reflectivity. In general, the deposited film has stress. The stress

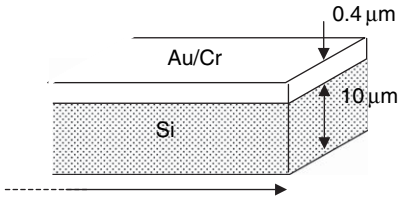

Figure 106 Schematic drawing of the cross section of the micromirror.

control becomes important for decreasing the bending of the structure.

As the simplest example, consider the two-layer structure. Figure 106 shows the cross-sectional view of the model. The substrate layer is assumed to have no stress. The structure is supposed to be a long beam having the same width. The bending moment M, which generates the deflection, is expressed as the sum of two factors.

$$M = \frac{t_f + t_s}{2}\left\{\frac{\sigma}{E_p\left(\frac{1}{E_f w_f} + \frac{1}{E_s w_s}\right)} + \frac{(\alpha_s - \alpha_f)\Delta T}{\frac{1}{E_f w_f} + \frac{1}{E_s w_s}}\right\} \quad [50]$$

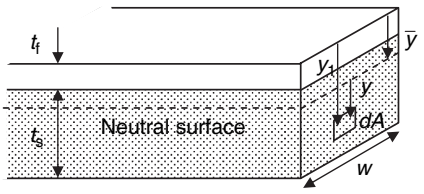
Subscripts f and s show the top film and substrate layer. σ is the intrinsic stress inside the film, E is the Young's modulus, ΔT is the temperature change, w and t are the width and thickness of the layer, respectively, and α is the coefficient of thermal expansion. When the temperature changes, the cantilever deflects generating the moment. This is the mechanism used in the thermal actuator. For making the following discussion simpler, assume ΔT to be negligible. When the beam (or mirror) length is long compared to its deflection, the deflection of the beam can be calculated using the following equation:

$$\frac{d^2 y}{dx^2} = -\frac{M}{EI} = -\frac{1}{R} \quad [51]$$

$$y = -\int\int \frac{M}{EI}\,dx\,dx + C_1 x + C_2 \quad [52]$$

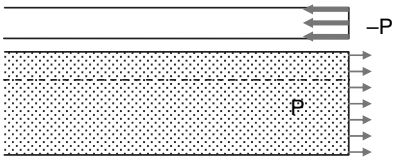
where R is the radius of curvature of the beam and I is the moment of inertia counting the neutral surface.

The position of the neutral surface $\bar{y}$ is decided from the balance of stress requiring the condition that the sum of the stress is 0 over the cross section of the beam. The position y is usually measured from the top surface.



$$\bar{y} = \frac{\sum_i E_i \int_{\text{Area } i} y_i \, dA_i}{\sum_i E_i A_i} = \frac{1}{2} \cdot \frac{E_f t_f^2 + E_s \{(t_f + t_s)^2 - t_f^2\}}{E_f t_f + E_s t_s} \quad [53]$$

The virtual film force P is introduced into the layers. For example, the film under the tensile stress is considered to be fixed to the substrate being pulled with P. In the center, the substrate layer is considered to be fixed to the film being pushed with P. The moment M generated by the force P can be calculated as follows:



$$M = M_f + M_s = w \int_{-\bar{y}}^{t_f - \bar{y}} \frac{-P}{w t_f} y \, dy + w \int_{t_f - \bar{y}}^{t_f + t_s - \bar{y}} \frac{P}{w t_s} y \, dy$$
$$= \frac{1}{2}(t_f + t_s) P \quad [54]$$

The value P can be obtained by the condition of continuity of the stain at the interface. This can be expressed as follows:

$$\frac{\sigma}{E_f} + \alpha_f \Delta T + \frac{P}{E_f w t_f} + \frac{y_{\text{interface}}}{R} = \alpha_s \Delta T - \frac{P}{E_s w t_s} + \frac{y_{\text{interface}}}{R} \quad [55]$$

From eqns [54] and [55], the value of the moment expressed by eqns [50] is obtained.The radius of curvature R can be expressed using eqn [51].

$$R = \frac{\sum_i E_i I_i}{M} \quad [56]$$

The moment of inertia I is counted form the neutral surface. So, the contributions from film layer I_f and substrate layer I_s can be expressed as follows:

$$I_f = w \int_{-\bar{y}}^{t_f - \bar{y}} y^2 \, dy = \frac{w}{3} \{(t_f - \bar{y})^3 - (-\bar{y})^3\} \quad [57]$$

$$I_s = w \int_{t_f - \bar{y}}^{t_s + t_f - \bar{y}} y^2 \, dy = \frac{w}{3} \{(t_s + t_f - \bar{y})^3 - (t_f - \bar{y})^3\} \quad [58]$$

Using the above values, the radius of curvature is obtained as follows:

$$R = \frac{E_f \frac{w}{3} \{(t_f - \bar{y})^3 + \bar{y}^3\} + E_s \frac{w}{3} \{(t_s + t_f - \bar{y})^3 - (t_f - \bar{y})^3\}}{M} \quad [59]$$

For the calculation in this chapter, the values in **Table 9** are used.

Table 9 lists reported values of residual stress (Lammel *et al.* 2002). Au/Cr film is for increasing the reflectivity. With the deposition condition, the film stress may be further decreased. Au is frequently used as it is resistant against HF etching. Au/Cr film generates tensile stress. The maximum bending $y_{\max}$ of peak-to-valley deflection is the difference of the deflection from the center to the edges.

$$y_{\max} = \frac{L^2}{8R} \quad [60]$$

where L is the length of the beam (or mirror). Assuming a base Si layer thickness of 10 μm, the bending profile is calculated. **Figure 107** shows the result. The values of E are the ones averaged for different materials and crystal orientations. Because the beam has a uniform bending moment M and a radius of curvature R, the larger mirror generates the larger deflection depending on the factor of L^2. One method for decreasing $y_{\max}$ is dividing one mirror into segments, making it into a mirror array. The gray curve shows such an example setting with the same value for R. Remember that the allowable deformation of the mirror is expressed by eqn [17]. The tolerance for the stress control and the available material will be wider in the segmented mirror. As for

Table 9 Reported values of residual stress of films

	σ (Mpa)	ρ (kg m^{-3})	E (Gpa)	Note
Au/Cr	325	–	265	$t = 0.4$ μm (Au 0.03 μm, Cr 0.37 μm), average of Au 78 GPa, Cr 280 GPa

the image, the mirror array architecture includes sharp transitions between pixels.

Figure 108(a) shows an example of a small micromirror array for the wavelength add-drop switching developed by Lucent Technologies (Ford *et al.* 1999). The focused light beam is incident on this mirror. The mirror has 3 nm of Cr, followed by 50 nm of Au onto the poly-Si layer. This composition is decided taking into consideration the lower stress. **Figure 108(b)** shows the mirror surface profile. The top is a gray map, indicating the two cross sections below. The curvatures of the cross sections indicate that the stress-induced sag is 20 nm across the full 57 μm size. This is $<\lambda/20$ for the optical communication wavelength of 1.55 μm.

If a single large micromirror is indispensable for the application, the controllable parameter is the substrate thickness t_s in eqn [48]. **Figure 109** shows the three curves changing the substrate thickness. The profile of $t_s = 3.5$ μm is an example of when the micromirror is prepared by the surface micromachining (the radius of curvature is ~4.3 mm). It is clear that the thin Si film easily deflects over $\lambda/4$. For suppressing the deflection $<\lambda/4$, assuming the wavelength to be that of visible light, a substrate thickness of at least ~30 μm will be necessary. The VOA mirror (diameter of 950 μm) from Santec Corporation has a Si thickness of 30 μm. The micromirror from Fujitsu has a Si thickness of 100 μm with the radius of curvature being <30 nm.

Another method for compensating the mirror deflection is depositing additional coatings for canceling the deflection. There is a combination for achieving optical flatness as well as high reflectivity simultaneously (Cao *et al.* 2001). This curvature compensation is possible with a single additional coating layer or with multiple numbers of coating layers. **Figure 110** shows an example before

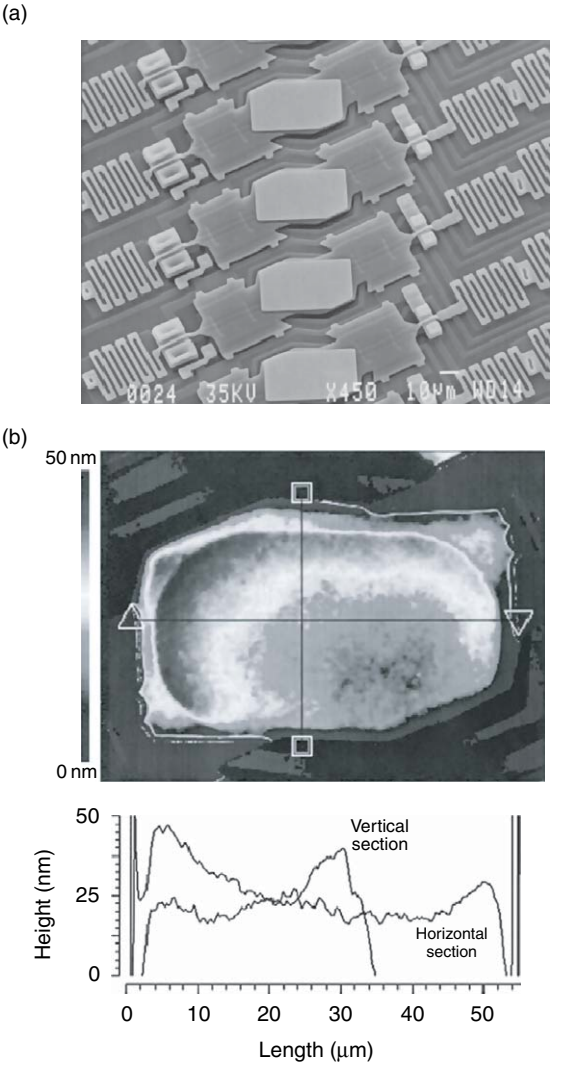

Figure 108 (a) Scanning electron microscope (SEM) image of the gold-coated tilt-mirror array for wavelength add-drop switching prepared by poly-Si surface micromachining. (b) Surface profile of mirror. (Source: Ford J E, Aksyuk V A, Bishop D J, Walker J A 1999 Wavelength add-drop switching using tilting micromirrors. *J. Lightwave Technol.* **17(5)**, 904–11.)

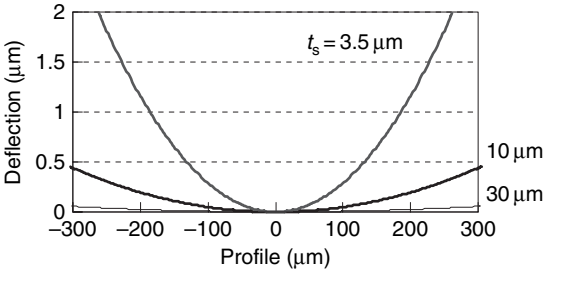

Figure 109 Calculated deflection of the gold-coated micromirror changing the base Si layer thickness.

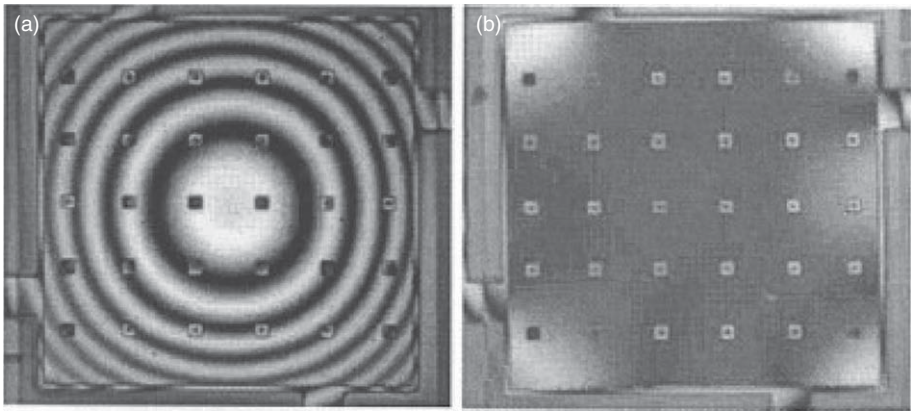

Figure 110 Interferometric images of micromirror (a) before and (b) after the flattening with multilayer deposition of dielectric films. (Source: Cao K, Liu W, Talghader J J 2001 Curvature compensation in micromirrors with high-reflectivity optical coatings. *J. Microelectromech. Syst.* **10(3)**, 409–17.)

(**Figure 110(a)**) and after (**Figure 110(b)**) flattening of the micromirror. Plasma-enhanced chemical vapor deposition is used for coating seven layers of additional SiO_2 and SiN films. The mirror is a $200\,\mu m \times 200\,\mu m \times 3.5\,\mu m$ poly-Si plate with gold film. The images correspond to zero and 175-nm dielectric thickness of top SiO_2 film, respectively. The center-to-edge deflection of the mirror before flattening is 2 μm while that of the flattened mirror is ~45 nm. It must be taken into account that the metal film begins to behave plastically at strains on the order of tenths of a percent. This behavior causes the curvature of a mirror to deviate from the simple prediction. The result shown in **Figure 110** uses the strain of the metal found empirically versus the thickness of dielectric film. As seen from the simple case of eqns [50] and [51], the radius of curvature of the mirror has the sensitivity against the temperature. The technique using the compensation coatings is also applicable for obtaining thermally invariant mirrors (Liu and Talghader 2002).

Although a thicker Si layer is a simple practical solution, there is a trade-off with the resonant frequency. The resonant frequency decreases due to the increase of inertia as expressed by eqn [27]. The flat mirror with the low inertia is ideal. The lightweight flat mirror is prepared by depositing thin films with tensile stress. **Figure 111** shows an embodiment of the

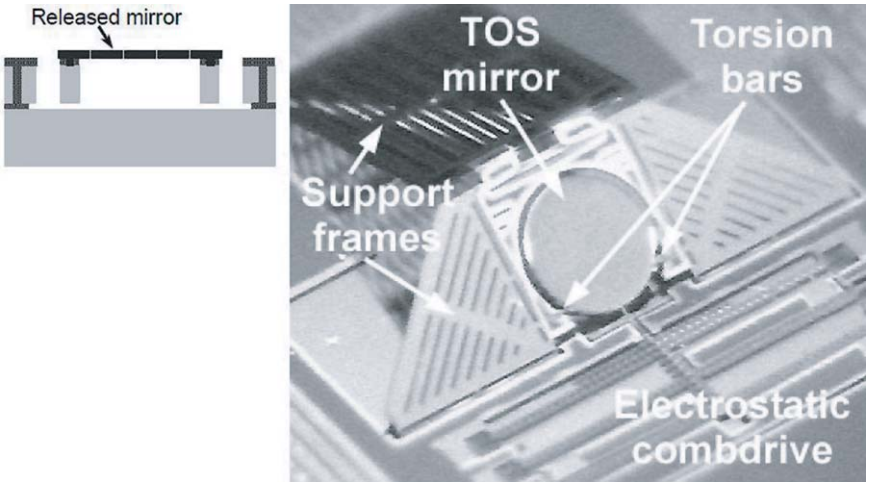

Figure 111 A tensile optical surface micromirror device after release and assembly. The mirror diameter is 550 m. (Source: Nee J T, Conant R A, Lau K Y, Muller R S 2000 Stretched-film micromirrors for improved optical flatness. *Proc. IEEE 13th Annu. Int. Conf. Micro-Electro-Mechanical Systems*, Miyazaki, Japan, pp. 704–9.)

reinforced mirror microstructure reported (Nee *et al.* 2000). A poly-Si membrane is stretched across a rigid c-Si cylinder preparing a drum structure. The tensile stress increases the stiffness of the mirror without increasing its mass significantly. The tensile film gives a flatter surface compared to that given by a standard poly-Si film. The central portion of the mirror is relatively flat (<500 nm deformation over 70% of the cross section).

The mirror with the structure of a honeycomb core is prepared for decreasing the inertia maintaining the solid faceplate as shown in **Figure 112** (Patterson *et al.* 2000). The honeycomb structure consists of c-Si hexagonal cells with sides of 100 μm and wall thickness of 10 μm. These honeycombs are prepared using the timed DRIE from the Si layer of the SOI wafer such that a thin layer remains for forming the mirror face. The two SOI wafers are fusion bonded. **Figure 113** shows the image of the fabricated mirrors. The bonded micromirrors with honeycomb structures (450 μm × 450 μm) show the radius of curvature of >1 m, which is as large as that of the solid mirror.

Timed DRIE can be applied to the SOI micromirrors using a simpler method. **Figure 114** shows two micromirrors (Milanovic *et al.* 2001) described recently. **Figure 114(a)** is the image from the backside of the mirror surface. **Figure 114(b)** is the image from the frontside of the mirror. The mass reduction is carried out from the backside.

3.01.8 Summary

The representative micromirror devices are described focusing on the optical performance. The potential of the micromirror can be seen from the established works and the progress. The micromirror is an advantageous tool for controlling light with high contrast in a small space. The commercial success of DMD from Texas Instruments is well known. This does not mean that DMD has the quality of satisfying

all the specifications required in general optical applications. Digital light processing is a method for avoiding the disadvantage of the inaccuracy of the rotation angle. Because the display is the application of a man–machine interface, the fast modulation that cannot be detected by the human eye can be allowed. If the device is supposed to work in the core of machines combining with other systems, the required performance of the micromirror will be rather strict. The OXC in the optical network is one such example. A higher accuracy of the mirror rotation angle and higher mirror quality are required. In case of the 238×238 OXC and the optical setup reported from Lucent Technologies, the accuracy of the micromirror rotation angle is estimated to be 0.04° for realizing the reported insertion loss of 0.15 dB (Aksyuk *et al.* 2003). This is the high quality for the micromirror, but the bulk galvanometric scanner guarantees the higher accuracy as shown in **Table 4**. The micromirror is aided with the tolerance generated by the optical setup. OXCs from Calient Networks or Fujitsu Laboratories are now being used in telecommunication networks. VOA from Santec realizes the large attenuation with the long optical arm increasing the change generated by the small mirror rotation angle. GLV is being used in the next generation CTP machines. The parallel light modulator that can deal with the high-power laser beam matches the market. There is still plenty of room for further development. If a higher performance is realized in the micromirror itself, a wide range of applications is possible. In 2006, the mirror array for maskless lithography and the micromirror for laser display were under research. Maskless lithography requires displacement accuracy at the subwavelength level. This has to be satisfied with a large number of mirror arrays. The laser display requires a higher scanning rate with the flat mirror surface having a large diameter. These are projects that are near commercialization. Integrations with ICs, sensors, or other optical elements are well-recognized directions of the technology. These are the longer-term perspectives. The performance of the micromirror will be stabilized realizing the advantages of higher reliability and functionality, and the lower assembly cost as in the case of ICs.

As described, there are many complications in designing and developing micromirrors. The balance of the performances depends on the applications. Nowadays, the developments regarding devices or systems are carried out rather independently. The systematic organization of the problems from the established works is important. In this chapter, the classification of some common problems is discussed. The research based on the systematic organization of the technology will clear the future direction.

Biographies

Minoru Sasaki received the M.S. and Dr. Eng. degrees from Nagoya University in 1993 and 1995, respectively. In 1996, he was a Research Fellow of the Japan Society for the Promotion of Science. From 1997 to 2007, he worked as a member of the Department of Nanomechanics, Tohoku University. Since 2007, he has been a professor of the Department of Advanced Science and Technology, Toyota Technological Institute, and is currently engaged in the research on Optical MEMS including three-dimensional lithography.

Kazuhiro Hane received the M.S. and Dr. Eng. degrees from Nagoya University in 1980 and 1983, respectively. From 1983 to 1994, he worked as a member of the Department Electronic-Mechanical Engineering, Nagoya University. From 1985 to 1986, he was a guest researcher of National Research Council of Canada. Since 1994, he has been a professor of the Department of Nanomechanics, Tohoku University, and is currently engaged in the research on microsensors and opto-mechanical systems.

3.02 Diffractive and Defractive Micro-optics

Stefan Sinzinger, Technische Universität Ilmenau, Ilmenau, Germany

Nomenclature

$\tilde{\boldsymbol{A}}(\nu)$	Array factor of a diffraction grating	$\boldsymbol{d}$	Distance between the electrodes of a capacitor
$\boldsymbol{a}$	Extension of an image formed by the individual microlenses of a microlens array	$\delta(\boldsymbol{x})$	δ distribution
α	Parameter describing a GRIN profile	ε, ε_1, ε_2	Dielectric constants of different materials
$\alpha_{\mathbf{diff}}$, $\Theta_{\mathbf{d}}$	Diffraction angles	$\varepsilon_\perp$, $\varepsilon_{\|\|}$	Dielectric constants of different planes of polarization
$\boldsymbol{C}$	Capacitance	λ, λ_1, λ_2	Wavelength
$\boldsymbol{D}$	Diameter of a microlens	ν_x, ν_y	Spatial frequencies
Δ	Size of a pinhole	$\boldsymbol{F}$, $\boldsymbol{f}$	Focal lengths
		$\tilde{\boldsymbol{F}}(\nu)$	Form factor of a diffraction grating

$g(x)$	Complex transmission function of a diffraction grating
$\tilde{G}(\nu)$	Fourier transform (diffraction amplitudes) of a diffraction grating
γ_{sl}	Surface energy of a surface–liquid interface
h	Sag of a lens
k	Propagation vector of an optical wavefront
l, Δl	Physical path lengths
n, $n(\lambda)$, $n(x)$	Refractive index
NA	Numerical aperture
N_F	Fresnel number
p, $p_{microlens}$, $p_{pinhole}$	Period of a grating, pitch of a microlens, and pinhole
R, r	Distance vector, radius
r_C	Radius of curvature
t	Thickness of a diffraction grating
$T_{element}$, T_{prism}, T_{lens}	Complex transmission function of optical elements
u	Aperture angle
U	Voltage
$U(x, y, z)$	Complex amplitude of a wave field
V_0	Voltage applied to a liquid crystal microlens
V_{cyl}, V_{cap}	Volume of specific elements
w_{min}	Minimum feature size
w	Width of a grating bar
X_C	Complex resistance of a capacitor
X_R	Complex resistance of a resistor
x, y, z, x_0, y_0, z_0	Spatial coordinates
z_T	Talbot distance

Glossary

Active microlenses Microlenses with actively controlled optical performance

CGH Computer-Generated Hologram; diffraction grating designed numerically for the generation of a specific diffractive behavior

Chirped microlens array Array of microlenses with locally varying optical properties

Diffraction limit The best performance one can expect from optical elements or systems due to diffraction at the physical aperture; aberrations are small enough to be neglected

Diffractive lens Diffraction grating with spherical symmetry, designed to collimate or focus an incoming wavefront

DOE Diffractive Optical Element, a microstructured optical element designed for a specific performance in the diffraction plane

Electrowetting Change in the wetting angle of polar liquids by application of electric fields

FOV Field of View; the angular range in which an optical system provides good imaging

Fraunhofer diffraction Far-field diffraction; the relation between the object amplitude distribution and the diffracted wavefront is calculated by a Fourier transform

Fresnel diffraction Near-field diffraction; the relation between the object amplitude distribution and the diffracted wavefront is calculated by a Fresnel transform

Fresnel number Number of Fresnel rings within an aperture determined by the curvature of the wavefront inside the aperture

GRIN microlenses Gradient index microlenses

Huygens' principle Explanation of the phenomenon of diffraction by propagation of elementary spherical waves interfering to form the respective complex diffracted wavefronts

Kirchhoff diffraction integral Mathematical formulation of the Huygens' principle

Liquid microlens Microlens fabricated of liquid material enclosed by a flexible membrane-like material; by deformation of the container, the optical properties of the lens can be tuned

OPL Optical path length; physical path length scaled with the refractive index of the medium through which the light propagates

Photon sieve Specific type of diffractive lens consisting of a number of holes in a nontransparent screen

PSF Point Spread Function; distribution of the image of a single object point in the image plane

Reflow microlens Microlens fabricated by melting photoresist

SBP Space-Bandwidth Product; the number of resolvable points (pixels) in an optical image

Scalar diffraction theory Approximation to the rigorous diffraction by neglecting the vectorial character of light (polarization); diffraction in the scalar domain is described by the Kirchhoff diffraction integral

Talbot effect Self-imaging effect of optical signals with lateral periodicity; an optical wave field with lateral periodicity also shows longitudinal periodicity

TEA Thin Element Approximation; in the TEA the interaction of a wavefront with an object takes place in a single plane; multiple interactions are neglected

Thick diffraction grating grating described by Bragg reflection; holographic grating

Zero-order grating High-frequency diffraction grating (periods smaller than the wavelength) with only one propagating diffraction order (zeroth order); due to the small period all nonzero orders are evanescent

3.02.1 Diffractive Micro-Optics

One of the most prominent effects of wave propagation phenomena, i.e., in our case of light propagation, is diffraction. It is, for example, responsible for the deviation of the propagation direction from the geometrical expectations behind obstacles. The most straightforward way to understand diffraction is the so-called Huygens' principle. The famous Dutch mathematician and physicist Christian Huygens (1629–1695) explained diffraction phenomena by stating that every point of a wavefront (i.e., a plane of equal phase) can be considered as the origin of a spherical elementary wave. After independent propagation, the interference of these spherical waves forms subsequent wave fields (**Figure 1**). In combination with the periodicity of the wave and the laws of interference this principle leads to an understanding of light propagating not only into the geometrical shadow regions behind diffraction objects but also to the discrete propagation directions behind periodic objects called diffraction gratings.

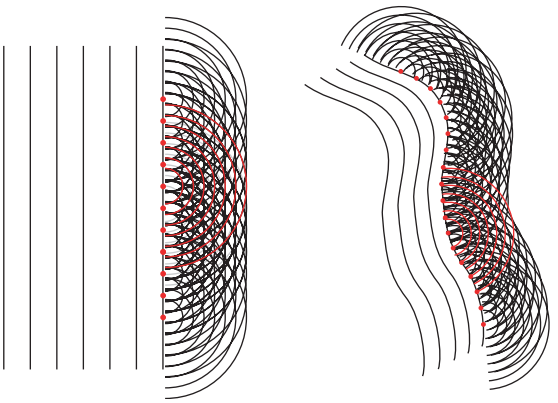

Figure 1 Illustration of the Huygens' principle. Diffraction is explained by the generation of spherical elementary waves propagating independently and interfering to form the diffracted wavefront.

3.02.1.1 Kirchhoff Diffraction Integral and Scalar Diffraction Theory

Mathematically, the Huygens' principle is formulated based on the Kirchhoff diffraction integral (Goodman 1996)

$$U(x, y, z) \propto \frac{\mathrm{i}}{\lambda} \iint U(x_0, y_0, z_0) \frac{\mathrm{e}^{\mathrm{i}|\underline{k}||\underline{r}|}}{|\underline{r}|} \cos\varepsilon \, \mathrm{d}x_0 \mathrm{d}y_0 \quad [1]$$

Here, $U(x, y, z)$ is the wave field at a distance $(z - z_0)$ behind the diffracting plane (x_0, y_0, z_0) with the wave field distribution $U(x_0, y_0, z_0)$; ε is the propagation angle. The term $(\exp(\mathrm{i}|\underline{k}||\underline{r}|))/|\underline{r}|$ represents the spherical wavefronts ($\underline{k}$ is the propagation vector of the wavefront $|\underline{k}| = (2\pi/\lambda)$) which are weighted through the complex amplitude of the incident wave field $U(x_0, y_0, z_0)$ and subsequently added (integrals). This diffraction integral can be derived rigorously by solving the wave equation and the resulting Debye–Sommerfeld diffraction integral, for example, through the method of stationary phase (Lohmann 2006, pp. 111–18).

3.02.1.1.1 Fresnel and Fraunhofer diffraction

The Kirchhoff diffraction integral is the foundation for the scalar diffraction theory where the vector character, that is, the polarization of the light wave, is neglected, and the distance between the plane of observation and the diffracting plane is considered to be much larger than the wavelength. Further approximations lead to the Fresnel and Fourier diffraction integrals, which define the regions of Fresnel and Fraunhofer diffraction. To this end, the distance

vector $|\underline{r}|$ is approximated through the following equation:

$$\begin{aligned}|\underline{r}| &= \sqrt{(x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2} \\ &\approx \underbrace{(z-z_0)\left[1 + \frac{1}{2}\left(\frac{x-x_0}{z-z_0}\right)^2 + \frac{1}{2}\left(\frac{y-y_0}{z-z_0}\right)^2\right]}_{\text{Fresnel approximation}} \\ &\approx \underbrace{(z-z_0)\left[1 + \frac{x^2-2xx_0}{2(z-z_0)^2} + \frac{y^2-2yy_0}{2(z-z_0)^2}\right]}_{\text{Fraunhofer approximation}} \end{aligned} \quad [2]$$

where it has been assumed in the Fraunhofer approximation that $x_0 << x$ and $y_0 << y$, i.e., the extension of the diffraction screen is much smaller than the extension of the observation plane, which is plausible for large distances from the diffraction screen.

The diffraction integrals resulting from the application of these approximations to the Kirchhoff integral are the Fresnel diffraction integral

$$\begin{aligned}U(x, y, z) \approx \frac{i}{\lambda}\frac{\exp(ik(z-z_0))}{z-z_0}\iint U(x_0, y_0, z_0) \\ \times \exp\left(\frac{i\pi}{\lambda(z-z_0)}[(x-x_0)^2 \right. \\ \left. + (y-y_0)^2]\right)dx_0dy_0 \end{aligned} \quad [3]$$

and the Fraunhofer diffraction integral

$$\begin{aligned}U(x, y, z) \approx \frac{i}{\lambda}\frac{\exp(ik(z-z_0))}{z-z_0} \\ \times \exp\left(\frac{i\pi(x^2+y^2)}{\lambda(z-z_0)}\right)\iint U(x_0, y_0, z_0) \\ \times \exp\left(2i\pi\frac{xx_0+yy_0}{\lambda(z-z_0)}\right)dx_0dy_0 \end{aligned} \quad [4]$$

One of the remarkable effects in Fresnel diffraction (eqn [3]) is the so-called Talbot self-imaging. This effect, which is sometimes referred to as Talbot effect directly, results from diffraction theory according to the Fresnel diffraction integral. As such, the term Talbot imaging or self-imaging is rather misleading. For optical elements that exhibit a lateral periodicity (e.g., gratings or microlens arrays), the diffracted field in the Fresnel approximation is periodic also in propagation direction. At specific distances, mz_T, the so-called Talbot distances, behind the periodic object with period p, the structure of the diffraction grating is reconstructed even without any imaging elements applied:

$$z_T = \frac{2p^2}{\lambda} \quad [5]$$

Generally speaking, according to the Talbot effect, a lateral periodicity in the wave field causes a longitudinal periodicity along the direction of propagation. This has important effects such as on the use of array of micro-optical components, for example, of microlens arrays, where it is quite difficult to find the correct focal plane among the periodically replicated planes, which occur due to the Talbot effect. Applications based on the Talbot effect can be found in interferometry (Lohmann 1971), optical interconnects (array illumination) (Lohmann 1988), as well as time domain filtering (Jahns and Lohmann 2004, Jahns *et al.* 2006).

In the case of Fraunhofer approximation (eqn [4]) the distribution in the diffraction plane results from a Fourier transform of the distribution in the diffracting screen.

While the Huygens' principle states that the interference of numerous spherical elementary waves forms the resulting diffracted wave, in the Fresnel approximation, these elementary waves are approximated as parabolic waves. Therefore, the Fresnel approximation is often called the parabolic approximation. If the distance to the observation screen is increased further, the former spherical waves can be approximated as sections of plane waves. Thus, the Fraunhofer approximation can be called plane wave approximation. Effectively, the wave field in the diffracting screen is disassembled into plane wave segments of a certain orientation, i.e., angle with respect to the optical axis. The corresponding orientation results in a specific location in the far-field observation plane. **Figure 2** illustrates this transition from the spherical elementary wave over the parabolic to the plane wave approximation.

3.02.1.1.2 The Fresnel number

Figure 2 illustrates that as the distance from the center of the elementary spherical wave increases, the curvature of the wavefront constantly decreases. Eventually, in the region of the Fraunhofer approximation, the observed section of the spherical wave can be considered a plane wave. This can also be illustrated when calculating the interference between the elementary wavefronts with a plane wave at different distances from the center. **Figure 2** shows that the number of interference fringes (i.e., the so-called Fresnel rings) in the observation aperture, which is a measure of the curvature of the wave, decreases with increasing distance. Thus, this number of fringes, which is called the Fresnel number N_F, can be used to define the diffraction regime according to the definition above. The distance between the fringes (black

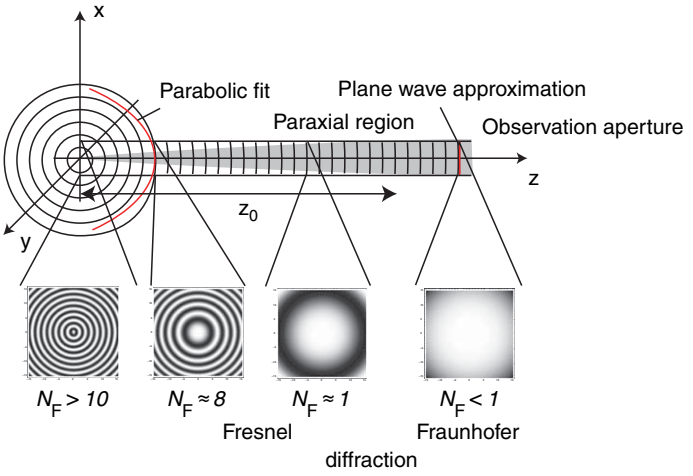

Figure 2 Illustration of the transition between the different diffraction regimes and the significance of the Fresnel number N_F.

and white) in the interference pattern is $\lambda/2$. Thus, in the general case, the Fresnel number N_F can be calculated from the optical path difference (OPD) between a spherical wave and a plane wave

$$N_F \frac{\lambda}{2} = z_0 \sqrt{\frac{x_{max}^2}{z_0^2} + \frac{y_{max}^2}{z_0^2} + 1} - z_0$$
$$\underbrace{\approx z_0 \left(1 + \frac{1}{2} \frac{x_{max}^2 + y_{max}^2}{z_0^2}\right)}_{\text{paraxial approximation}} - z_0$$
$$= \frac{1}{2} \frac{x_{max}^2 + y_{max}^2}{z_0} \Rightarrow N_F = \frac{x_{max}^2 + y_{max}^2}{\lambda z_0} \quad [6]$$

The Fresnel number can also be interpreted as the ratio of the focusing aperture angle (also called the numerical aperture (NA))

$$\sin u \approx \underbrace{u = \frac{x_{max}}{z_0}}_{\text{paraxial appr.}}$$

and the diffraction angle $\Theta_d = \lambda / x_{max}$:

$$N_F = \frac{\sin u}{\Theta_d} \quad [7]$$

or the ratio of the aperture diameter $2x_{max}$ and the diameter of the diffraction limited spot $2\lambda/\sin u$:

$$N_F = \frac{2x_{max}}{\frac{2\lambda}{\sin u}} \approx \frac{2x_{max}}{\frac{2\lambda z_0}{x_{max}}} = \frac{x_{max}^2}{\lambda z_0} \quad [8]$$

In these cases, we limited ourselves to the 1D situation with $y = 0$ without limitation of the generality.

In summary, the Fresnel number is an important measure indicating the ratio of geometrical and diffraction effects on the beam propagation. The Fresnel number is used in the definition of the diffraction regime according to Gross (2005, p. 532) as follows:

$N_F \leq 1 \Rightarrow$ Fraunhofer diffraction regime
$N_F = 1 - 10 \Rightarrow$ Fresnel diffraction regime
$N_F >> 1 \Rightarrow$ Geometrical optics region, diffraction negligible

3.02.1.2 Thin Diffractive Optical Elements

The diffraction integrals in eqns [3] and [4] allow the calculation of the wave propagation through homogenous media in the approximations discussed above. For a comprehensive analysis of the optical functionality of optical systems, we additionally need to discuss the description of optical components. The conceptually simplest consideration of optical elements is known as thin element approximation (TEA), sometimes also called Kirchhoff approximation. The TEA is applicable in scalar diffraction theory. In this case, optical elements are assumed to interact effectively with the incident wave field in only one single plane along the optical axis. Mathematically, the effect of the optical element is then calculated by a simple multiplication of the complex amplitude of the incident wave field with a complex amplitude distribution representing the optical component (Goodman 1996).

$$U(x, y, z + 0) = U(x, y, z - 0) T_{element}(x, y, z) \quad [9]$$

where $U(x, y, z + 0)$ represents the complex amplitude distribution of the wavefront immediately behind the optical element, $U(x, y, z - 0)$ denotes

the complex amplitude distribution in front of the optical element, and $T_{\text{element}}(x, y, z)$ represents the complex amplitude transmission of the optical element. The transmission function $T_{\text{element}}(x, y, z) = A(x, y)\exp(\mathrm{i}\varphi(x, y))$ thus influences the amplitude as well as the phase of the incident wave. For amplitude-only objects (e.g., amplitude gratings) consisting of a more or less absorbing layer, $T_{\text{element}}(x, y, z)$ is real valued. Phase-only functions, on the other hand, are characterized by $A(x, y) = 1$ and a function $\varphi(x, y)$, which defines the shape of the phase profile. Physically, the TEA is a crude idealization because for the modulation of both the amplitude and the phase, a finite physical thickness is required. A specific phase variation, for example, results from a wave traveling through a dielectric material with a specific shape, i.e., thickness variation. A prism, for example, is a wedge of transparent material (refractive index n), while for the lens a plano-convex spherical shape with a radius of curvature R needs to be considered (**Figure 3**). Thus, for the OPD between rays passing through the elements at different positions x, we find for the prism (surrounding medium $n_0 = 1$) (Lohmann 2006):

$$\begin{aligned}\mathrm{OPD}_{\text{prism}}(x) &= (n-1)D(x) = (n-1)x\tan\alpha \\ &\approx (n-1)x\alpha \Rightarrow \varphi_{\text{prism}}(x) \\ &= \frac{2\pi}{\lambda}(n-1)x\tan\alpha \end{aligned} \quad [10]$$

This consideration results in a TEA representation of a prism:

$$T_{\text{prism}} = \exp(2\pi\mathrm{i}(n-1)x\tan\alpha) \approx \exp(2\pi\mathrm{i}(n-1)x\alpha) \quad [11]$$

Similarly for a TEA representation of a spherical lens:

$$T_{\text{lens}} = \exp\left(-\pi\mathrm{i}\frac{(n-1)x^2}{\lambda R}\right) = \exp\left(\pi\mathrm{i}\frac{x^2}{\lambda f}\right), \quad \text{where } f = \frac{R}{(n-1)} \quad [12]$$

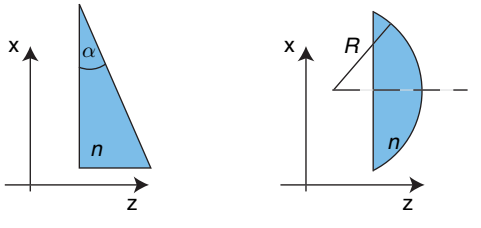

Figure 3 The shape of a prism and a plano-convex refractive lens.

3.02.1.3 Diffraction Gratings

The complex amplitude distribution of periodic diffractive elements (i.e., diffraction gratings) can be expanded in a Fourier series:

$$g(x) = g(x+p) \Rightarrow g(x) = \sum_{m=-\infty}^{+\infty} A_m \exp(2\pi\mathrm{i}m(x/p)), \quad \text{with } A_m = \frac{1}{p}\int_0^p g(x)\exp(-2\pi\mathrm{i}m(x/p))\mathrm{d}x \quad [13]$$

Due to their potentially high efficiency, phase gratings of varying complexity need to be considered. The most general form of a multilevel phase profile is shown in **Figure 4**.

If N is the number of phase levels per 2π phase depth, the transmission function of such a multilevel phase grating can be written mathematically as ($p = 1$) (Jahns 1994):

$$g(x) = \sum_{k=-\infty}^{+\infty} \exp\left(-2\pi\mathrm{i}\frac{k}{N}\right)\mathrm{rect}\left[\frac{x - \frac{k}{N} - \frac{1}{2N}}{\frac{1}{N}}\right] \quad [14]$$

The complex amplitude in the diffraction plane can be calculated by means of a Fourier transform (Fraunhofer diffraction) and is thus represented by the Fourier coefficients A_m as:

$$\begin{aligned} A_m &= \int_0^1 \sum_{k=0}^{N-1} \exp\left(-2\pi\mathrm{i}\frac{k}{N}\right)\mathrm{rect}\left[\frac{x - \frac{k}{N} - \frac{1}{2N}}{\frac{1}{N}}\right] \\ &\quad \times \exp(-2\pi\mathrm{i}mx)\mathrm{d}x \\ &= \exp\left(\mathrm{i}\pi\frac{m}{N}\right)\mathrm{sinc}\left(\frac{m}{N}\right)\frac{1}{N}\sum_{k=0}^{N-1}\exp\left(-2\pi\mathrm{i}\frac{k(m+1)}{N}\right) \\ &= \begin{cases} \exp\left(\mathrm{i}\pi\frac{m}{N}\right)\mathrm{sinc}\left(\frac{m}{N}\right) & \text{if } m = jN-1,\ j \text{ is an integer} \\ 0 & \text{else} \end{cases} \end{aligned} \quad [15]$$

The A_m represent the complex amplitudes of the diffraction orders of the grating where

$$\mathrm{rect}[x] = \begin{cases} 1, & \text{if } x < 0.5 \\ 0, & \text{else} \end{cases}$$

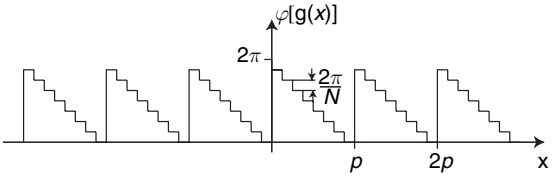

Figure 4 The shape (phase profile) of a multilevel diffraction grating. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

is the rectangular function and

$$\mathrm{sinc}(x) = \frac{\sin(\pi x)}{\pi x}$$

The diffraction angles under which these diffraction orders of a thin diffraction grating appear can be calculated from the important relation:

$$\sin\alpha_{\mathrm{diff}} = m\frac{\lambda}{p} + \sin\alpha_{\mathrm{inc}}, \quad m = 0, 1, 2, 3, \cdots, \quad [16]$$

here, α_{diff} and α_{inc} are the diffraction angle and the angle of incidence of the light beam on the grating, respectively.

Thus, in the scalar diffraction theory (eqn [15]), we find that for a linear phase grating with only N phase steps, every Nth diffraction order has a nonzero diffraction amplitude. If only one diffraction order (here A^{-1}) is considered for the optical functionality, it is obvious that the efficiency of this diffraction amplitude can be significantly larger if the number of phase steps is increased. In other words, the number of undesired stray orders can be reduced significantly by increasing the number of phase steps N per 2π. This is illustrated in **Figure 5**.

More generally diffraction gratings consist of a possibly complex structure ($f(x)$), which is replicated periodically (period length p). Thus, the transmission function of a diffraction grating with Q periods can be written as:

$$g(x) = \sum_{n=-\frac{Q}{2}}^{\frac{Q}{2}} f(x+np) = f(x) * \sum_{n=-\frac{Q}{2}}^{\frac{Q}{2}} \delta(x+np),$$
$$\text{where } f(x) \neq 0 \text{ only in } \left[-\frac{p}{2}, \frac{p}{2}\right] \quad [17]$$

Here, $*$ denotes the convolution operation and $\delta(x)$ is the so-called δ distribution:

$$\delta(x) = \begin{cases} +\infty, & \text{if } x = 0 \\ 0, & \text{else} \end{cases} \quad \text{and} \quad \int \delta(x)\mathrm{d}x = 1 \quad [18]$$

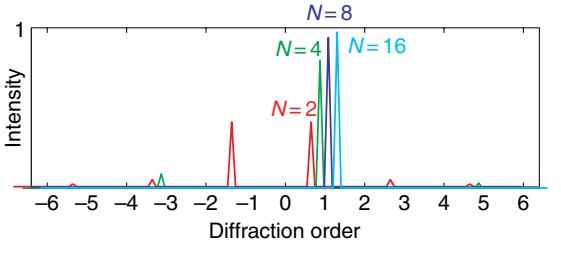

Figure 5 Diffraction amplitudes of phase gratings with varying numbers of phase levels (N).

The Fraunhofer diffraction distribution $\tilde{G}(\nu)$ of such a grating is calculated by a Fourier transform of $g(x)$

$$\tilde{G}(\nu) = \int g(x)\exp(-2\pi i\nu x)\mathrm{d}x = \tilde{F}(\nu)\tilde{A}(\nu),$$
$$\text{where } \tilde{A}(\nu) = \int \sum_{n=-\frac{Q}{2}}^{\frac{Q}{2}} \delta(x+np)\exp(-2\pi i\nu x)\mathrm{d}x$$
$$= \sum_{n=-\frac{Q}{2}}^{\frac{Q}{2}} \exp(-2\pi i\nu(x+np)) \quad [19]$$

In this case $\tilde{F}(\nu)$ is called the form factor since it exclusively depends on the shape $f(x)$ of the individual periods. $\tilde{F}(\nu)$ is calculated as the Fourier transform of $f(x)$. $\tilde{A}(\nu)$ is called the array factor, which has its origin in the periodicity of the diffraction grating. For a large number of periods Q, $\tilde{A}(\nu)$ again becomes an array of δ peaks with a spacing $1/p$. The smaller the number of effective periods, the wider is the extension of the individual diffraction orders, which is a typical phenomenon of multiple beam interference. Thus, the shape of the individual periods forms an envelope for a discrete array of diffraction orders generated due to the periodic structure of the grating (**Figure 6**). This is to say that in the diffraction plane the form factor $\tilde{F}(\nu)$ is sampled by the discrete array of δ peaks with distances proportional to $1/p$. If only a finite number of periods of the diffraction grating are illuminated, the sampling peaks can be described by a series of peaks with finite width, e.g., approximated by the sinc function $\sin(\pi x)/\pi x$ (Lohmann 2006).

3.02.1.4 Zero-order Gratings and Form Birefringence

According to eqn [16] a reduction in the size of the grating period leads to larger diffraction angles. Thus, the number of propagating diffraction orders (with $\sin(\alpha) < 90°$) and stray orders can be reduced with decreasing grating period (**Figure 7**). This leads to an increase in the diffraction efficiency. If the grating period is on the order of wavelength λ or smaller, even the diffraction angles of the first diffraction orders ($m = \pm 1$) reach 90°. As a result, even these first diffraction orders are converted into so-called evanescent waves. These evanescent waves are not propagating like conventional wavefronts but they are merely electromagnetic field distributions existing along the grating surface whose strengths decrease rapidly as the

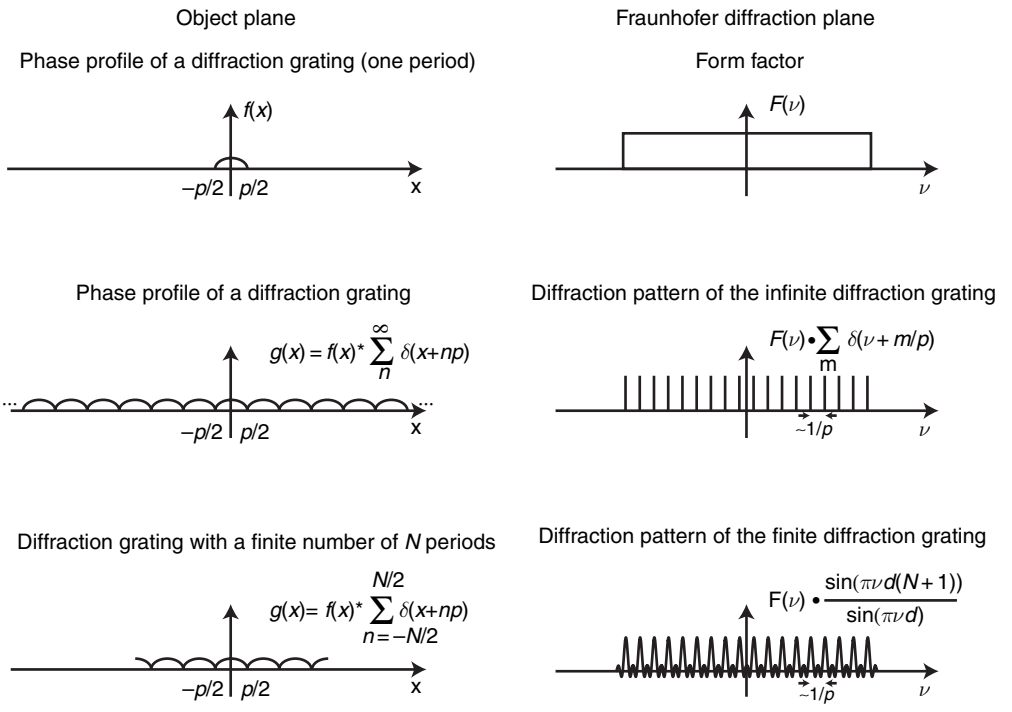

Figure 6 Illustration of the form factor and the array factor of a diffraction grating (here a microlens array).

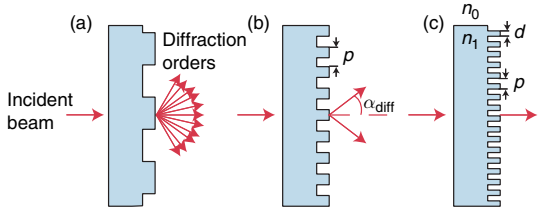

Figure 7 Diffraction orders of gratings with different period sizes. (a) $p >> \lambda$ (scalar theory); (b) $p \sim \lambda$ (rigorous diffraction theory); and (c) zero-order grating: $p < \lambda$ (effective medium theory).

distance from the grating surface increases (Lohmann 2006, pp. 163–8). Without elaborating on the extremely interesting physical background of these evanescent fields, we would like to point out their significance for near-field and waveguide optics (Saleh and Teich 1991). If the far field of such a high-frequency grating is considered, only the zeroth order can be observed as a propagating order. Even though the zeroth order is not deflected through the diffraction at the grating, the grating has an important influence on the propagation. Depending on the duty cycle w/p of the grating, i.e., the ratio between the grating period p and the width of the grating bar w, the propagating zeroth order experiences a refractive index whose value is between the value of the grating material and the surrounding medium. In the approximation of the effective medium theory, the propagating zeroth order experiences a dielectric medium with dielectric constants $\varepsilon_\perp$ and $\varepsilon_{||}$, or refractive indices $n = \sqrt{\varepsilon}$. Obviously, the optical properties depend on the orientation of the polarization with respect to the grating orientation (Born and Wolf 1980):

$$\varepsilon_{||} = \varepsilon_1 \frac{w}{p} + \varepsilon_2 \left(1 - \frac{w}{p}\right); \quad \varepsilon_\perp = \frac{\varepsilon_1 \varepsilon_2}{\varepsilon_2 \frac{w}{p} + \varepsilon_1 \frac{p-w}{p}} \quad [20]$$

This rather crude approximation shows the possibility to influence the optical properties of materials through subwavelength micro- or nanostructuring. It is possible to generate materials with specific refractive indices as well as birefringence (the so-called form birefringence) (**Figure 8**). This has become well known as the possibility to tailor optical properties through micro- and nanostructuring and leads to the field of photonic crystals (Joannopoulos and Meade 1995, Kraus and De La Rue 1999).

3.02.1.5 Thick Diffraction Gratings – Holographic Optical Elements

An alternative way of improving the diffraction efficiency of diffraction gratings is through the implementation of thick gratings, for example,

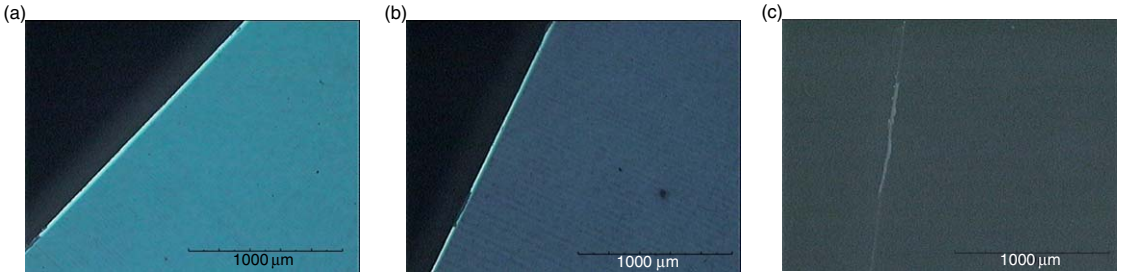

Figure 8 Anisotropy induced in isotropic materials through microstructuring: The pictures, taken from a polariscope, show the anisotropy of a diffraction grating (period 840 nm) replicated in poly(methyl methacrylate) (PMMA). The grating is introduced between two polarizers oriented perpendicular to each other. Then the grating is rotated around the optical axis. The pictures show the output when the grating structures are aligned at an angle of (a) 45°, (b) 60°, and (c) 80° relative to the axes of the polarizers. Due to the anisotropic properties of the grating (form birefringence) the plane of polarization of the incident wavefront is rotated depending on the orientation of the grating. Thus the portion of the light passing the analyzer depends on the grating orientation.

through holographic recording in optically thick photographic material. While in thin optical elements, the light is considered to interact with the elements just one single time, in thick optical elements multiple interactions with the element have an important influence on the optical functionality. As shown in **Figure 9**, due to the multiple interactions with the thick periodic structure, the Bragg effect results in an efficient additional interference filter, which is combined with the thin element. This Bragg filter is designed such that it selects precisely one of the diffraction orders, which would be generated by a thin grating of the same period. The Bragg grating can be considered as a stack of alternating layers with high and low refractive indices. The thickness of each of these layers is $p/2$, if p is the period of the holographic interference grating. By calculating the path difference Δl between two rays reflected at the high and low refractive index layer, respectively, the condition for a ray to be reflected at such a stack layer can be derived, i.e., to interfere constructively at the respective angle:

$$\Delta l_{\text{opt}} = 2\frac{p}{2}\sin\alpha_{\text{stack}} = \frac{\lambda}{2} \Rightarrow p = \frac{\lambda}{2\sin\alpha} \qquad [21]$$

Here, an additional phase shift of π, taking place when the beam is reflected at the higher refractive index layer, was taken into account (the refractive indices of the different layers were neglected). It is interesting to point out that an identical relation results from the calculation of the period of the sinusoidal interference fringes resulting for the interference of two wavefronts propagating at a relative angle of α. Thus, we understand that once these interference fringes are recorded in a holographic material and are illuminated by either of these wavefronts, the second wavefront is automatically reconstructed as a diffraction pattern (Solymar and Cooke 1981). This is the fundamental concept of diffraction. In the context of diffraction gratings, it is important to note that as multiple beam interference occurs at these optically thick Bragg gratings, very efficient diffraction gratings can be fabricated. For a detailed analysis of thick holographic gratings, rigorous solutions to the diffraction problem in periodic media need to be found (Petit 1980). One of the successful approaches to this type of problem is the so-called coupled wave theory (Knop 1978).

The transition from the case of Bragg reflection at thick gratings to the approximation of thin diffraction gratings that generate a significant number of diffraction orders can also be described with rigorous diffraction theory. This is possible for the assumptions that the light beam is incident parallel to the

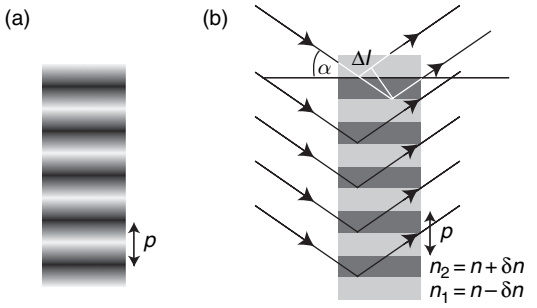

Figure 9 (a) Thick volume gratings generated by a holographic interference grating; (b) Bragg reflection at the multilayer stack modeling the holographic grating. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

Bragg reflecting layers (i.e., $\alpha = 0$ in **Figure 9** and thus the Bragg condition is clearly violated) and that the variation of the electric field in y-direction can be neglected. In this case, the well-known grating equation for directions of the diffraction orders can be derived:

$$\sin \alpha_{\text{diff}} = m\frac{\lambda}{p}, \; m \text{ is an integer} \qquad [22]$$

This regime is called Raman–Nath diffraction named after the Indian scientists who suggested the theoretical approach for the diffraction of light at acousto-optical waves (Solymar and Cooke 1981).

This Bragg filtering effect being based on the principle of multiple beam interference becomes more and more selective when more layers of the multilayer stack are effectively involved in the propagation of light through the element. Thus, the effect of thickness also gradually becomes more important with larger diffraction angles (since in this case the number of interfering beams increases due to the effectively increasing thickness of the stack) and the larger the physical thickness of the element. There is no strict limit as to when scalar diffraction theory is valid and when the gratings can be approximated as thick Bragg gratings. As a rule of thumb the ratio between the physical thickness t and the grating period p can be used for approximation of the validity of the approximations (Caulfield 1979):

$$\underbrace{\left(\frac{t}{p}\right)_{\text{thick}} > 10}_{\text{Bragg approximation}} \cdots \underbrace{1 > \left(\frac{t}{p}\right)_{\text{thin}}}_{\text{scalar approximation}} \qquad [23]$$

In the region in between those two extreme cases of thick and thin diffraction gratings, none of the two approximations is valid to a sufficient precision. In this case, rigorous methods for the calculation of the diffraction amplitudes have to be applied. Various methods for a rigorous solution to the diffraction problem have been suggested, which we cannot elaborate on in this context. It is important to note that scalar theory does correctly predict the propagation directions of the diffracted beams. However, for a precise analysis of the diffraction amplitudes, a rigorous calculation becomes necessary in many cases.

3.02.1.6 Specific Diffraction Gratings and Applications

The biggest potential applications of diffractive optical elements (DOEs) lies in the possibility to fabricate very compact and lightweight components and systems with complex functionality. This becomes possible because of the periodicity of the optical wave field, which allows one to reduce the thickness of the diffractive components to an optical thickness of one wavelength. With a subsequent quantization step, the structure of a binary or multilevel phase grating can be derived directly from this consideration (**Figure 10**). Despite this very clear and straightforward transition from the conventional refractive component to the corresponding diffractive element, there are very significant consequences on functional principle as well as on the fabrication process.

The physical parameter that determines the optical functionality of refractive components is the shape of the refractive surface profile. This shape eventually determines the angle of incidence of the beam onto the refracting boundaries and thus, together with the refractive indices, the refraction angles. This leads to extremely challenging fabrication techniques applying 3D profiling and polishing with optical surface quality. In DOEs, on the other hand, the fabrication technology is reduced to the fabrication of binary absorbing elements (for amplitude gratings) or etching steps (for phase gratings), which can be fabricated with extremely high precision through lithographic fabrication technologies. The optical functionality of the DOE is exclusively achieved through the positioning of these small binary diffracting phase shifting segments. Thus, in diffractive optics, no complex surface profiles need to be fabricated. This has a further consequence on the complexity of the optical functionality, which can be realized using diffractive elements. All DOEs consist of the same inherent structure, i.e., binary

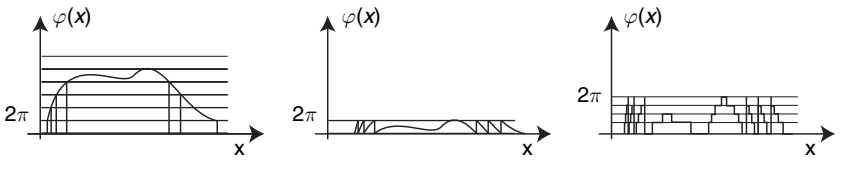

Figure 10 Illustration of the quantization of a refractive phase profile: reduction of the element thickness due to the periodic wave field; quantization of the analog sections into a step profile.

microstructures, which is independent of the optical functionality. Therefore, various functionalities such as beam splitting and focusing can be combined within a single diffractive element without negative effects on the fabrication processes. However, the quantization needs to be adjusted properly, which might eventually lead to very small feature sizes. In summary, the challenges of refractive optics fabrication, i.e., the precise 3D profiling, in diffractive optics are shifted to the precise positioning of micro- or nanoscaled diffracting features.

Many of the most important applications of DOEs can be listed under the headline multiple beam splitting or beam shaping. Recently, the term wavefront engineering has been coined for this wide field of applications. Generally speaking, the purpose of any optical element, no matter if prism, lens, or DOE, is beam shaping, i.e., to redistribute the incident wave field to a desired complex amplitude distribution in a specific plane behind the element (**Figure 11**). This is possible by influencing the complex amplitude of the incident wave field, e.g., by manipulating the amplitude and the phase of the wavefront. Fundamentally, with the ability to calculate the propagation of a specific wave field, for example, in the Fraunhofer or Fresnel approximation, it is rather simple to inversely propagate the desired complex amplitude distribution into the element plane. Then, with suitable modeling of the beam shaping element, for example, in the TEA, it is straightforward to calculate the necessary structure of the DOE from the knowledge of the incident wave field. Due to the challenging fabrication process of classical refractive elements, various beam shaping elements and thus also various beam shaping tasks in refractive optics are limited, for example, to focusing or deflection. More complex beam shaping tasks are possible with various individual elements, e.g., anamorphotic imaging with different magnifications in x- and y-directions. With the invention of DOEs, originally coined as computer generated holograms (CGHs), and the development of the technological basis for their fabrication, the variety of achievable tasks has increased dramatically. Nowadays, almost any physically realistic light distribution can be generated using DOEs. Fundamentally, it is possible to generate any complex amplitude distribution in a specific plane by influencing the amplitude as well as the phase within one plane. The only optical elements that allow such a complex manipulation of an incident wavefront are holograms. However, from the technological perspective, there are limitations to this concept (Sinzinger and Jahns 2003).

3.02.1.7 Design of Diffractive Optical Elements

Obviously, a phase only modulation, for example, using diffractive elements fabricated through lithographic surface patterning, has the advantage of high transmission since no absorption takes place in the element. During the design process of these diffractive phase elements, the task is thus to optimize the phase distribution in order to generate a desired amplitude distribution in the output plane (Soifer *et al* 1997). One of the most widely used approaches for this task is the iterative Fourier transform algorithm illustrated in **Figure 12**. In this algorithm, the phase profile of the diffractive element is adjusted iteratively to improve the approximation of the diffraction pattern generated in the Fraunhofer diffraction plane. It is thus applicable for the optimization of the far-field diffraction pattern of DOEs. The fundamental algorithm has been adopted from the reconstruction of image phase information from knowledge of the intensity distribution of the diffraction pattern in electron microscopy (Fienup 1982, Gerchberg and Saxton 1972). The algorithm starts with either a predesigned or a random phase distribution. The far-field diffraction pattern for this distribution is calculated by means of a Fourier transform and is compared to the desired output. Very often, the goal of the design process is a specific

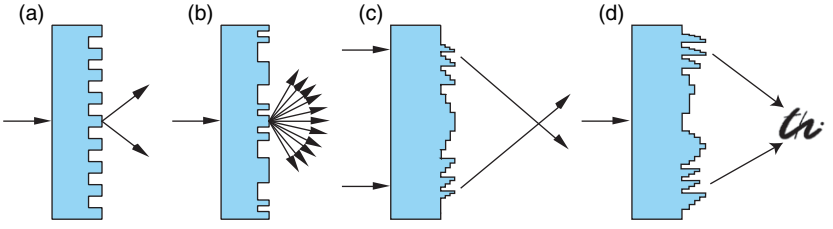

Figure 11 Functionality of diffractive optical elements. (a) 1 × 2 beam splitter; (b) multiple beam splitter; (c) diffractive lens; and (d) arbitrary beam splitting (beam shaping).

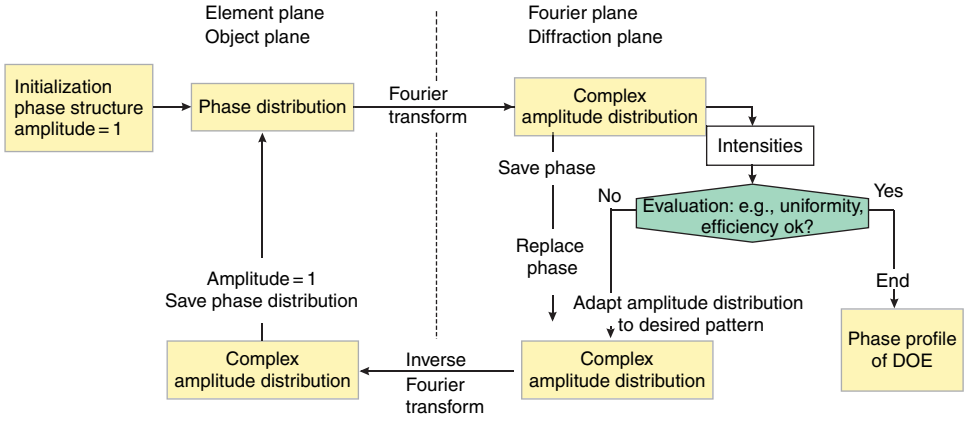

Figure 12 Schematic of the iterative algorithm for the design of phase-only diffractive optical elements (DOEs).

amplitude distribution, while the phases of the diffraction amplitudes are free design parameters. Thus, the next step in the algorithm is to force the amplitudes to the desired values while keeping the phase information as calculated. After an inverse Fourier transformation, we are back in the plane of the DOE. Here, for efficiency reasons, we require the element to be a pure phase element. We thus adjust the amplitudes of all element pixels to be unity. After another Fourier transform we find a new diffraction pattern. This iteration continues until a phase distribution is found, which generates a diffraction pattern that approximates the desired output amplitude distribution sufficiently well. The advantage of this iterative design procedure is its inherent simplicity and the flexibility with respect to the desired output distributions. The algorithm is often applied to the design of beam splitter gratings, in which case it is not restricted to symmetrical spot arrays or equal intensity diffraction orders (Bryngdahl and Wyrowski 1990). It can thus be applied to the design of DOEs for the generation of raster images (Gruber 2001). It is also possible to design diffraction orders with predetermined phases if a sufficient number of free design parameters are available. The algorithm can also be adapted for diffraction regimes other than Fraunhofer diffraction, e.g., for the design of DOEs generating specific distributions in the Fresnel regime (Dorsch *et al.* 1994). In this case, however, the limitations as to the design freedom have to be considered thoroughly.

In conventional diffractive elements, it is only possible to modulate either the phase or the amplitude. Truly complex filtering is thus possible only with two optical elements separated by a specific distance (Bartelt 1984; Sinzinger and Jahns 2003, pp. 273–8). Most flexibility is achieved if the two elements are positioned in the optical systems such that their relationship is defined through far-field diffraction. However, flexible beam shaping with two DOEs has also been demonstrated in the Fresnel relationship (**Figure 13**).

Diffractive optical elements designed in the way outlined above have been applied for lateral, axial, and temporal or spectral shaping of wave fields (Sinzinger and Jahns 2003, Chap. 11). From a very general perspective almost any application of DOEs can be categorized in this respect. Nevertheless, we want to mention briefly some more specific applications.

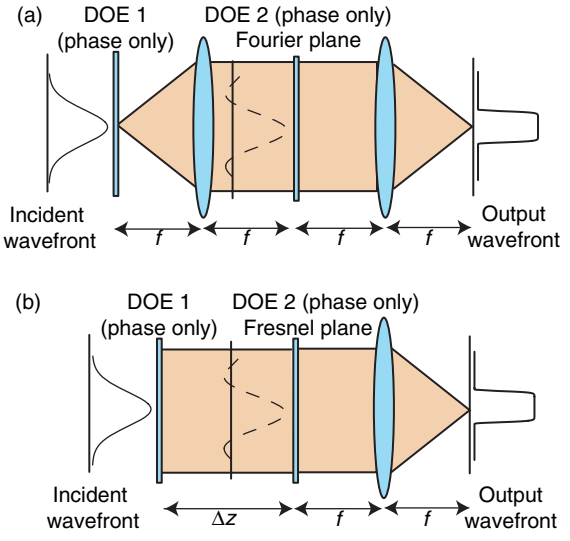

Figure 13 The concept of complex beam shaping by using two phase-only diffractive optical elements (DOEs) in corresponding planes in the optical system. (a) Fourier plane relation and (b) Fresnel diffraction relation between the DOEs. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

Computer-generated holograms, for example, have been invented for so-called spatial filtering, which is useful, for example, in feature extraction, character recognition, or optical correlation (Vander Lugt 1992). The basics of optical spatial filtering are best illustrated in the example of the 4f configuration schematically shown in **Figure 14**. In this application, a specifically designed DOE is located in the Fraunhofer plane of an incident wave field, which, for example, is formed by a uniformly illuminated object. Through complex or phase only filtering in the Fraunhofer plane it is possible to select specific features of the object, which are then imaged in the observation plane after an additional Fraunhofer diffraction step. Since a multiplication of two functions in the Fourier plane corresponds to the convolution of the two functions, the fundamentals of the approach are understood immediately. The basic concepts of spatial filtering go back to the 1960s (Goodman 1996, Lohmann 2006, Weaver and Goodman 1966). Traditionally this approach has been applied to analog signal processing as well as for the implementation of associative memories and neural network systems (Cassasent 1978, Horner 1987). In combination with modern design and fabrication technologies they have been adjusted and are applied, for example, in optical cryptography, optical document security, etc. (Javidi 2006, Javidi and Horner 1994, Sinzinger 2002).

DOEs are specifically useful components for spectral analysis, which is traditionally the most important area of the application of diffraction gratings. This is due to the strong wavelength selectivity of the diffraction angles illustrated through eqn [16]. Consequently in the Fraunhofer diffraction plane of a linear grating (period p), the wavelength spectrum of the incident wave field is separated laterally. The basic configuration of a grating spectrometer is shown in **Figure 15**. The lateral separation Δx of the mth diffraction orders for different wavelengths λ_1 and λ_2 is calculated from:

$$\Delta x = \frac{mf}{p}(\lambda_1 - \lambda_2) = \frac{mf}{p}\Delta\lambda \qquad [24]$$

Taking into account the size of the lateral resolution element $\delta x \approx (\lambda/\mathrm{NA})$, we find that the number of grating periods N illuminated in such a configuration determines the spectral resolution of the system:

$$\frac{\lambda}{\Delta\lambda} = mN \qquad [25]$$

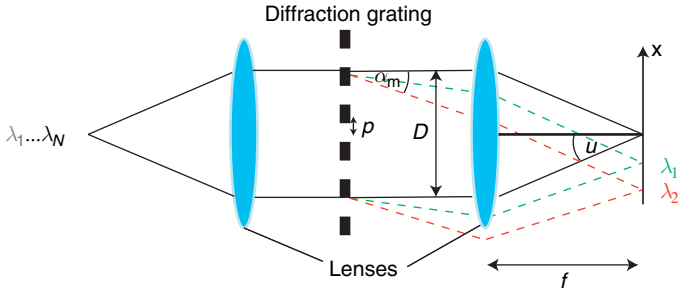

Figure 15 Schematic of a grating spectrometer for spectral analysis of the first stage toward spectral or temporal beam shaping.

High-resolution spectral systems are, for example, used in communication technology for wavelength division (de-)multiplexing, in sensing for sensors in the security as well as in environmental monitoring area. Specifically in sensor systems, the desire to build highly integrated compact systems currently provides the challenges.

For spectral or temporal beam shaping, the configuration shown in **Figure 15** is extended to a 4f-(correlation) configuration (**Figure 14**). In this case the diffractive spatial filter also automatically represents a spectral filter capable of selecting specific wavelengths. Since the temporal profile of laser pulses is directly related to their spectral distribution, such a configuration can be applied to temporal pulse shaping (Froehly *et al.* 1983, Nuss *et al.* 1994, Weiner *et al.* 1992). Similarly, time to space conversion in such setups can also be applied to ultrafast signal transmission (Konishi and Ichioka 1999).

3.02.1.8 Diffractive Lenses

It is possible to design diffraction gratings in such a way that they focus an incoming collimated beam of light into a focus spot, i.e., they work as lenses. To this end, it is necessary to design the diffracting microstructure such that the diffracted elementary waves interfere constructively in the focus plane. This is the case in the focus spot if the OPDs between these elementary waves are equal to multiples of the wavelength λ (**Figure 16**).

These straightforward requirements lead to the fundamental design rules for diffractive lenses:

$$r_j^2 + f^2 = (f + j\lambda)^2 \Rightarrow r_j^2 = 2j\lambda f + (j\lambda)^2$$

$$\xrightarrow{\text{paraxial: } f >> j\lambda} r_j^2 \approx 2j\lambda f \Rightarrow f = \frac{r_1^2}{2\lambda} \qquad [26]$$

Here, r_j is the radius of the diffracting rings, f is the focal length, and λ is the design wavelength (Miyamoto 1961, Nishihara and Suhara 1987). Very often, the paraxial approximation of this relation is used for the design of diffractive lenses (Sinzinger and Jahns 2003). As expressed by eqn [26] the structure of the diffractive lens is periodic in r^2 with period r_1 (Jahns and Walker 1990). Thus, the distance between the rings decreases with increasing radius. This can also be understood from eqn [12] where we discussed the phase profile of a thin paraxial (quadratic) lens. Conceptually it is easy to understand that beams hitting the lens at the edges need to be deflected to a larger diffraction angle, which can be achieved only with smaller grating periods.

As in linear diffraction gratings, the form factor (i.e., the shape of the individual periods of the diffractive grating) determines the distribution of the diffraction amplitudes, i.e., the diffraction efficiency. For a conventional binary amplitude diffractive lens a large portion of the energy is deflected into higher diffraction orders. It is important to note that these higher diffraction orders form additional foci f_m as indicated in **Figure 16**. Consequently, such a diffractive lens

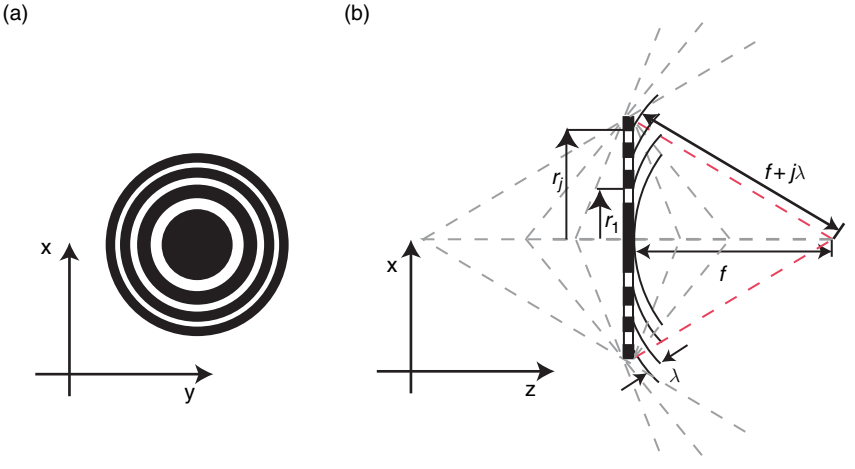

Figure 16 Microstructure of a diffractive lens. (a) View from the top and (b) side view with indication of various diffraction orders. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

is a multifocus lens that additionally acts both as a positive and as a negative lens:

$$f_m = \frac{r_1^2}{m2\lambda},\ m \text{ is an integer} \qquad [27]$$

Besides the low diffraction efficiency, these higher foci lead to a significant contrast reduction due to stray and background light. In order to increase the diffraction efficiency and contrast of the diffractive lens, the same approach is feasible as for linear gratings. Multilevel phase steps within one period of the circularly symmetric diffractive lens lead to a largely increased efficiency and significantly less background noise. As seen in eqn [15] only eight phase levels per 2π are sufficient to reach a theoretical diffraction efficiency of 95% in the scalar approximation.

The limitations of diffractive lenses result from the fabrication processes. As we have seen, the smallest features in diffractive lenses occur at the edges of the lenses. Thus, for a given minimum feature size $w_{\min}$, the maximum aperture angle (or NA) is limited to (N is the number of phase levels):

$$\mathrm{NA} = \frac{\lambda}{N w_{\min}} \qquad [28]$$

The so-called photon sieve (**Figure 17**) has been suggested to overcome this limitation with the aim of building diffractive lenses for X-rays. Due to their extremely short wavelength, the features of conventional diffractive microlenses for this wavelength regime are extremely small and often beyond what can be fabricated. Instead of the ring structure, Kipp *et al.* (2001) suggested a structure consisting of small holes in a nontransparent screen. Again in order to achieve focusing properties, it is necessary that the waves diffracted at the holes interfere constructively in the focal plane. This can be achieved by arranging the holes of the sieve on the transparent rings of the Fresnel ring structure of conventional diffractive lenses. However, if the holes are larger than the ideal ring, diameter portions of the diffracted light interfere constructively in the focal plane. This results in a decrease in the focus intensity. Nevertheless, even larger holes can have a net contribution to the focus intensity (Cao and Jahns 2002). The potential of the photon sieve thus lies in the possibility to trade focusing power (NA) for lens efficiency.

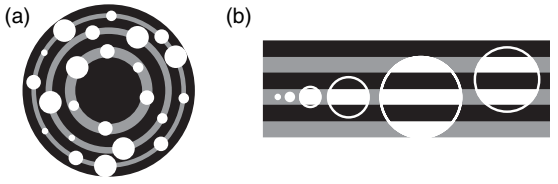

Figure 17 The concept of the photon sieve. (a) Focusing with a distribution of holes in a screen and (b) effect of the size of the holes with respect to the corresponding Fresnel rings. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

Two features of diffractive lenses can be pointed out here as their most outstanding advantages. First, the diffractive implementation is not limited to the quadratic or spherical shape that we have been discussing above. It is, for example, equally straightforward to implement aspherical lenses in the diffraction concept. Optimized astigmatic diffractive lenses, for example, have been used to optimize folded optical systems fabricated using the concept of planar optics (Jahns and Acklin 1993, Shiono and Ogawa 1992). Second, just like linear diffraction gratings, diffractive lenses have a strong dispersion with an opposite sign rather than the normal dispersion of refractive elements. The focal length of a diffractive lens depends on the illumination wavelength according to the following equation:

$$\frac{\partial f}{\partial \lambda} = -\frac{f}{\lambda} \qquad [29]$$

This chromatic behavior can be exploited, for example, in optical system design for chromatic error correction. To this end, however, diffractive lenses are necessary, which exhibit a very high efficiency over a very broad spectral band. This requirement was thought to be unsolvable for a long time until multilayer diffractive elements had been suggested by Nakai in the late 20th century (Nakai and Ogawa 2002, Nakai and Ogawa). Such multilayer DOEs consist of a stack of two or more blazed diffractive DOEs fabricated from different materials. With a suitable choice of materials it is possible to achromatize the functionality of the individual zones of the stacked DOE. Thus, the multilayer DOE has an efficiency close to 100% over the whole visible spectrum. This development triggered an enormous development leading to the successful application of DOEs in photographic objective lenses as well as in high-quality inspection microscope objective lenses (Dobschal *et al.*). The compactness, the lightweight, the complex optical functionality, and good possibilities for integration are the most important advantages.

3.02.2 Refractive Microlenses and Microlens Arrays

Microlenses and microlens arrays turn out to be the most crucial components for microsystems, which incorporate optical functionality. As in macroscopic optical systems, the most important functionality in optical microsystems is the imaging, focusing, or collimation of light (Daly 2001, Herzig 1997, Sinzinger and Jahns 2003). Various new innovative fabrication technologies allow fabrication of microlenses with good optical quality in large quantities at a relatively low cost per element (Borrelli 1999). With increasing availability, numerous applications of optical microlenses and microsystems have been developed within the past decades. These applications range from sensing, special purpose imaging, optical security devices to optical interconnects.

In this section, we summarize the basics of microlenses as well as microlens arrays and introduce the latest trends in microlens fabrication and applications.

3.02.2.1 Performance of Lenses at Small Dimensions

The properties of microlens arrays compared to macro-optical elements are dominated by two specifics, i.e., the small physical dimensions of the individual microlenses and the array character (periodicity) if a number of microlenses are illuminated by a single expanded beam of light. In this case, the microlens array acts like a diffraction grating where the shape of the individual grating period has the phase profile of the lens.

First, we want to consider the effect of miniaturization on the performance of the individual lens elements. To this end, it only makes sense to compare lenses with equal optical performance but different physical dimensions (diameters) (**Figure 18(a)**). This means that we compare lenses that have, for example, the same (diffraction limited) optical resolution (Lohmann 1989). The optical resolution is defined as the size of the smallest resolvable features δx in an image with

$$\delta x \approx \frac{\lambda}{\mathrm{NA}}; \quad \mathrm{NA} = n \sin u \qquad [30]$$

where λ is the wavelength and NA is called the numerical aperture, with n being the refractive index of the surrounding medium and $2u$ the aperture angle of the lens. Thus, lenses with equal NA have the same diffraction-limited point spread function (PSF). On the other hand, if we consider, for example, the amount of wavefront aberrations to be constant, their effect in the image plane is reduced for lenses with a smaller diameter due to their smaller focal lengths (at constant NA). In summary, this results in the observation that the performance of microlenses is limited by the diffraction limit rather than by the aberrations, which generally limit the performance of macroscopic lenses. Thus, it becomes easier to fabricate lenses with diffraction-limited performance if their diameters are smaller. On the other hand, if we consider the space-bandwidth product (SBP), i.e., the number of image points resolvable with the corresponding lenses, which is an important quality criterion for optical systems and elements, their performance improves significantly with increasing diameters (at constant NA). This is a result of the larger image field size, which increases quadratically with the lens diameter. These circumstances are shown in **Figure 18(b)**, which illustrates the fact that macrolenses perform better if aberrations can be controlled (black curve).

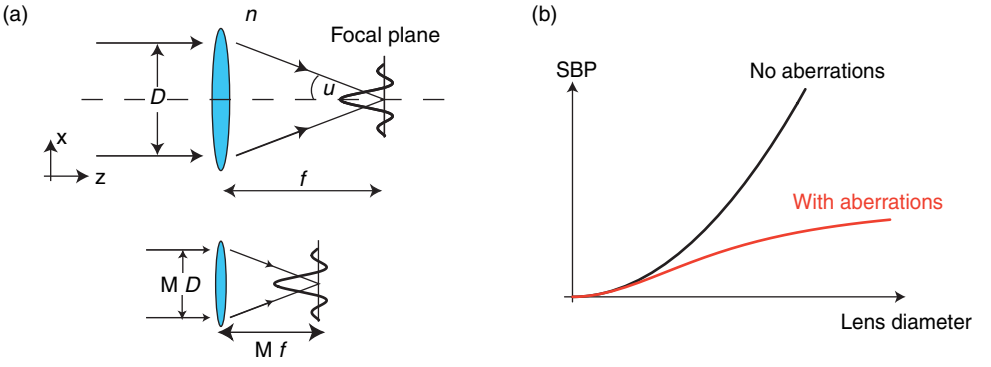

Figure 18 Scaling behavior of lenses. (a) Scaling (factor M) with constant numerical aperture; (b) the curves show the number of resolvable image points (SBP, space bandwidth product) of (micro-)lenses as a function of the lens diameter. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

The Fresnel number N_F (eqn [6]), which we have already discussed in the context of diffraction theory, is another important parameter, which is useful for judging the quality of (micro-) lenses. As we mentioned above, the Fresnel number is a measure of the relative impact of diffraction on the propagation of a wavefront. As the Fresnel number decreases, diffraction gains more and more importance, which has significant effect on the focusing and imaging behavior of wavefronts, such as focus shifts and space invariance of the imaging behavior (Li 1981, Li and Platzer 1983, Sheppard 1986, Wang *et al.* 1993). The Fresnel number can be interpreted as the ratio of the NA and the diffraction angle (eqn [8]). Consequently, at constant NAs, the Fresnel number decreases linearly with decreasing lens diameters. In other words, diffraction gains more and more importance on the wavefronts propagating behind microlenses, even if the NA and with it the diffraction limit are kept constant. Thus, in order to calculate the best focus of microlenses with small diameters, it is significant to take into account the diffraction at the aperture stop of the lens. It is straightforward to see that diffraction at the aperture stop, which by itself has a certain focusing effect, limits the maximum focal length of lenses with the corresponding diameters (Ruffieux *et al.* 2006). For diffraction gratings, a rule of thumb states that at least 10 periods of a diffraction grating should be illuminated in order to achieve a clear-cut diffractive behavior. Similarly, one can state that the behavior of microlenses with $F_N > 10$ can be estimated to a decent precision (errors $< 10\%$) according to the laws of geometrical optics.

Besides the smaller sensitivity to aberrations, the use of microlenses and microlens arrays is interesting because they enable very compact imaging systems. As a rule of thumb for conventional optical elements, it can be assumed that the lens diameter needs to be at least as large as the size of the image field. For imaging systems with constant NA, this automatically means that large field sizes come along with large distances between the object and the image (**Figure 19**). Especially for large image fields, macroscopic lens systems thus tend to become large, also in axial direction, i.e., in the z-direction. By microchannel imaging where microlens arrays are applied for such an imaging task it is, however, possible to separate image size from the length of the imaging system. Since each individual microlens system images only a small section of the object, the distance between the object and the image can remain rather small. Thus, extremely compact imaging systems for large object sizes are possible using microlens arrays. This is the fundamental concept of microlens lithography, which has gained significant commercial importance during the last decade (Völkel 1996).

3.02.2.2 Microlens Arrays

With the introduction of microlenses into optical systems, very often a reduction in the pupil size of the individual microchannel system is introduced. However, in many applications the overall pupil remains macroscopic in its dimensions while a microlens array splits the aperture into a large number of subapertures (**Figure 19**). Consequently, it is also generally necessary to consider the effect of the array properties on the performance of the complete system. In this section, we first discuss some of the important array parameters of periodic micro-optical components. Then we outline the analytical treatment of those array parameters as well as their effect on the performance of the array. Finally, we address

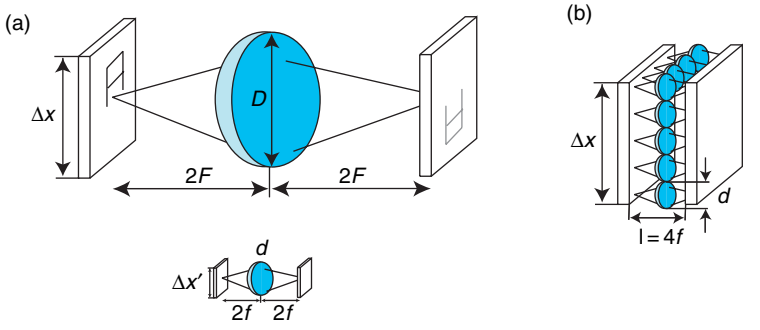

Figure 19 Scaling of the image field size. (a) Conventional imaging system at different scales and (b) microchannel imaging system. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

the new possibilities that arise when the regularity of these arrays is broken.

3.02.2.2.1 Array parameters

In addition to the performance parameters of the individual elements, it is necessary to consider the so-called array parameters when using arrays of micro-optical components. The most important array parameter is the uniformity of the elements throughout the array. Specifically for the fabrication of large arrays of micro-optical components (e.g., microlens arrays), it is quite a challenging task to achieve uniform properties for all the lenses in the array. On the other hand, it is similarly difficult to characterize the uniformity of the optical performance if the number of individual elements (microlenses) is very large. Shack–Hartmann sensors (Beyerlein *et al.* 2005, Pfund *et al.* 2001), Moirè sensors as well as arrays of microinterferometers (e.g., of the Smartt type) have been discussed for this so-called array testing (Schwider and Sickinger 1997; Sinzinger and Jahns 2003, Chap. 4).

The second important array parameter is the fill factor of the array. It corresponds to the packaging density of the individual components and determines whether there are gaps between the individual microlenses in the array. Obviously, also the shape of the array (array grid, e.g., hexagonal or Cartesian grid) as well as the shape of the individual microlenses influence the packaging density. Microlenses with circular apertures or profile shapes, for example, cannot completely fill the pupil aperture without dead spaces in between the microlenses. Microlenses and micro-optical elements with square apertures can be packed to extremely high fill factors. The diffractive implementation is well suited for the fabrication of such elements with square apertures. On the other hand, microlens arrays with high fill factors have also been achieved for refractive microlens arrays fabricated through reflow and optimized ion exchange in glass.

3.02.2.2.2 Regular microlens arrays

Generally, microlens arrays are considered to be packed as densely as possible on a Cartesian grid. In this case, if a significant number of microlenses are illuminated within the pupil of the optical system, the microlens array can be treated like a diffraction grating where the form of the individual microlens corresponds to the form of one period of the diffraction grating. This situation is illustrated in **Figure 6** and analyzed in Section 3.02.2.3. For microlenses, the form factor corresponds to the Fourier transform of the microlens profile and thus provides a uniformly illuminated area in the Fraunhofer diffraction plane. The extension of this homogeneously illuminated area depends on the NA of the individual microlenses. This area is sampled by an array of sharp peaks, which have the origin in the periodicity of the microlens array. It depends on the specific application if this periodicity has a positive or negative effect on the desired output pattern (**Figure 20**).

Microlens arrays, for example, have been suggested for multiple beam splitting or array generation (Streibl *et al.* 1991). In this application, the goal is to generate an array of uniformly illuminated diffraction orders in the Fraunhofer diffraction plane. To this end, microlens arrays can be very useful. However, instead of observing the distribution in the focus plane of the microlenses, the distribution in the Fraunhofer diffraction plane is considered. In combination with an array of an additional phase correcting field lenses, this approach enables the efficient generation of a large number of orders with very good uniformity in the intensity distribution. To this end, obviously the periodicity of the microlens array is useful and necessary for the optical performance.

Microlens arrays, on the other hand, are also suggested for beam homogenizing in the so-called fly's eye condenser configuration. Considering the effect of one single microlens in the Fraunhofer diffraction plane of the condenser lens, we again find a uniformly illuminated area. Since the same area is illuminated by every single microlens, conceptually, a very uniform illumination results in this area. However, problems arise for coherent sources. In this case, the interference of the individual beams destroys the uniformity in the illuminated area. Again, the sharp peaks of the array factor show up as expected theoretically. Thus, for

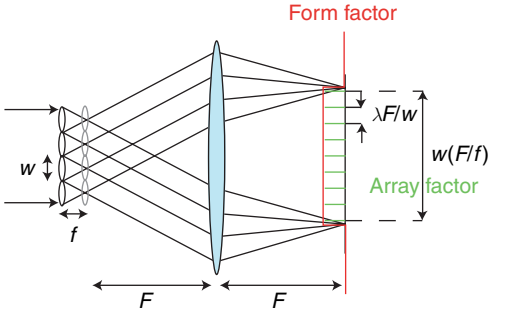

Figure 20 Form factor and array factor of a microlens array used, for example, as fly's eye condenser for beam homogenization. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

beam homogenizing, the regularity of the microlens arrays results in serious problems.

An additional effect to be observed in periodic microlens arrays is the Talbot effect. This results in the observation of a large number of focal planes at periodic distances. It is thus quite challenging, for example, to experimentally find the first and the best focal plane of microlens arrays.

3.02.2.2.3 Nonuniform microlens arrays

For microchannel imaging of large arrays of data channels it has been pointed out that arrays of microlenses with varying parameters offer additional degrees of freedom for the optimization (Sinzinger and Jahns 1997). For example, the focal length of each microlens can vary depending on the position of the lens within the array. Similarly, additional deflection angles can be introduced and can vary for each individual element of the array. These additional design parameters allow one to adjust the properties of the microlens array to the very specific imaging task (Wippermann *et al.* 2006a). For an optimized microchannel imaging systems, for example, this effectively resulted in the combination and integration of the microlens array with an additional macroscopic lens element, which represents the variation of the array parameters across the array (Sinzinger and Jahns 2003, Chap. 8). The fabrication of such a microlens array with spatially varying microlens properties is even more challenging than the fabrication of a regular microlens array. A diffractive implementation is possible without additional effort, while refractive implementations, for example, can be realized using direct writing schemes such as direct electron or laser beam writing (Wippermann *et al.* 2006b).

Recently nonuniform arrays of microlenses for which the term chirped arrays has been coined have been demonstrated for various applications. The additional design freedom of the individual microlenses can be applied, for example, for the optimization of specific imaging situations like microchannel systems for ultraflat camera objective lenses (Duparré *et al.* 2005a,b). Inhomogeneous microlens arrays can also be advantageous as beam homogenizers (Wippermann *et al.* 2007). Thus, for a completely random distribution of the microlens arrays within the array, a very uniform illumination profile without peaks due to the periodicity results. In this case, the array factor is a constant, which depends on the number of microlenses. However, there is a certain peak observed in the zeroth diffraction order (Lohmann 2006, p. 241).

3.02.2.3 Fabrication of Microlenses

In this section, we outline some of the most widely applied principles for the fabrication of microlens or a microlens array. In Section 3.02.2, the structure of diffractive microlenses by identifying them as specific forms of diffraction gratings has been discussed. The fabrication of diffractive microlenses is possible through standard lithographic approaches using suitable optical materials. In this section, the focus is on the fabrication of refractive microlenses. The most widely used techniques such as photoresist reflow, ultraprecision micromachining for micro-optics fabrication, as well as the ion exchange technique for the fabrication of gradient index (GRIN) microlenses have been briefly described.

3.02.2.3.1 Functional principles of optical components

As described above, the TEA optical elements are identified as phase profiles modifying the incident wavefront. For refractive optical components in general and thus also in microlens arrays this phase profile is generated by a variation of the optical path length (OPL) of optical rays incident onto the component at different lateral locations. The OPL is a product of the physical path length l and the refractive index $n(\lambda)$ of the propagation medium at the corresponding wavelength:

$$\mathrm{OPL} = ln(\lambda) \qquad [31]$$

From this equation two fundamental possibilities to generate a local variation of the OPL (or a phase profile) can be identified (**Figure 21(a)**) (Sinzinger and Jahns 2003). If the light, for example, propagates along different physical path lengths through a dielectric medium with homogenous refractive index, the concept of conventional refractive lenses results. Their functionality can also be described by refraction of the rays at the surface, which defines the element. Alternatively, the physical path length

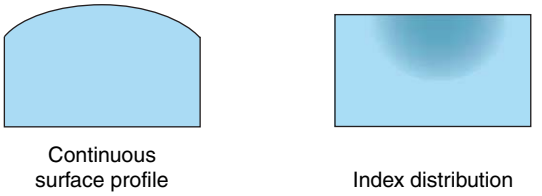

Figure 21 The functionality of refractive microlenses generated by (a) a surface profile and (b) a refractive index distribution.

inside the element is constant for all locations but the refractive index of the dielectric medium varies locally (**Figure 21(b)**). In this case, at least if we have a smoothly varying refractive index profile we speak of GRIN optical media. Propagation in such a medium can also be approximated in geometrical optics by assuming a large number of transitions between media with slightly different refractive indices (Iga *et al.* 1984).

Based on these two basic functional principles of refractive microlenses, various different fabrication technologies can be applied for their fabrication.

3.02.2.3.2 Reflow microlenses

The conceptually simplest and quickest techniques for microlens fabrication exploit the natural effect of surface tension. This leads to the formation of spherical islands, for example, once liquids are dropped onto surfaces or once cylindrical islands on substrates are melted. These spherical islands or caps can be exploited as microlenses. The most widely applied technique has been suggested originally by Popovic who fabricated cylindrical islands of photoresist through lithographic techniques (Daly 2001, Hutley 1990, Popovic *et al.* 1988). Upon heating these photoresist islands above the melting temperature of the resist material, spherical microlenses are formed. In spite of this straightforward fabrication concept the technology proves to be rather challenging. Specifically, for the reproducible fabrication of microlenses with specific optical parameters, it is necessary to control all processing parameters to very high precision. The significance of the different parameters can be understood by considering various parameters influencing the fabrication result.

The focal length of the resulting plano-convex microlenses can be determined from the refractive index of the lens material n and the radius of curvature r_c of the spherical surface:

$$f_{\text{reflow}} = \frac{r_c}{n-1} \qquad [32]$$

In order to determine r_c, we compare the volume of the cylindrical islands of photoresist after lithographic fabrication V_{cyl} and the spherical photoresist caps V_{cap} after the reflow process:

$$V_{\text{cyl}} = \pi\left(\frac{D}{2}\right)^2 t; \quad V_{\text{cap}} = \pi h^2 \frac{3r_c - h}{3} \qquad [33]$$

where D is the diameter of the photoresist cylinders, which is also considered to be the diameter of the resulting microlenses; t is the thickness of the photoresist layer; and h is the height of the spherical photoresist caps resulting after melting (sometimes also called the sag of the microlens) (**Figure 22**). For simplifying the following derivation, we assume that the photoresist volume and the diameter of the contact area between the resist and the substrate surface do not change during the reflow process. Even though these are rather crude assumptions, the results show the relations that we are interested in. For more precise calculations, the volume shrinkage as well as a detailed analysis of the surface energies need to be performed.

Under the above assumptions, we can derive equations for the radius of curvature as well as the relation between the resist thickness and the sag and diameter of the formed microlenses:

$$r_c = \frac{h^2 + \frac{D^2}{4}}{2h}; \quad t = \frac{h}{6}\left(3 + 4\frac{h^2}{D^2}\right) \qquad [34]$$

The impact of these equations is illustrated by the curves in **Figure 23**. They show the dependence of the focal lengths on the diameter and on the thickness of the photoresist layer. It is obvious that in order to work in an appropriate parameter region it is necessary to be able to fabricate rather thick photoresist layers with very good uniformity. This proves to be one of the most serious challenges in the fabrication of

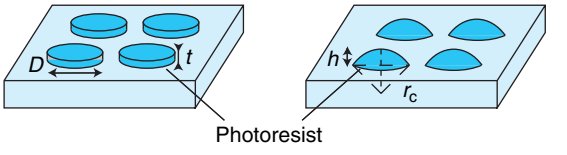

Figure 22 Photoresist reflow for shaping spherical microlenses from lithographically fabricated photoresist cylinders.

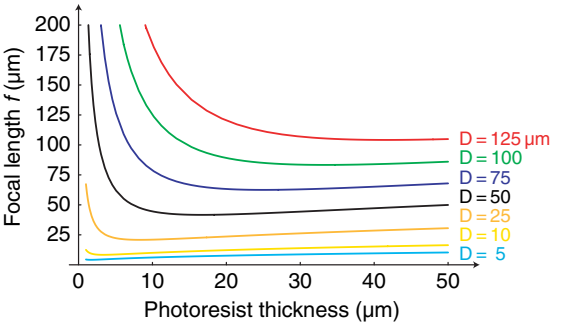

Figure 23 Illustration of the relations in eqn [34]; focal lengths resulting from the reflow process as a function of the photoresist thickness for various lens diameters.

microlenses with diameters larger than several hundred microns. Thanks to the progress in the development of highly viscous photoresists, very uniform layers with thicknesses of several tens of microns can be fabricated nowadays. The next step after the coating of sufficiently large and uniform photoresist layer thickness is the melting process, which can become quite challenging if the cylinder volume is quite large. The ideal lens shape is achieved only if the whole resist volume reaches temperatures above the glass temperature simultaneously. Once the volume is too large, the outer regions reach high temperatures too quickly and can be cured before the center portions reach the melting point. These and other additional problems result in the fact that very good reflow microlenses can be fabricated only in a rather limited parameter range up to diameters of about 500 μm. At the same time, surface tension always results in rather small radii of curvature, i.e., large NAs. The reflow process is thus applicable for microlenses with diameters <2 mm and NA > 0.1 (Sinzinger and Jahns 2003, Chap. 4). Efforts to extend this parameter range include preshaping of the photoresist as well as the application of contact coatings in order to influence the contact angles between the resist and the substrate and as such also the radius of curvature. In spite of the technological challenges outlined above, this fabrication approach has been commercialized and successfully applied to the fabrication of very large arrays of microlenses. Obviously to this end, the additional challenges of uniform processing conditions over the whole wafer area need to be solved (Suss 2006).

In order to transfer the photoresist microlenses into materials with advantageous optical and physical parameters, such as chemical, mechanical, or thermal stability, generally a reactive ion etching process is performed. This allows the transfer of the profile into the glass substrates. Through a precise control of the composition of the processing gas, the relative etching rates between the photoresist and the glass can be controlled (so-called differential etching) in such a way that the profile depth inside the substrate can be changed (Eisner and Schwider 1996, Stern and Jay 1994). Even the profile itself can be optimized by a variation of the conditions during the etching process. Alternatively, galvanic forming and replication techniques can be applied to the transformation and replication of the reflow photoresist microlenses (Gale 1997).

A large variety of approaches to microlens fabrication have been suggested, which are all based on the principles of surface tension. The conceptually simplest technique uses small droplets of curable materials such as polymers, which are applied to a planar substrate. Due to surface tension, these drops assume spherical profiles, which actually provide microlenses of a reasonable quality. Alternative ways to exploit surface tension in a similar way are techniques that exploit local volume growth or shrinkage for microlens formation. Even in compound semiconductor materials, surface tension is helpful to achieve polishing of multilevel phase profiles to achieve analog refractive micro-optical elements (Herzig 1997; Sinzinger and Jahns 2003, Chap. 4).

3.02.2.3.3 Ultraprecision micromachining for microlens fabrication

Within the last two decades, the mechanical precision of micromachining tools has been refined to a very high precision. Thus, the fabrication of high-quality microlenses and microlens arrays is nowadays feasible with high precision micromachining such as single point diamond turning or ultraprecision milling. Diamond turning provides the very good surface quality for spherical surface profiles. Ultraprecision milling, on the other hand, provides more flexibility with respect to aspherical or freeform profiles. However, the surface quality achieved with these milling processes is limited and additional polishing steps are necessary for high-quality elements. In spite of the challenges related to the fabrication of micro-optical elements using ultraprecision micromachining, the approach looks very promising and is the only fabrication approach providing microlenses with diameters in the range of a few millimeters, which is not accessible for alternative methods. This is even more important since these sizes can turn out to be the most important for application in complex microsystems (Lee and Cheung 2002, Zhang *et al.* 2005).

3.02.2.3.4 Planar GRIN microlenses fabricated by ion exchange – GRIN lenses

GRIN elements are a different type of refractive optical elements. In GRIN components, rather than being refracted at a surface profile, the light is deflected by a refractive index gradient within the substrate. In this section, the focus is on the fabrication of spherical index gradients and their application as microlenses. Historically, the field of GRIN optics gained significance with the introduction of GRIN optical fibers. The guiding mechanism in these fibers is based on a radial refractive index profile in the core

of the GRIN fibers. This index profile leads to the bending of the ray trajectory in such a way that for suitable shapes of the index profiles the light is constantly refocused during propagation through the fiber (**Figure 24**). In comparison to conventional step index fibers, this has the tremendous advantage that GRIN fibers can be designed to have zero waveguide mode dispersion. Mode dispersion is the relative difference between the propagation constants for different waveguide modes (which can be identified with propagation directions) and normally limits the transmission bandwidth of multimode waveguides. Thus, even if a large number of modes are guided in the GRIN fiber with suitable index profile all OPLs of the light through the fiber are equal. In other words, the GRIN fiber acts like a series of microlenses distributed along the fiber length such that the optical beam is constantly refocused when propagating through the index gradient. Thus, it has been realized soon that a short piece of such a GRIN fiber effectively acts as a microlens if the index profile is designed properly (Rawson *et al.* 1970, Tomlinson 1980). In the first approximation, the parabolic index profile is described by the following equation

$$n(x) = n_0\left(1 - \frac{1}{2}\alpha^2 x^2\right) \qquad [35]$$

where α is the design parameter defining the shape of the profile. In this case, the ray trajectory can be approximated as in **Figure 24** (Saleh and Teich 1991):

$$x(z) = x_0 \cos(\alpha z) + \frac{\Theta_0}{\alpha}\sin(\alpha z) \qquad [36]$$

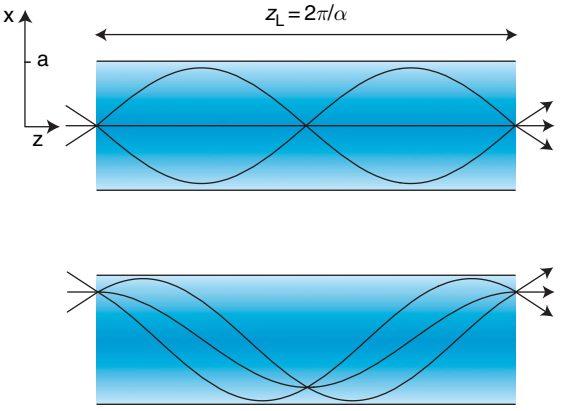

Figure 24 Light propagation in GRIN rod lenses with radial index profiles. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

Due to their lengthy shape, those lenses consisting of a short piece of GRIN fiber are called GRIN rod lenses and became well known under the trade name SELFOC™ (micro-) lenses also (Iga *et al* 1984). Large numbers of those rod lenses stacked to a 1D array have been used in scanners, copying machines, and laser printers for scanning and imaging the document onto the photosensitive drum. As in microlens imaging in general, the use of microlenses in this application enables the imaging of widely extended objects with very compact systems. For this application, GRIN rod lenses have the additional advantage that they can be designed to form upright images with a magnification of 1. With conventional microlenses this is achieved through stacking of at least two microlens arrays, which leads to additional efforts with respect to the assembly technology.

On the other hand, due to the complex fabrication process of fiber pulling, GRIN rod lenses cannot be easily fabricated in batch-like processes. Nor is it possible to fabricate 1D or 2D arrays of such lenses for integration in complex microsystems directly. Therefore, in the early 1980s the focus in GRIN micro-optics shifted to the fabrication of planar GRIN microlenses. Different from GRIN rod lenses for planar lens functionality, index profiles with specific point symmetries are necessary. As a suitable fabrication technology an ion exchange process in glass has been suggested by Oikawa and later on refined by numerous other authors (Oikawa 1994, Oikawa and Iga 1982).

In order to generate the index profile with point symmetry, which is necessary to achieve planar microlens functionality, the substrate (generally a glass substrate with well-controlled properties and ion composition) is coated with a mask providing local protection from the subsequent ion exchange process. After etching the mask structures (e.g., small circular openings can be used for microlens fabrication), the substrate is immersed into a melt containing ions suitable for replacing some of the ions from the substrate (**Figure 25**). The ion exchange takes place at temperatures of several hundred degrees Celsius in a diffusion-like process. At these temperatures, the ion mobility is large enough so that some of the ions (generally the alkali ions, such as Na^+) from the glass are replaced by ions from the melt (e.g., Ag^+ or Tl^+). Due to different polarization characteristics of the ions, this exchange influences the dielectric properties of the glass matrix and effectively changes the refractive index of the substrate. For a given material and ion combination,

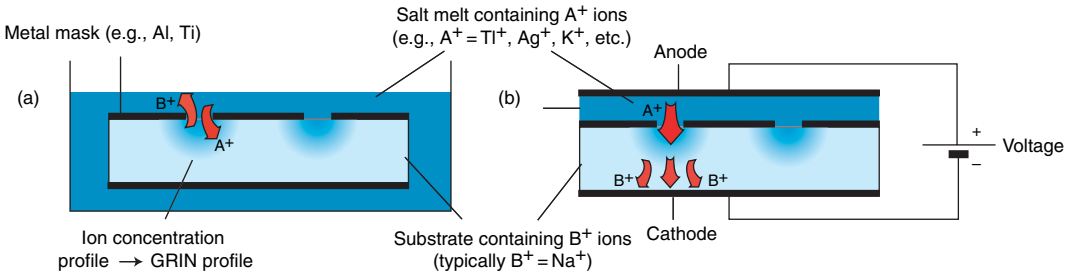

Figure 25 The ion exchange process for the fabrication of planar GRIN. (a) Thermal ion exchange and (b) field-assisted ion exchange. Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

the amount of index change is proportional to the percentage of exchanged ions. Since the ion exchange is an isotropic process, it does not stop at the edges of the mask. The ratio of exchanged ions drops gradually from a maximum at the surface of the substrate areas with no mask layer to zero at the maximum penetration depth of the ions inside the substrate (typically on the order of several hundred micrometers) or at similar distances in a lateral direction under the mask. An ion concentration profile with point symmetry is generated, which causes a refractive index distribution of a corresponding shape. The resulting refractive index profile is characteristic of the substrate and the exchanging ion pairs. If the exchange process is sufficiently nonlinear, the radial index distribution acts as a microlens. In order to accelerate and optimize the thermal ion exchange process described above, an electric field can be applied during the diffusion process. In the field-assisted ion exchange, also called electromigration, the electric field is used to increase the ion mobility across the interface between the substrate and the salt melt. Due to this electric field, the movement of the ions from the melt into the substrate is accelerated and the penetration depth of the ions is increased significantly. Additionally the shape of the electric field directly influences the resulting index profile.

The ion pairs used in the exchange process and the type of glass substrate are the most important parameters in the ion exchange process. A variety of different ion pairs have been investigated for the fabrication of planar GRIN microlenses. The most promising results were achieved with sodium–thallium and sodium–silver ion exchange. Both ion combinations yield comparable maximum index changes of about $\delta n = 0.1$ at the substrate surface in commercially available glass substrates (Findakly 1985, Oikawa 1982). Extremely large index changes (e.g., $\delta n > 0.2$) have been achieved in glasses with high sodium content (~25 vol.%) (Coutaz and Jaussand 1982, Misawa *et al.*1984). These substrates tend to suffer from high internal tension, which builds up because of the different diameters of the exchanged ions. Therefore, most of the microlenses have been fabricated with lower index changes being achieved in glasses with lower sodium content.

Generally, it is the maximum achievable index modulation that determines the NAs of the resulting planar GRIN microlenses. Consequently, the variety of NAs that has been demonstrated are rather limited and restricted to fairly small values of $NA < 0.1$ at typical diameters below 1 mm. Large NAs up to $NA = 0.6$ have been demonstrated by Oikawa; however, in this case a significant portion of the focusing effect stems from the surface profile effect, which was caused by surface swelling during the ion exchange process. This was caused by the fact that the thallium ions diffusing into the glass substrate have a larger diameter than the sodium ions, which are replaced in the glass matrix.

Bähr *et al.* demonstrated that complex mask shaping in combination with field-assisted diffusion and postdiffusion are useful tools in order to significantly extend the parameter region of ion-exchanged GRIN microlenses. Most importantly, they managed to fabricate microlens arrays with very high fill factors (Bähr and Brenner 2001).

3.02.2.4 Implementation of Active Microlenses

For various applications, it is desirable to be able to tune the parameters of an optical system within a certain range of parameters. This is a specific challenge in compact microsystems where the manual tuning or the integration of actuators for automatic tuning by positioning of the individual components is challenging. In this section, some of the techniques

that have been suggested for the fabrication of tunable microlenses are discussed briefly.

3.02.2.4.1 Microlenses based on liquid crystal elements

3.02.2.4.1.(i) Fundamentals of liquid crystals

Liquid crystal materials are the most widespread materials used in order to achieve dynamic optical functionality. This is due to the tremendous development in the field of flat panel displays, which has been triggered by the consumer market. In order to understand the functionality and the tuning behavior of liquid crystal-based optical elements, it is necessary to discuss the microscopic structure of LC materials. Without going into details, we try to focus on the basics necessary to understand the working principles.

After the discovery of the LC effect on cholesteryl benzoate by the Austrian biologist F. Reinitzer in the late 19th century, the challenge to be overcome before the effect could become of practical use was to find LC materials that were sufficiently stable at room temperature. Nowadays, a large variety of different types of LC materials are available and are used in an even larger variety of applications (Chigrinov 1999, Collings and Hird 1997, Lueder 2001).

The microscopic structure of LCs can be considered to consist of long chain-like molecules (other shapes of the molecules such as disc-like shapes can also be observed but can be ignored here for simplicity). In contrast to regular liquids, these organic or polymer molecules are subject to significant intermolecular forces. In the LC phase, these intermolecular forces result in the arrangement of the molecules in regular orientations as it is common in solid (crystalline) materials. Like crystalline materials, LCs can also change their intrinsic order in a phase transition, i.e., a transition between different states of order. The anisotropic structure of the molecules in combination with the intrinsic order of the LC results in interesting anisotropic optical functionality. A further consequence of the anisotropic susceptibility of the molecules is that, for example, external electric fields can be used for the dynamic manipulation of the states of order in the crystals. Energy considerations lead to the observation that the molecules align along the field lines of the external electric field.

The optical functionality of the LC material depends on the relative orientation of the molecules with respect to the polarization of the incident wavefront. In the liquid phase with the molecules floating around statistically, every orientation has the same probability. Thus, no anisotropic optical functionality is observed. However, the intrinsic order in the LC phase leads to optical anisotropy, i.e., birefringence. Different states of polarization transmitted through the LC thus experience different refractive indices. If the material thickness is optimized this anisotropy can be exploited to achieve a rotation of the polarization direction for the transmitted light. If the orientation of the LC molecules is changed by applying an electric field of a specific orientation, the anisotropy of the LC is changed and so is the polarization state of the transmitted light. If stacked between two polarizers with corresponding orientation such as a switchable LC cell, it can thus be used for amplitude modulation. This is the very basic functional principle of LC displays.

For efficient (micro-)optical elements the implementation of phase only modulators is desirable. To this end, the orientation of the LC molecules and the polarization of the incident wavefront need to be synchronized. Phase-only modulation requires that the plane of polarization is always oriented parallel or perpendicular to the mean orientation of the LC molecules (called the director). In order to avoid a change in the polarization state upon propagation through the cell, this needs to be true for all switching states. Such a configuration is possible if the molecules are aligned in the plane parallel to the cell surface. If the external electric field then triggers a rotation around an axis parallel to the surface but perpendicular to the director, light polarized parallel to the director experiences a variation in the refractive index but no influence on the state of polarization. In this case, the plane of polarization remains parallel to the main axes of the LC. Thus, the anisotropy does not affect the incident direction of polarization.

In spite of the identical fundamental functional principle, a large variety of alternate LC structures have been developed mainly for display purposes. During the fabrication of the cell, it is possible to influence the orientation of the LC molecules in the relaxed state, i.e., in absence of an electric field. The structure of the substrate surfaces, for example, has a significant influence on the alignment of the LC molecules. The addressing concept of the LC layer is of crucial importance for the quality of the optical functionality. For display purposes, the active matrix thin film transistor (TFT) structure provides best results with respect to contrast, interpixel crosstalk, and gray scale representation.

3.02.2.4.1.(ii) Liquid crystal (micro-)lenses

3.02.2.4.1.(ii).(a) Dynamic microlenses on pixelated LC devices

Throughout the last decade, the quality of LC TFT displays has improved significantly. Enhanced microstructuring techniques allow fabrication of pixelated displays with pixel sizes significantly smaller than 10 μm and very high fill factors in the area of 95%, i.e., very little space between the pixels. Once the polarizers that are necessary to achieve gray scale display functionality are removed such high-quality displays enable the implementation of phase diffractive lens functionality. Generally, refractive lenses cannot be implemented in LC cells for displays since the limited thickness of the LC layers enables only a phase modulation depth of about 4π at visible wavelengths. This modulation depth is sufficient for standard diffractive lenses with decent performance. Limitations of such diffractive elements can be easily derived from the relations about diffractive microoptics presented above. The pixel size, for example, which results in a coarse spatial quantization, limits the NA as well as the quality of diffractive microlenses (Carcolé *et al.* 1994, Davis *et al.* 1989, Tam *et al.* 1992).

3.02.2.4.1.(ii).(b) Modal liquid crystal lenses

Liquid crystal lenses with analog refractive phase profiles can be realized using relatively thick layers of LC in order to enable a large maximum phase shift when applying an external electric field (Naumov *et al.* 1998). **Figure 26** shows the basic structure of a modal LC lens. The necessary analog phase profile is generated through a suitable electrode structure generating the electric field inside the LC layer. The LC response to high-frequency voltage can be exploited in order to generate the suitable electric field distribution. Once a high-frequency voltage is applied to the annular electrode, the cell can be considered as a series of low-pass filters (**Figure 27**). The LC acts like a capacitor in this context. The longer the effective high resistance electrode section, the larger is the voltage drop in this layer. This low-pass characteristic is described by the following equation:

$$V_o = V_i \frac{|X_C|}{\sqrt{X_C^2 + X_R^2}}, \quad \text{with } X_C = \frac{1}{j\omega C} \text{ and } C \sim \frac{1}{d} \qquad [37]$$

where V_i and V_o are the input and output voltages to the low-pass filter, respectively; X_C and X_R are the complex resistances of the capacitors and the resistor, respectively, and C is the capacitance of the LC layer.

The remaining voltage drop occurs across the LC leading to the stable electric field distribution inside the crystal. Thus, from the characteristic of low-pass filters, we find that for a suitable relation between the high-resistance electrode and the capacity of the LC layer a parabolic electric field distribution results. Since the capacitance of the layer depends on the

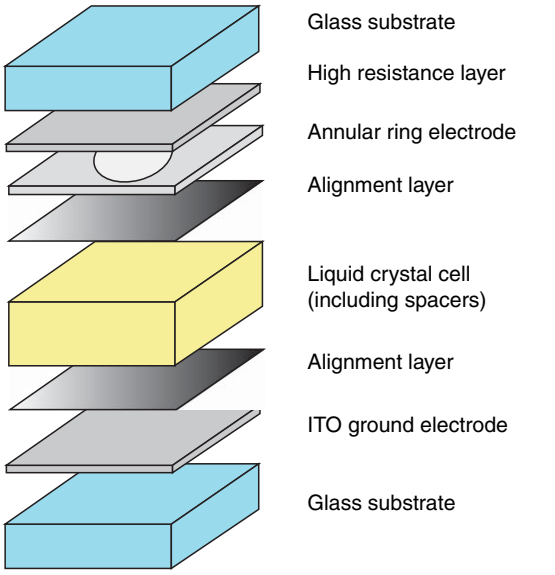

Figure 26 Schematic structure of a liquid crystal modal lens.

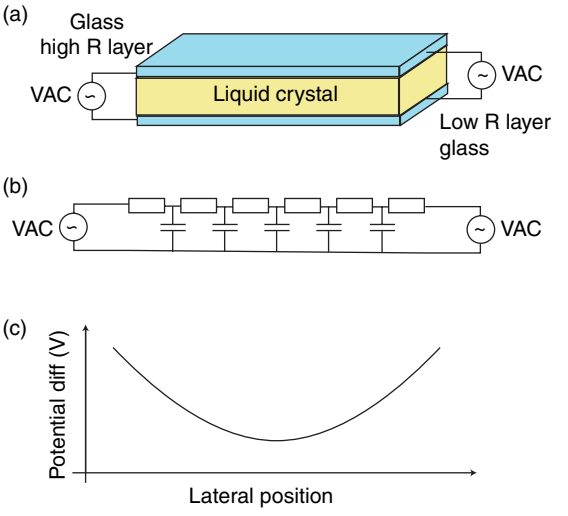

Figure 27 Electric equivalent of a modal liquid crystal lens. (a) Contacting of the cell; (b) electric equivalent as a series of low pass filters; and (c) potential profile inside the liquid crystal.

layer thickness, the resistance of the electrode layer needs to be adjusted to the corresponding layer thickness in order for the modal effect to occur at reasonable frequencies.

For modal lenses, nematic LCs are used and aligned homogeneously. This is achieved, for example, through a slight polishing step, where the substrate surface gets the necessary preferential orientation along which the LC molecules tend to align. In the electric field, the LC molecules align about the ordinary axis and change the effective refractive index of light polarized properly. Portions of the incident beam polarized perpendicular to the director will not be affected by the change of the cell due to the electric field. By stacking two of these cells with perpendicular orientation, polarization-independent modal lenses can be realized (Love 1993). The theoretical phase modulation depth, which can be achieved with modal lenses, can be calculated from the birefringence of the LC and the thickness of the LC cell. Typical values for birefringence are $\Delta n = 0.225$, which results in a phase depth of about seven wavelengths in a cell with a thickness of 20 μm. This also illustrates the limitations of this technological approach to fabricate dynamically tunable microlenses. Due to the relatively small relative refractive index change, a large thickness of the layer is necessary in order to achieve decent microlens performance. On the other hand, increasing the thickness results in slow tuning speeds as well as increasing stray light due to scattering in the LC volume. Modal LC microlenses thus have rather low NAs in the range of 10^{-2}.

One of the advantages of this approach for the fabrication of tunable microlenses can be found in the planar cell structure. Since the LC lenses exploit index variations of the LC material rather than surface profiles, the surface of the cell is not changed during the tuning process. Thus, these LC lenses are extremely well suited for micro-optical systems integration, e.g., in planar optical systems. A planar integrated micro-optical system that incorporates dynamic functionality based on modal LC microlenses has recently been demonstrated (Amberg *et al.* 2006).

3.02.2.4.2 *Liquid tuneable microlenses*

The difference between the index modulation generated in tunable LC microlenses, is that in liquid microlenses, the alternative approach is to tune the shape of the elements (**Figures 28** and **29**). As in fabrication of reflow microlenses, the natural formation of spherically shaped droplets through surface tension is exploited in these cases. It has been discussed above that the spherical droplets themselves provide decent lens functionality. This approach has the advantage, that effectively, the large index difference between the liquid lens medium and the environment is available for the optical functionality and the tuning. This results in a significantly wider tuning range, which is available for liquid lenses compared to tunable optical elements based on index modulation, e.g., in LCs. Here, the concept of two different approaches to the generation of liquid tunable lenses is discussed.

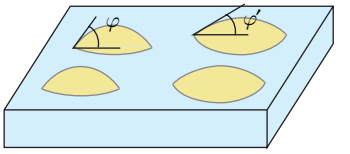

Figure 28 Concept of switching in liquid lenses. The wetting angle of the liquid lens can be changed dynamically.

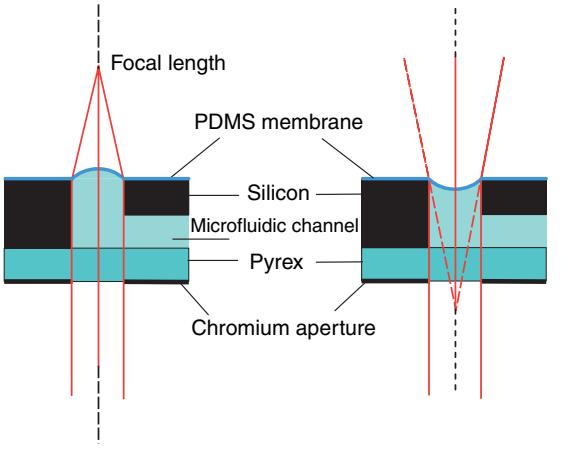

Figure 29 Basic structure of a tunable liquid lens. (Source: Werber and Zappe 2005.)

3.02.2.4.2.(i) *Microfluidic liquid microlenses*

The implementation of tunable microlenses with the help of complex fluidic systems has been demonstrated by several authors. In the general approach, microcavities filled with liquid are used, which are covered by a flexible membrane (e.g., PDMS of a thickness of 50 μm) (Chen *et al.* 2004, Krupenkin *et al.* 2000, Sugiura and Morita 1993, werber and zappe 2005). By varying the pressure inside the cavity, this membrane is bent to form a plano-concave microlens of a variable radius of curvature. Arrays of microlenses with comparable properties can be

realized by connecting a single reservoir to various membrane-covered microcavities through a microfluidic channel system. Analog tuning of the pressure leads to analog tuning of the focal length. With the application of negative pressure, the implementation of negative, that is, plano-concave, microlenses is also possible. This yields a large tuning range, which so far has not been achieved by any other technological approach. Due to the fact that these liquid microlenses are working on the basis of refraction at the interface between the liquid and the surrounding atmosphere, relatively large NAs can be achieved (Xie and Lu 2005). Werber *et al.* demonstrated that high optical quality of the lens performance can be achieved over the large tuning range (Werber and Zappe 2005). Instead of mechanically controlling the pressure Dong suggested the use of hydrogel materials, which can be activated, for example, by chemical (pH)-, thermal-, electromagnetic-, or electric field-induced stimuli. By fabricating a hydrogel ring structure this stimulus can be exploited for pressurizing the microfluidic channel and thus tune the microlens (Dong *et al.* 2006).

3.02.2.4.2.(ii) Electrowetting for the fabrication of tunable microlenses A further technological approach to activate microlens fabrication is based on a phenomenon called electrowetting (Bergé and Peseaux 2000, Vallet *et al.* 1999). Here, the formation and tuning of the shape of liquid droplets is realized through the application of electric fields. By tuning a voltage applied between an electrode immersed into a droplet of conductible or polar liquid and an electrode below the dielectric substrate carrying the droplet, the shape of the droplet can be tuned within a broad range. This effect can be best understood by performing an energy balance considering the surface energy between the liquid and the substrate γ_{sl} and the electrostatic energy $(1/2)\varepsilon\varepsilon_0(U^2/d)$ in the capacitor between the two electrodes:

$$\gamma_{sl}(U) = \gamma_{sl} - \frac{1}{2}\varepsilon\varepsilon_0\frac{U^2}{d} \qquad [38]$$

Here, U is the applied voltage and d is the thickness of the dielectric layer (dielectric constant ε). This surface energy, which depends on the applied voltage, influences the wetting angle between the substrate and the liquid and thus the extension of the droplet.

For practical purposes, the electrode in contact with the droplet is disturbing the optical performance of these liquid droplet microlenses. In order to overcome this problem, Mönch *et al.* (2005) developed a microsystem where the electrowetting liquid is immersed into a microcavity together with a nonpolar liquid, which effectively forms the lens (**Figure 30**). By varying the wetting angle between the polar liquid and the sidewalls of this microcavity the shape of the lens liquid inside the cavity can be varied. For this effect, the name competitive electrowetting has been coined. Compared to the conventional electrowetting effect, where high voltages result in strong positive lens functionality, the effect is reverse in competitive wetting since the polar liquid is not identical with the lens liquid. Competitive electrowetting has significant advantages with respect to lens quality and stability (vibration damping). However, the total achievable optical functionality and tuning range are reduced

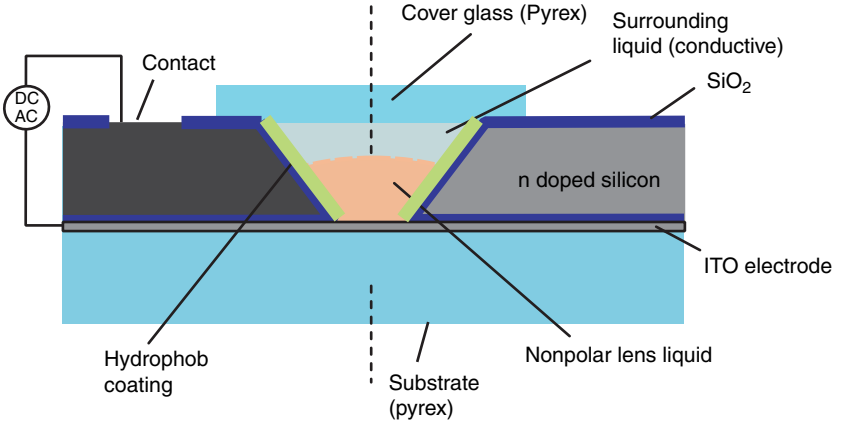

Figure 30 Schematic setup of tunable liquid microlenses generated by competitive electrowetting. (Source: Mönch W, Krogmann F, Zappe H 2005.)

due to the embedding of the tunable lens into the polar liquid, which causes a significant immersion effect. Consequently, microlenses demonstrated with this technology so far showed rather low NAs. A linear tuning range over a relatively broad range of focal lengths was demonstrated by Mönch *et al.* (2005).

Miniature- or microlenses are currently being commercialized for applications in miniature camera objectives for mobile phones or personal digital organizers (pdas).

3.02.2.5 Applications of Microlens Arrays

3.02.2.5.1 Wavefront sensing – Shack–Hartmann sensor

One of the most widespread application of microlens arrays is in wavefront sensing. To this end, the microlens array is used for wavefront division. Each single section of the wavefront is focused onto a position sensitive detector by the individual microlenses. Thus, the position is a measure for the inclination (gradient) of the specific section of the wavefront (Malacara 1992). The local gradients of the wavefront expressed by the inclination angles α_x and β_y with respect to the x- and y-axes, respectively, can be calculated from the following equation (**Figure 31**):

$$\sin\alpha_x = \frac{\Delta x}{\sqrt{\Delta x^2 + \Delta y^2 + f^2_{\text{microlens}}}}; \qquad \sin\beta_y = \frac{\Delta y}{\sqrt{\Delta x^2 + \Delta y^2 + f^2_{\text{microlens}}}} \qquad [39]$$

From the measurement of these local gradients the shape of the wavefront can be calculated, e.g., by polynomial fitting. One challenge connected to Shack–Hartmann wavefront measurements is interchannel crosstalk due to difficulties when assigning the focus spots to the correct microchannels, which is specifically important for the measurement of wavefronts with large local gradients (i.e., curvatures). This problem has been overcome with optimized evaluation algorithms resulting in a large achievable dynamic range. The smallest radius of curvature that can be measured with Shack–Hartmann sensors is approximately given by twice the wavelength of the individual microlenses (Pfund and Beyerlein 2002). The measurement precision depends on the spatial resolution of the position sensing system. Subpixel resolution can be achieved with suitable algorithms when determining the center of gravity of the focus spots (Pfund *et al.* 1998).

The conceptually very simple principle of Shack–Hartmann sensors allows the implementation of high-quality wavefront sensors with very simple optical setups. In recent decades, the development of arrays of microlenses with small submillimeter apertures and very good uniformity combined with high-resolution CCD or CMOS cameras and optimized evaluation software have triggered a wide range of new application areas for Shack–Hartmann sensors. Alternative methods for high-quality wavefront sensing require, for example, complex interferometric setups, which are potentially very sensitive to instabilities of the configuration, and often require multiple measurements for unambiguous results (Koch *et al.* 2000).

As a specific advantage, Shack–Hartmann wavefront sensors yield very quick results, which is specifically important, for example, for real-time applications in adaptive optics. The evaluation of the wavefront sensor is directly used for an optimization of the optical system in order to achieve optimum optical performance. Adaptive systems and thus Shack–Hartmann sensors are of great importance, e.g., in medical imaging or astronomy where the effects of atmospheric distortions on the optical imaging quality are to be corrected. Further fields of application are laser beam characterization and consumer optics testing (Hardy 1978, Tyson 1998).

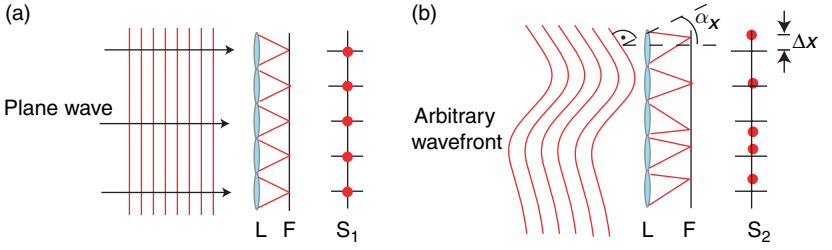

Figure 31 Schematic illustrating the concept of the Shack–Hartmann wavefront sensor. (a) Plane wave incident onto a microlens array L and top view of the focal plane S1 (distance F) and (b) arbitrary wavefront incident onto the microlens array L (again with top view of the focal plane S_2). Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

Finally, Shack–Hartmann sensing is an impressive application of large microlens arrays. Due to the potentially very fast measurements, Shack–Hartmann sensors have also been suggested for array testing of the properties of the array of micro-optical elements, specifically microlens arrays. Due to the very large number of elements present in these arrays, it is a serious challenge to test, e.g., arrays uniformity. With precise Shack–Hartmann measurements, which allow a thorough characterization of an individual element within a few seconds, it can become affordable to even perform 100% testing of arrays of thousands of micro-optical elements (Beyerlein *et al.* 2005).

3.02.2.5.2 Microlens array imaging

For various situations in everyday life it is desirable to develop ultracompact optical systems for imaging or image sensing. Compact digital cameras, for example, are nowadays integrated into mobile phones or handheld organizers. Very often, the size of the objective lenses really determines the limits to the integration of the whole system. Even though very small microlenses can be fabricated they have strict fundamental limitations with respect to the space bandwidth product (i.e., the number of resolvable pixels) as has been pointed out earlier. Thus, for conventional single pupil imaging systems there is a direct conflict between the size of the imaging system and the achievable image quality. Microlens array imaging to a certain extent allows overcoming this trade-off. There is a direct relation between the field size, the lens diameter, and the length of the imaging system. In order to be able to reduce the overall extension of the whole imaging system it is necessary to reduce the diameter of the individual imaging elements. In this case, a large number of those individual pupils are necessary in order to provide the necessary field size and overall pupil diameter. This is the concept of microchannel imaging (**Figure 19**) (Andersen 1979).

Besides the potentially very compact longitudinal extension of the microchannel imaging system, an additional advantage results from the discussion of the scaling behavior of optical lens elements. Since for large lens diameters it is becoming increasingly difficult to control wavefront aberrations, the quality of the individual microlenses used in microlens array imaging can be significantly lower. Also, because microlens arrays can be fabricated in large arrays using lithographic fabrication and replication processes, such systems can be significantly cheaper than the systems with large lenses. At the same time the systems are compact since the geometrical length l is now determined by the diameter d of the microlenses rather than by the diameter of the total image field.

However, for the generation of high-quality images with this setup several aspects have to be considered in designing the system. First, if a single microlens array imaging system is to be applied for the imaging task, each of the microlenses generates an inverted image of a portion of the object plane. Unless the object has a very specific symmetry, this local inversion distorts the image. This can be avoided by using two microlens arrays forming an array of microtelescopes (Sinzinger and Jahns 2003, Chap. 14).

Since the field of view (FOV) of each microlens is not limited to the diameter of the lens, multiple images of each part of the object field are formed in the image plane. The origin for these alternate imaging channels, for example, can be due to diffraction at the multiple aperture grid of the microlens array or due to scattering effects. Geometrical considerations illustrate that these multiple images coincide with a strictly symmetrical configuration and form a so-called composite image. The relation to be fulfilled for the formation of the composite image is given by the following equation:

$$z_C = z_O \qquad [40]$$

However, as illustrated in **Figure 32**, this does not necessarily occur in the same plane I, where sharp images are formed by the individual microtelescopes. The distance z_I can be found by applying the basic imaging equation for each of the two imaging steps. If $z_I \neq z_C$, in the image plane, multiple images of the object occur as indicated in **Figure 32**. High-quality imaging is possible in symmetrical setups, where the

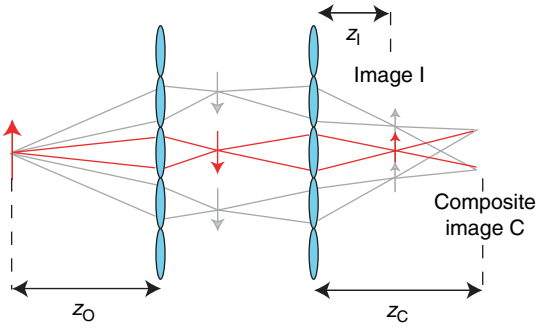

Figure 32 Microlens array imaging: geometrical considerations (detailed explanations see text). Adapted from Sinzinger S, Jahns J 2003 *Microoptics*, 2 edn. Wiley-VCH, Weinheim, Germany, with permission.

composite image plane coincides with the image plane of the microlenses. This symmetrical configuration leads to imaging systems that are free from antisymmetrical aberrations such as coma or distortion.

Second, in completely symmetrical microsystems where the image plane I and the composite image plane C coincide, the only source of background noise stems from light transmitted through noncorresponding microlenses. Field lenses as well as high aspect ratio walls separating the optical channels help to reduce this background noise due to crosstalk between the imaging channels (Duparré *et al.* 2004, Völkel *et al.* 1996).

Furthermore, for the design of a microlens array imaging system, it is necessary to consider the image field size of the microlenses as well as the fill factor of the arrays. For covering the whole image plane uniformly, it is required that the lenses are capable of imaging field sizes larger than the lens area. Depending on the lens quality, this can be achieved at the expense of lateral resolution if larger object and image distances are chosen.

Array imaging systems as described above have already been used for years in fax machines, photocopiers, and similar applications. Frequently, 1D arrays of GRIN SELFOC lenses are used for imaging. In such systems, it is important to achieve good uniformity in the intensity over the image plane. Aperture stops in the entrance and exit pupils as well as in the field lenses can be applied for increasing the uniformity. Combinations of refractive and diffractive microlens arrays with interesting imaging behavior have been demonstrated (Andersen 1979). The improvement of lithographic fabrication technology for microlens arrays with good imaging quality and high packaging density allows constructing array imaging systems for high-resolution imaging. One of the high-end applications of such systems is microlens lithography, which is being commercialized, for example, by Suss Microtec, Inc., Neuchatel (Suss 2006). In this application, microlens arrays are used for the imaging of a lithographic mask onto the wafer. Due to the small aperture, even diffraction-limited microlens imaging systems do not allow submicron resolution. Thus, with regard to the lateral resolution they cannot compete with sophisticated lens systems designed, for example, for high-resolution lithography. Microlens array imaging systems with a resolution of 2–5 μm have been demonstrated. The potential of microlens lithography lies in the possibility of using arrays with a large number of microlenses in imaging systems, which can, nevertheless, be compact and cheap. They can be applied for projection lithography of large field sizes without the need of step and repeat or scanning systems, which cause subsequent stitching errors. In microchannel or microlens lithography, compared to lensless proximity printing, which can also conceptually work on very large field sizes, large depths of focus are achieved. This is of specific importance for applications in microsystems fabrication, where often resist depths of several tens to hundreds of micrometers are to be achieved. Due to the parallel arrangement of a large number of microimaging systems, the overall SBP is very large. Of course, the fabrication of huge numbers of microlenses with uniform optical properties over the whole array turns out to be a severe technological challenge.

Significant efforts have been undertaken to optimize ultracompact imaging systems based on microlens arrays. Duparré *et al.* (2004) fabricated flat camera objective lenses, for example, for mobile phone systems. The challenge in this context is to image a large environmental scene onto a small camera detector, e.g., a CCD or a CMOS array. Again, the microchannel approach is necessary in order to avoid the unfavorable longitudinal size of single pupil imaging systems. Duparré *et al.* suggested an approach where each pixel is illuminated through an individual microlens channel. This configuration corresponds to the so-called apposition eye, which is well known from nature since the eyes of small invertebrates are built this way (Horridge 1977, Snyder 1977). In order to achieve the large viewing angle, in this configuration, the microlens array is combined with an array of detectors, eventually combined with pinholes, with a pitch significantly smaller than the microlens array. From geometrical considerations, it is easy to understand the functional principle (**Figure 33**). Each microlens array generates an individual image of the object. The pinholes in front of the detector array are actually sampling each of these images at specific positions. Thus, the detector signals combine to a compound image of the complete object. The maximum FOV of such an apposition imaging system is thus determined by the NAs of the individual microlenses:

$$\mathrm{FOV} = \arctan\left(\frac{a}{f}\right) < \arctan\left(\frac{p}{f}\right) = 2\mathrm{NA} \qquad [41]$$

Here, a is the size of an image formed by the individual microlenses. Consequently, a is smaller than the diameter D of the microlenses, which

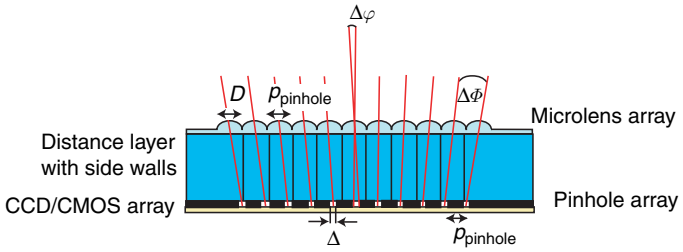

Figure 33 Compound eye imaging sensor; due to the mismatch in the period of the microlens array and the pinhole array, a large field of view can be achieved.

corresponds to the optimum fill factor of the pitch $p_{\text{microlens}}$ of the microlens array.

Other important parameters of the system are the viewing angle difference $\Delta\Phi$ between the individual microchannels, the so-called interommatidial angle, and the acceptance angle of the individual microchannel $\Delta\varphi$ where

$$\begin{aligned}\Delta\Phi &= \arctan\left(\frac{\Delta p}{f}\right);\\ \Delta\varphi &= \arctan\left[\frac{\text{FWHM}(\Delta \otimes \text{PSF}_{\text{microlens}})}{f}\right]\\ &\approx \sqrt{\left(\frac{\Delta}{f}\right)^2 + \left(\frac{\lambda}{D}\right)^2}\end{aligned} \qquad [42]$$

and $\Delta p = p_{\text{microlens}} - p_{\text{pinhole}}$ is the pitch difference between the microlens and the pinhole arrays.

FWHM denotes the full width half maximum diameter, $\text{PSF}_{\text{microlens}}$ denotes the point spread function of the individual microlens (diameter, D), Δ is the size of the pinhole, and $\otimes$ denotes the convolution. From the relations in eqn [42] the achievable angular resolution can be estimated (Duparré *et al.* 2005a). In the compound eye configuration, as every microlens is used for the generation of one pixel of the image, the overall resolution is quite limited. Thus, it can be more appropriate to apply this approach for the implementation of imaging sensors as has already been suggested and demonstrated by Sanders and Halford (1995).

Again in such a multichannel imaging concept, interchannel crosstalk is the most severe challenge. This can be avoided by stacking the microlens and the pinhole array with an array of absorbing walls separating the channels optically. These walls can be fabricated by ultraprecision micromachining or deep etching techniques (**Figure 33**).

For an optimization of the imaging quality, i.e., for the correction of the large field curvature, the array of microlenses needs to be fabricated with spatially variable lens properties (Duparré *et al.* 2005b, Sinzinger and Jahns 1997). The potentially large viewing angles of the microlenses at the edges of the described apposition eye imaging systems result in a significant amount of spherical aberrations. This can be reduced by adjusting the properties of the individual imaging channels. To this end, the imaging properties of each of the microlenses are adjusted to the specific imaging situation of the individual microchannels. In this case, the regularity of the microlens array is destroyed. For microlens arrays with varying properties of the individual microlenses the term chirped microlenses has been coined (Duparré *et al.* 2005b).

The most critical feature of microlens arrays for imaging systems is the uniformity of the microlenses. The availability of cheap high-quality microlens arrays will further increase the interest in array imaging techniques such as integral photography or Gabor's superlens. Here, the array imaging approach is generalized to the use of microlens arrays that differ in pitch or focal lengths. Significant potential can also be found in combination with DOEs to form more general array of optical elements (Davies *et al.* 1994, Hembd-Solner *et al.* 1999, Stevens and Harvey 2002).

3.02.2.5.3 Laser diode beam shaping and beam homogenization

One of the commercially most interesting applications of microlenses is laser diode beam shaping and beam homogenization (Leger 1997, Turunen and Wyrowski 1997). The challenge here is to cope with the different divergence angles as well as the different waist positions of the laser radiation emitted, for example, from edge-emitting laser diodes. Microlenses with specific astigmatism that can be integrated directly within the semiconductor substrate can potentially perform this task. An approach for their realization as GRIN microlenses

using ion exchange in glass substrates has been suggested. Such approaches in combination with optimized microtechnological approaches for the assembly and integration of the corresponding elements directly with the laser diodes offer unique possibilities for compact laser sources with preshaped beam profiles.

For many tasks, for example, in material processing or lithography, very homogeneous beam profiles are required. To this end, it is necessary to convert a Gaussian beam profile into a rectangular profile. Various different approaches to beam homogenization mostly based on DOEs have been suggested (Sinzinger *et al.* 1995). One of the most widespread techniques applies microlens arrays in the configuration of a fly's eye condenser. However, in this case, as described above, the periodicity of the array (array factor) results in destruction of the periodicity due to strong peaks in the diffraction pattern. Recently, promising approaches that focus on the use of irregular microlens arrays have been suggested (Wippermann *et al.* 2007).

3.02.3 Summary and Conclusions

Diffractive optics and microlenses are of crucial importance in microsystems, which incorporate optical functionality. This chapter outlines the fundamental theoretical and technological aspects of these fields. The main focus is to present an overview, describe current trends as well as most popular current applications, and provide crosslinks to the literature for a more thorough treatment of the various topics. It is certainly safe to forecast that microoptical elements and systems based on diffractive optics and microlens technology will even gain in significance with the progress of functional integration in complex microsystems in the near future.

Acknowledgment

The author would like to acknowledge the active collaboration with an enthusiastic team of colleagues and students with whom it is a lot of fun to work. Specific thanks also goes to agencies and state departments who provide funds for our research, which helps us to keep learning, i.e., the Thüringer Minsisterium for Wirtschaft, Technologie und Arbeit, the Thüringer Kultusministerium, The German and Europeas Science foundations (DFG and ESF). Specific thanks for proof reading go to Sebastian Stoebenau who did his job once more with amazing diligence.

Most importantly I would like to thank my wife Sabine and daughter Ronja for everything.

Biography

Stefan Sinzinger received his Dipl.-Phys. and Dr. degrees from the Friedrich-Alexander Universität (FAU) Erlangen-Nürnberg (Germany), Institute for Applied Optics (Prof. Dr. A. W. Lohmann), in 1989 and 1993, respectively, where he was involved in the design, fabrication, and characterization of diffractive and refractive micro-optical elements. Between 1990 and 1991 he spent 9 months at the NEC Research Center performing research on computer holography. In 1994, he joined Prof. Dr. J. Jahns at the Institute for Information Technology (Optische Nachrichtentechnik) at the Fernuniversität Hagen where he was performing research on planar micro-optical systems integration. In 1998 he received the Bennigsen-Foerder Award for young scientists in Nordrhein-Westfalen for the project Mikrooptischer Lesekopf für Kopierschutzhologramme (Micro-optical Readout Device for Security Holograms). After finishing his Habilitation on Planar-optical Systems Technology in 2002 he became Professor of Optical Engineering (Technische Optik) at the Technische Universität Ilmenau, Fakultät für Maschinenbau (Mechanical Engineering Department). He (co-)authored more than 30 publications in peer reviewed journals as well as more than 70 conference proceedings including various invited presentations. He is coauthor of the textbook Microoptics published in the second edition in 2003 by Wiley-VCH and editor of the textbook Optical Information Processing (author A.W. Lohmann) published in 2006 by the Universitätsverlag Ilmenau. He is performing as a reviewer for various international optical journals and is Associate Editor of the SPIE Journal on Microlithography, Microfabrication, and Microsystems. His current research is focused on the design, fabrication, and integration of micro-optical elements and hybrid optofluidic microsystems, the manipulation of micro- and nanoparticles through electromagnetic fields, as well as ultra-precision machining for optical microsystems.

3.03 Photonic Crystals

Susumu Noda[1], Department of Electronic Science and Engineering, Kyoto University, Kyoto, Japan

Nomenclature

2D	Two-dimensional
3D	Three-dimensional
PC	Photonic constant
a	Lattice period
f_i	Resonance frequency
Q	Quality factor
Q_i	Quality factor in-plane
Q_v	Quality factor vertically
SOI	Silicon on insulator
λ	Wavelength
T	Transmittance
R	Reflectance
D	'Drop' efficiency, for emission vertically from a defect
V	Modal volume

3.03.1 Introduction

The photonic crystal represents one of the most exciting recent developments in optics. Through periodic structuring of optically transparent materials with features whose spacing is on the order of the wavelength of light, a photonic band structure is generated in the optical transmission spectrum (Noda and Baba 2003, Yablonovitch 2000). Thereby, in the same manner that the electronic band gap, which results from the periodic atomic lattice structure in crystalline materials, prohibits the transport of electrons in a certain energy range, the photonic band gap prohibits the transport of photons in a certain energy range.

As shown in **Figure 1**, both 2D and 3D photonic crystals may be conceived (Ho *et al.* 1990, Noda *et al.* 1996, 2000), in which the uniform periodic structure prohibits transmission of light for wavelengths in the photonic band gap. Such photonic band gap structures become even more interesting through the introduction of defects, as shown in **Figure 2**, allowing light to be controlled in a number of ways. For example, by introducing a line-shaped defect, it is possible to form an ultra-small waveguide that permits the transmission of light only along the defect. Alternatively, light can be trapped at certain points by introducing point defects, thereby forming a photonic nanocavity.

By combining these line and point defects, it is possible to design ultra-small photonic circuits (or chips) with various functions. Furthermore, the band gap itself makes it possible to suppress spontaneous emission, which is a fundamental factor limiting the performance of various photonic devices. Finally, the recent introduction of the photonic heterostructure concept has further expanded the spectrum of applications for photonic crystals.

Photonic crystals are thus artificially structured materials whose optical behavior may be finely tuned by varying their periodic features. Two-dimensional structures, more easily fabricated than their 3D counterparts, form the basis for a wide

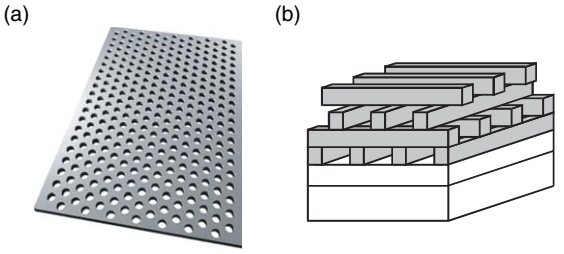

Figure 1 Schematic representations of (a) a 2D photonic crystal and (b) a 3D photonic crystal.

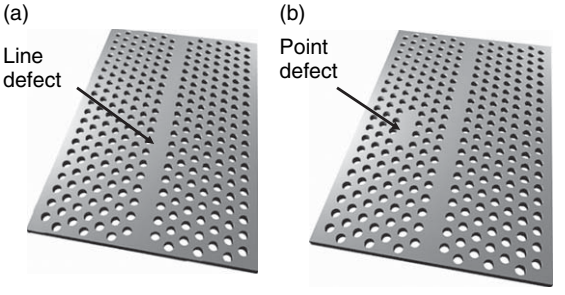

Figure 2 Schematic representations of (a) a line-defect waveguide introduced into a 2D photonic crystal slab and (b) a combined point-defect resonator and line-defect waveguide system.

variety of waveguide configurations and have enjoyed considerable popularity in a range of microsystems applications. For this reason, we focus on the design, composition, and application of 2D photonic crystals in this chapter.

3.03.1.1 Photonic Crystals in Microsystems

Optical microsystems are typically assembled from a variety of micro-optical components, including microlenses (Chapter 3.02) and micro-mirrors (Chapter 3.01). Optical systems based on integrated optics (Chapter 3.05) rely on the guiding of light in waveguides; these play a central role in the application of photonic microsystems to optical communications (Chapter 3.07). As photonic crystals move from the laboratory to the real world, they will allow the development of new types of waveguide-based optical components and will ultimately prove to be a driving force in reducing the size while enhancing the functionality of integrated optical systems.

Numerous applications have emerged for photonic crystals (Benisty *et al.* 2006, François *et al.* 2002, Prather *et al.* 2006), with relevance to microsystems. Premier among these are 2D waveguide structures with ultra-compact couplers, splitters and bends, as we will see in greater detail below. Using fabrication techniques borrowed from microsystems engineering, where soft lithography is of particular interest (Pisignano *et al.* 2004), photonic crystal waveguide structures have been used as compact waveguide circuits and circuit boards (Lee *et al.* 2006) and their dispersive properties have allowed the conceptualization of wavelength monitors (Viasnoff-Schwoob *et al.* 2005) as well as multichannel filters (Kee *et al.* 2006). Further uses of photonic crystal structures in passive optical systems include resonators for ultimate use as optical force sensors (Stomeo *et al.* 2006), polarizing beam splitters (Zhen and Li 2005), and large-area biosensors (Block *et al.* 2007).

Photonic crystals have also proven useful when combined with active optical elements, particularly light emitters. For example, nanoimprint lithography has been employed for the fabrication of photonic crystal structures on green LEDs (Kim *et al.* 2007), thereby strongly enhancing the luminescence intensity. Alternatively, using a focused-ion beam to generate the periodic structure on the surface of a vertical cavity laser, single-mode operation with high side-mode suppression has been demonstrated in this class of semiconductor laser (Leisher *et al.* 2006). As photonic crystals continue to find more applications in new and different areas of micro-optics, optical microsystems will benefit from the concomitant improvements in functionality.

3.03.1.2 Microsystems in Photonic Crystals

Just as microsystems may take advantage of advances in photonic crystals, these in turn profit from the capabilities offered by mechanical, electrical, and fluidic microsystems. The primary areas of interest include the use of microsystems to tune photonic crystals or to aid in their assembly.

The etch and assembly technologies used in microsystems engineering have proven beneficial for the flexible manufacture of optical devices based on photonic crystals. A general-purpose platform may be modified to act as a waveguide, a modulator, or a switch, based on details in the fabrication process (Zhou *et al.* 2005, 2006). Sophisticated MEMS assembly techniques have been employed to allow manufacture of 3D photonic crystal devices with considerable flexibility in the number and composition of the vertical layers (Aoki *et al.* 2003).

Finally, prospects for tuning the transmission characteristics of photonic crystals have recently improved due to the availability of various microsystems-based

actuation mechanisms. Precisely applied deformation of suspended membranes into which photonic band-gap structures have been etched has been shown to be effective in tuning the optical behavior (Rajic *et al.* 2003). Nano/micromechanical actuators have been employed to distend a flexible photonic crystal substrate (Park and Lee 2004), essentially stretching the periodic structure and thereby changing its period and thus optical transmission. Tunability has also been achieved using micro-fluidic structures (Chapter 2.13), whereby the refractive index contrast of individual holes of an etched photonic crystal may be addressed and modified using injection of fluids (Erickson *et al.* 2006); the entire microsystem consists of photonic, fluidic, and control layers, assembled into a single opto-fluidic microsystem.

These examples demonstrate the utility of photonic crystals for advanced optical microsystems as well as the importance of MEMS technologies for further advances in the photonics field. As the photonic crystal field matures, we expect that the spectrum of applications will continue to grow.

3.03.2 Two-Dimensional Photonic Crystal Slabs

Two-dimensional photonic crystal research initially targeted structures with periodicity in two dimensions and a third dimension assumed to be of infinite length (Joannopoulos *et al.* 1997), but recently the focus of research has been on slab structures (Noda and Baba 2003, Noda *et al.* 2000a, Painter *et al.* 1999), such as the one shown in **Figure 1(a)**, that have a thickness of the order of the wavelength of the light. The photonic crystal in this figure has a triangular lattice structure. The slab material is assumed to be a high refractive index medium, such as Si and III–V semiconductors, and the lattice points are assumed to be composed of a low refractive index medium, such as air. In 2D photonic crystal slabs, the confinement of light occurs in the in-plane direction due to a photonic band gap effect, and light is confined in the perpendicular direction by total internal reflection due to a difference in refractive indices. Pseudo-3D light control becomes possible as a result. It is, of course, important to optimize the structure so that the leakage of light in the direction perpendicular to the slab is minimized. Recently, as described in Section 3.03.2.1, 2D photonic crystal slabs have been subjected to various types of band gap/defect engineering, and research with the aim of realizing ultrasmall photonic circuits has been advancing steadily.

3.03.2.1 Control of Light by Combined Line- and Point-Defect Systems

As shown in **Figure 2(a)**, when a line defect is introduced into a 2D photonic crystal slab, it will act as an ultrasmall optical waveguide. In order to operate the waveguide efficiently, it is necessary to devise a way in which the leakage of light in the direction perpendicular to the slab can be nullified. In 1999, an optical waveguide experiment was reported (Baba *et al.* 1999), but the perpendicular leakage of light was not taken into consideration and the propagation loss was hence extremely large, exceeding 70 dB mm^{-1}. A year later in 2000, detailed results of an examination of the effects of the slab thickness and the ratio of the low refractive index (the medium (air) that forms the lattice points) to the high refractive index (the slab material) were reported, and a theoretical zero-loss waveguide structure was proposed for the first time (Chutinan and Noda 2000). In 2001, based on these design guidelines, a new waveguide experiment was conducted in which a low propagation loss of 7 dB mm^{-1} was obtained (Notomi *et al.* 2001). At the same time, discussions were taking place regarding the effect of modulation of the waveguide width on various waveguide characteristics. It was also pointed out that an increase in propagation loss was caused by vertical asymmetry in the slab (Tanaka *et al.* 2003). Regarding this, the importance of using crystals with a 2D in-plane full band gap was pointed out (Takayama *et al.* 2005). Recently, an extremely low waveguide loss less than 0.7 dB mm^{-1}, one-tenth of the previous best value, has been achieved (Kuramochi *et al.* 2005, McNab *et al.* 2003, Sugimoto *et al.* 2004b), and it should be possible to fabricate waveguides with propagation losses of less than 1 dB cm^{-1} in the near future. In view of the merits of the miniaturization made possible by the use of photonic crystals, these recent developments show that the minimization of waveguide loss in 2D crystal slabs has advanced to the point where it can almost be ignored.

In conjunction with studies of straight-line waveguides, detailed investigations of waveguide bends have also been carried out. It was initially pointed out that the bending of a waveguide was possible in purely 2D crystals, in regions of very broad wavelength transmission (Joannopoulos *et al.* 1997, Mekis *et al.* 1996), but that, in slab structures, the effect of light scattering to the outside of the slab meant that the low-loss band region in the bend part of the waveguide could not be enlarged to a great extent (Chutinan and

Noda 2000). Thereafter, the importance of controlling lattice point shapes positioned in the curved part was highlighted (Chutinan *et al.* 2002), and the enlargement and the shifting of the band area in the curved region were then reported (Sugimoto *et al.* 2004a, Takano *et al.* 2004). In 2004, it was also shown that low-loss curvature of a waveguide at a very broadband area might be possible even for a bend of 120° (Borel *et al.* 2004). In addition, there have been some studies of low-loss connections between line-defect waveguides and external optical systems (Gomyo *et al.* 2004, Miyai and Noda 2004, Miyai *et al.* 2002, Notomi *et al.* 2004, Shoji *et al.* 2002). Empirical studies have demonstrated that such waveguides can be connected with optical fibers with losses of less than a few decibels (Notomi *et al.* 2004, Shoji *et al.* 2002).

When a point defect is introduced into a photonic crystal, it becomes possible for this to act as a photonic nanocavity, in other words, as a trap of photons (Noda *et al.* 2000a, Painter *et al.* 1999). In photonic crystals, a point defect and a line defect can integrate quite spontaneously; thus, point defects have been extensively discussed with respect to their combination with line defects. High-Q nanocavities and fusion with nonlinear and/or active media will be discussed in Sections 3.03.2.3 and 3.03.2.4. **Figure 2(b)** shows such a combined system of defects (Akahane *et al.* 2003a, Noda *et al.* 2000a). Here, the point defect is formed by filling three lattice points with a high refractive index medium. If the resonant frequency of the point defect is defined as f_i and light with various wavelengths is introduced from the waveguide, light that has a frequency of f_i is trapped by the point defect. The trapped light resonates in the point-defect cavity and is emitted perpendicular to the slab surface due to a breakdown in the total internal reflection conditions. Such optical behavior in a combined line- and point-defect system could be used, for example, as a surface emitting-type ultracompact channel add/drop functional device. It would also be possible to apply it as an ultracompact device for sensing and/or trapping of nanomaterials.

In combined line- and point-defect systems, a maximum of 50% of the light introduced into the waveguide is trapped by the point defect and is emitted to free space (Chutinan *et al.* 2001), which can be deduced by coupled mode theory. This maximum efficiency is obtained when $Q_{in} = Q_v$, where Q_{in} and Q_v are defined as the quality factors of point-defect cavity for in-plane and vertical directions, respectively. More concretely, Q_{in} is determined by the optical coupling between the point-defect cavity and line-defect waveguide, and Q_v is determined by the total internal reflection conditions of the point defect in the direction perpendicular to the slab. The overall Q factor is expressed by $1/Q = 1/Q_{in} + 1/Q_v$ and it determines the wavelength resolution. **Figure 3** shows an

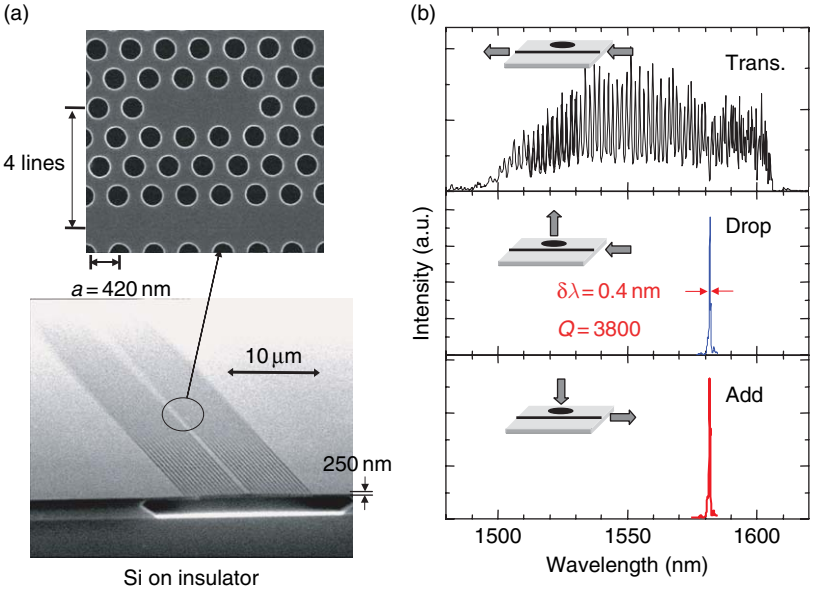

Figure 3 Device based on the photonic crystal slab design in **Figure 2(b)** and its characteristics: (a) electron microscopic image and (b) transmission, drop, and add spectra.

electron microscopic image of a sample composed of a combined point and line defect, and its transmission, drop, and add spectra (Akahane *et al.* 2003a). The device was created using $Si/SiO_2/Si$; that is, an SOI system. A photonic crystal is formed in Si in the top layer. The SiO_2 layer beneath was removed. In the transmission spectrum shown in **Figure 3**, the many sharp resonance peaks observed are attributed to Fabry–Perot resonance at both the edges of the waveguide. This phenomenon can be eliminated by applying an antireflection coating at the waveguide surfaces. An important point to note is the sharp decrease in transmission seen in the vicinity of 1.58 μm, which was attributed to the emission of light through the point defect in the perpendicular direction. **Figure 3** also shows the add spectrum obtained when light was introduced from free space into the point defect. It can be clearly seen that light is effectively entering and exiting through an extremely small point-defect cavity. The resolution determined from these drop and add spectra was estimated to be 0.4 nm, and a relatively large Q value of 3800 was obtained. By comparison with theoretical calculations, a high optical drop or add efficiency of up to 50% was obtained.

As outlined earlier, the use of 2D photonic crystal slabs has allowed the investigations of the basic behavior of line and point defects, individually and in combination, and a basis has been established for the realization of advanced functional photonic circuits.

3.03.2.2 The Effect of Introducing Heterostructures

Along with the advances in band gap/defect engineering described earlier, new concepts for controlling light with a greater degree of freedom are also emerging. One of these is the fabrication of photonic crystal heterostructures (Kawakami *et al.* 2003, Song *et al.* 2003). In the field of semiconductor electronics, the fundamental technology involving heterostructures is concerned with optical/electronic devices such as laser diodes and transistors, the importance of which does not need elaboration here. However, in addition to their functions in electronic systems, heterostructures are also playing important, albeit different, roles in photonic crystal research. The purpose of developing heterostructures in photonic crystals is explained below using an in-plane heterostructure (Song *et al.* 2003) in a 2D crystal slab.

Figure 4 shows an example of an in-plane heterostructure. This photonic crystal has the same basic structure as that shown in **Figure 3**, except that the lattice constant has been slightly varied to give seven different values. **Figure 4** also shows an electron microscopic image of each part of the sample actually created. The schematic drawing emphasizes the variation in lattice constant, but in the fabricated sample the lattice constant in adjacent areas differed by only 1.25 nm, too small to be discerned from the electron microscopic image. One of the promising properties of this type of in-plane heterostructure is the possibility of obtaining an optimized multiwavelength behavior

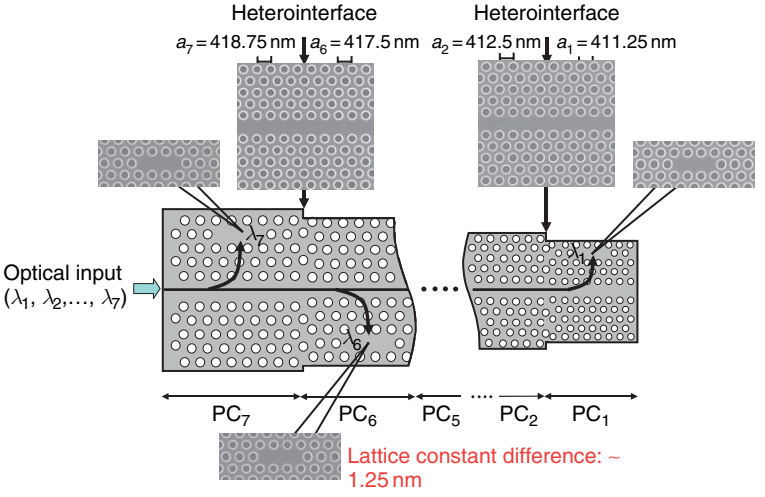

Figure 4 Example of an in-plane heterostructure: the insets show electron microscopic images of a fabricated sample. The schematic drawing highlights the differences in lattice constant, which is too small (1.25 nm) to be seen in the microscope images.

while maintaining the high values of Q (3800) and high drop efficiency (50%) for the configuration shown in **Figure 3**. As described in the previous section, the overall point-defect Q value is determined by a combination of the in-plane value Q_{in} and the vertical value Q_v, and the radiation efficiency is highest when $Q_{in} = Q_v$. If the size of only one point defect is changed, in turn changing the operational wavelength, the effective refractive index of the defect will also be altered, resulting in a change in Q_v. On the contrary, Q_{in} will be relatively unaffected: therefore, the overall Q value will be altered and the drop efficiency will change together with the wavelength. The difference in the overall Q value will also cause a change in the wavelength resolution. When a heterostructure such as that in **Figure 4** is used to vary the structure of the overall crystal proportionally, although the operating wavelength will change with the lattice constant, the Q value and drop efficiency, which are dimensionless quantities, will be maintained at constant values. In other words, multiwavelength operations will be possible as long as the wavelength resolution and drop efficiency are kept constant. **Figure 5** shows the results of such an experiment. It shows the light emitted from the point defect in each region as the irradiated wavelength is varied. **Figure 6** shows the corresponding drop spectra. The spectrum for λ_7 has been omitted due to light scattering effects at the waveguide edge. The relationship between the transmission and drop spectra is also shown. It can be seen that the drop wavelength interval was almost constant at approximately 5 nm, as per the design, and the Q value was maintained at 3800 in all wavelength regions. It is also demonstrated that the drop efficiency was essentially constant for λ_1 to λ_4.

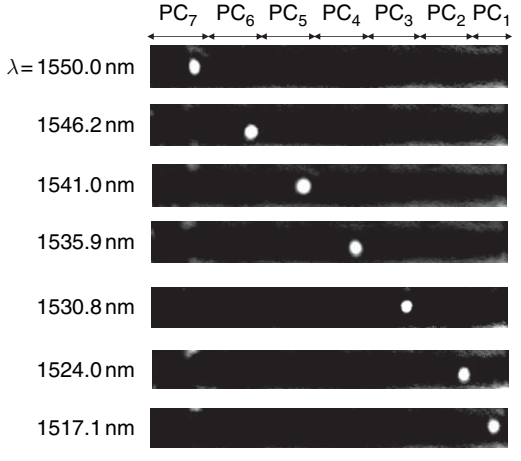

Figure 5 Multichannel drop operation of a device with an in-plane heterostructure.

Detailed calculations showed that in these wavelength areas a high drop efficiency of approximately 40% was obtained. In contrast, although the Q values for λ_5 and λ_6 were similar to those for λ_1 to λ_4, it is clear that far greater drop efficiencies than the theoretical maximum of 50% were obtained. The reason for this unexpected observation is concealed in the relationship between the transmission spectrum and the drop spectrum in the inset to **Figure 6**. It can be seen that λ_5 and λ_6 are outside the transmission area, that is, the cutoff area. **Figure 7(a)** illustrates this mechanism, where a heterostructure composed of two photonic crystals, PC_m and PC_n, that have different lattice constants is shown: a part of the light introduced into the waveguide in PC_m is transmitted (T) without being trapped by the point defect. A different part of the light is trapped by the point defect, but it is reflected (R) to the entrance side of the crystal without being emitted in the upward direction. The rest of the light is emitted upward from the point defect; that is, it drops (D). As described previously, based on coupled mode theory, it can be deduced that light D will have a maximum radiation efficiency of 50% and that $T = R = 25\%$. When there is a heterointerface and the emitted light cannot enter PC_n, or in other words, a cutoff condition is reached, the transmitted light T will be reflected by the interface. When the reflected light T interferes with R in an

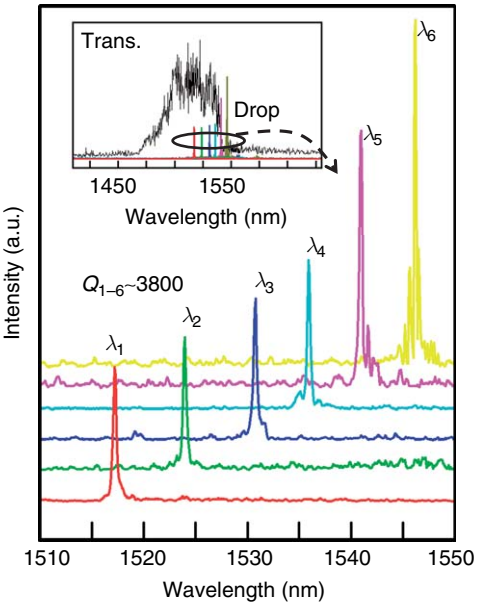

Figure 6 Drop spectra of a device with an in-plane heterostructure: the inset shows the relationship between the transmission spectrum and the drop spectrum. (Source: Song B S, Noda S, Asano T 2003 Photonic devices based on in-plane hetero photonic crystals. *Science* **300**, 1537; **Figure 1**).

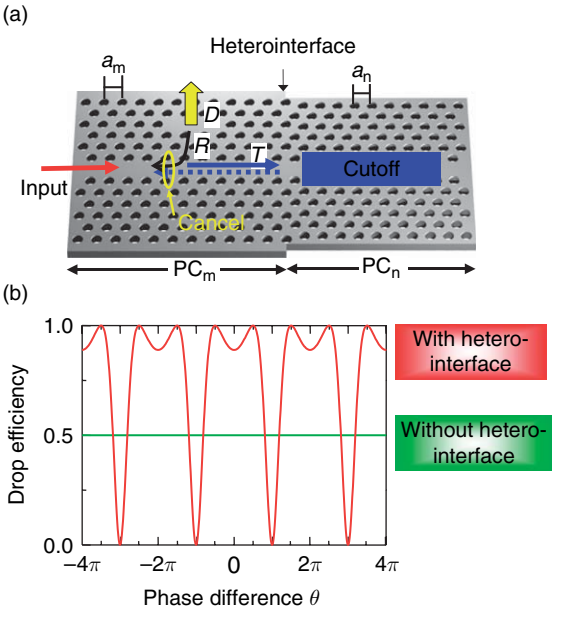

Figure 7 Schematic drawing showing (a) the effects of reflection at a heterointerface (*T*, *R*, and *D* represent the transmitted light (transmission rate), reflected light (reflection rate), and drop light (drop efficiency), respectively) and (b) the calculated properties of these effects.

out-of-phase fashion, T and R will cancel each other out and, as a result, the efficiency of light D becomes 100%. **Figure 7(b)** shows the calculated radiation efficiency when reflection at the interface is incorporated. The phase difference (θ) between light T reflected by the heterointerface and light R reflected by the defect is shown on the horizontal axis, and a high D efficiency can be obtained due to the broad phase conditions. If θ is carefully selected, it is possible to obtain a light radiation efficiency of 100%. The experimental results for λ_5 and λ_6 in **Figure 6** clearly show this effect.

As described above, important effects can be expected from the use of heterostructures, such as dramatically improving the degrees of freedom available in the design of devices and improving the operation efficiency. As described later, reflection at a heterointerface also plays an important role in the realization of ultrahigh-Q nanocavities. Furthermore, chirped photonic crystal waveguides could be made feasible through heterostructure deformations, and it might also be possible to use such heterostructures in a broad sense for controlling light propagation (Mori and Baba 2004). In the future, it is expected that heterostructures will continue to gain in importance as a technology for the realization of photonic crystal devices.

3.03.2.3 High-Q Nanocavities

The devices shown in **Figures 3** and **4** utilize photons that have been emitted to free space from a point-defect cavity. However, if the Q factor of the point defect could be increased sufficiently, the emission of photons outside the slab plane would be suppressed, even if photons were trapped by the point defect. An in-plane light circuit can then be composed (Takano *et al.* 2004, 2006).

It is thus expected that the development of high-Q nanocavities with very small modal volumes (V) will advance to enable the development of in-plane photonic circuits and to play an extremely important role in a broad range of other applications. Examples include the creation of strong coupling system between photon and electron systems for quantum computing, single-photon source for quantum communication, future photonic memory, and supersensitive sensing. The applications envisaged will be based on the extreme strengthening of the interaction between light and matter by strongly trapping light in a very small area over an extended timescale. In the following, discussions on recent advances in high-Q nanocavities are described.

The Q factor of the point-defect cavity shown in **Figure 3** was 3800, but recently, as shown in **Figure 8**, a phenomenon has been discovered whereby Q can be increased by at least a factor of 10 by simply tuning the lattice points (air holes) at both edges of the point-defect cavity (Akahane *et al.* 2003b). Before this phenomenon was found, it was revealed that a major cause

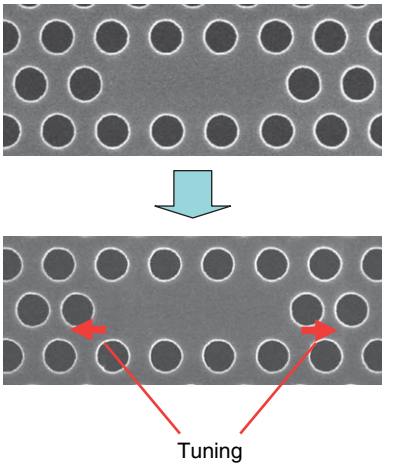

Figure 8 Method of enlarging the Q value of a donor-type defect in which three lattice points are filled (**Figure 3**). (Source: Akahane Y, Asano T, Song B S, Noda S 2003b High-Q photonic nanocavity in a two-dimensional photonic crystal. *Nature* **425**, 944–7; **Figure 1**).

of the leakage was light within the cavity being emitted in the direction perpendicular to the slab, due to abrupt reflection at the ends of the cavity along the long axis. In order to prevent such leakage, it is important that steep changes in the electric field gradient at the edge of the defect be avoided: the electric field gradient should have a gradual (ideally Gaussian) distribution (Akahane *et al.* 2003b). The tuning of the lattice points, as shown in **Figure 8**, corresponds to a change in the Bragg reflection condition at the cavity edge. The Bragg reflection is determined by a summation of partial reflections at a series of lattice points near the cavity. When lattice points near the cavity edges are tuned, the Bragg reflection condition should be modified. Because the phases of partial reflections at the tuned rods are changed, the resultant phase mismatch weakens the magnitude of Bragg reflection. To compensate for the reduction in the reflection, light is considered to penetrate more inside the Bragg reflection mirror and be reflected perfectly. It means that the electric field profile at the cavity edge becomes gentler. Based on the above ideas, nanocavities with various lattice point shifts were created, as shown in **Figure 9**, and the corresponding Q factors were measured. The highest value of Q (45 000) was obtained when the lattice point was shifted by approximately $0.15a$ (60 nm), where a is lattice constant. When the modal volume was standardized, this value corresponded to a record light-confinement effect.

Thereafter, tuning was performed not only for lattice points directly adjacent to the nanocavity but also for those that were two and three points away. A Q value of 100 000 was attained as a result (Akahane *et al.* 2005). Furthermore, very recently it was discovered that a photonic double heterostructure (**Figure 10**) that utilizes reflection based on mode gap effects at in-plane heterointerfaces, discussed previously, is able to achieve even higher Q values of ~1 000 000 (Asano *et al.* 2006, Song *et al.* 2005).

It can be concluded from the above results that, in accordance with the guidelines derived from Gaussian confinement, the use of even simple structures such as a 2D slab, together with lattice point tuning and the concept of a photonic double heterostructure, means that the realization of a cavity that does not leak is no longer just a dream.

3.03.2.4 Introduction of Nonlinear and/or Active Functionality

As described earlier, various advances have been made in 2D photonic crystal slab structures. All of these have occurred based on the use of material with a constant refractive index that forms the photonic crystals, the

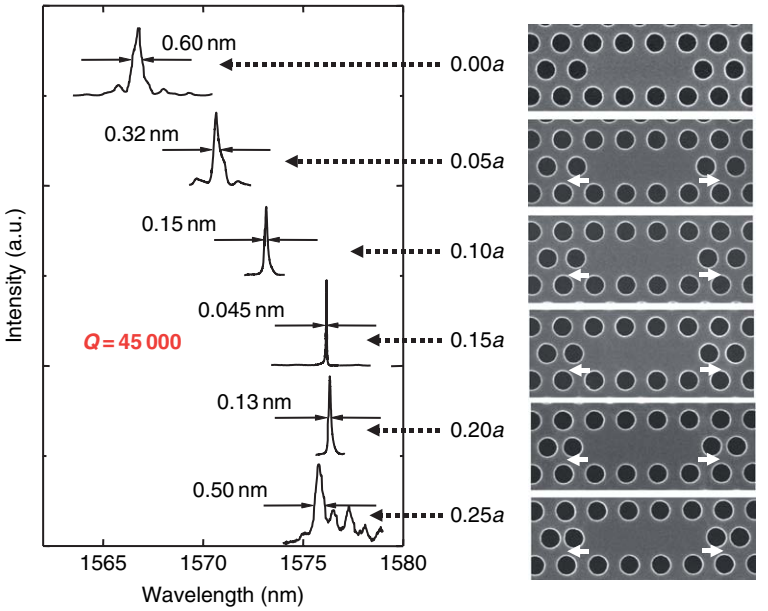

Figure 9 Electron microscopic images of a nanocavity with various lattice point shifts and their corresponding resonance spectra. (Source: Akahane Y, Asano T, Song B S, Noda S 2003b High-Q photonic nanocavity in a two-dimensional photonic crystal. *Nature* **425**, 944–7; **Figure 4**).

(Source: Song B S, Noda S, Asano T 2005 Ultra-high-Q photonic double-heterostructure nanocavity. *Nat. Mater.* **4**, 207–10; **Figure 1**).

material used being transparent. As ever, more advanced functionality is demanded, dynamic control of the photonic crystals becomes important. Great effort is currently being undertaken to realize such control. For example, in **Figure 3** the resonance (drop) wavelength is fixed, but if the refractive index of the defect is dynamically varied, it becomes possible to tune the resonance wavelength. Changes in the refractive index can be induced by thermal effects and/or carrier plasma effects (Asano *et al.* 2005, Baba *et al.* 2003). **Figure 11** shows an example of the outcome of such tuning. By introducing light into the point defect and thermally changing the refractive index of the defect, tuning of the resonance wavelength by up to 5 nm is achieved. This device is extremely compact, so that even the use of a thermal effect allows a dynamic speed to be obtained in a matter of microseconds. Implementation of a high-speed, nonlinear effect has recently been tried. There have also been recent reports of the fabrication of a bistable switch that is operated at a low-input intensity (Notomi *et al.* 2005).

Advances have also been made in the realization of extremely small active devices by the introduction of active media into a 2D photonic crystal slab. Two-dimensional photonic crystal point-defect lasers were first reported in 1999 (Painter *et al.* 1999). Thereafter, various improvements to the structure of the resonator were made, improving the performance. In 2004, a current injection operation into a single point-defect device was carried out (Park *et al.* 2004). Research into line-defect lasers was continuing at the same time, and, in 2002, the first oscillations from a line-defect laser were reported (Sugitatsu and Noda 2003). This showed that substantial wavelength tuning was possible by varying the width of the waveguide (Sugitatsu *et al.* 2004). Very recently, an attempt was made to introduce quantum dots (Arakawa and Sakaki 1982, Nabetani *et al.* 1994, Tabuchi *et al.* 1992) into the high-Q nanocavity shown in **Figure 8** (Yoshie *et al.* 2004). Further research and development related to single-photon sources and optical quantum information devices is expected using methods that introduce an active medium.

Lett.* **41**, 37–8; **Figure 2**).

3.03.3 Summary and Future Prospects

Recent advances in photonic crystals have been discussed in terms of band–gap/defect engineering. Although many of the explanations given may have been insufficient due to space limitations, it is hoped that the reader gets a sense of the steady advances made in the last few years in fundamental technology for operating and controlling light in extremely small volumes, which was the initial expectation of photonic crystals.

It is expected that, over the next 10 years, nanoprocessing technology will dramatically advance and that more reliable and precise devices will continue to be developed. In the case of 2D photonic crystal slabs, there is promise of remarkable advances in Si-based systems, together with progress in integration with electronic circuits. Further advances can be expected in combined optical and electronic circuits equipped with features such as optical switching, tuning, and delay functionality. It is expected that the main components of such circuits will be optical, and optical/electronic chips will be developed. There is no doubt that the size and power consumption of such devices will be more than tens to hundreds of times smaller than they are now. Advances in a large number of applications can also be expected, including developments in next-generation miniaturized multiwavelength light sources based on the addition of active functionality, supersensitive sensors, optical memory functions that require a high Q value, and single-photon light sources.

Biography

Susumu Noda received B.S., M.S., and Ph.D. degrees from Kyoto University, Kyoto, Japan, in 1982, 1984, and 1991, respectively, all in electronics. In 2006, he received an honorary doctor degree from Gent University, Gent, Belgium. From 1984 to 1988, he was with the Mitsubishi Electric Corporation, and was engaged in research on optoelectronic devices including AlGaAs/GaAs distributed feedback (DFB) lasers and multiple quantum well (MQW) DFB lasers. In 1988, he joined Kyoto University and is currently a Professor with the Department of Electronic Science and Engineering. His research interest covers physics and applications of photonic and quantum nanostructures including photonic crystals and quantum dots. He is an author of more than 200 scientific journal papers including *Nature* and *Science* on these research fields. Prof. Noda is a member of IEICE and the Japan Society of Applied Physics (JSAP). He received various awards including the IBM Science Award (2000), the JSAP Achievement Award on Quantum Electronics (2005), and Optical Society of America, Joseph Fraunhofer Award/Robert M. Burley Prize. From 2003 to 2005, he served as IEEE/LEOS Distinguished Lecturer.

3.04 IR Imaging

Masafumi Kimata, Department of Micro System Technology, College of Science and Engineering, Ritsumeikan University, Shiga, Japan

Glossary

Nomenclature *Definition*

Resonant optical cavity An infrared-absorbing structure having a metal reflector, a thin-metal film absorber, and a dielectric layer between them.

1/*f* noise The noise whose power is inversely proportional to the frequency.

Absorptivity The ratio of absorbing light energy to incident light energy.

Background fluctuation noise-limited *D** The D^* that is determined by the noise due to the fluctuation of radiation between the thermal infrared detector and the surroundings.

Background fluctuation noise-limited NETD The NETD that is determined by the noise due to the fluctuation of radiation between the thermal infrared detector and the surroundings.

Blackbody *D** The D^* specified for a blackbody light source having a specified temperature.

Curie temperature The temperature at which a phase transition due to heating occurs in a ferroelectric.

Cutoff wavelength The wavelength beyond which a photodetector has no useful response.

***D** (dee star, normalized detectivity)** A figure of merit that normalizes the detectivity in terms of the signal bandwidth and detector area.

Detectivity The inverse value of the noise equivalent power.

Dielectric bolometer A ferroelectric infrared detector that uses the temperature dependence of the dielectric constant near its Curie temperature.

Diode bolometer A thermometer or infrared detector using temperature current–voltage characteristics of a diode.

Field-enhanced pyroelectric coefficient The pyroelectric coefficient in which enhancement by the temperature dependence of the dielectric constant is taken into consideration.

Fill factor Ratio of the infrared-absorbing area to the pixel size.

Hybrid structure An IRFPA structure in which a detector chip is mated with a readout IC by bump bonding.

Infrared focal plane array (IRFPA) The infrared imaging device that has a number of photodetection pixels and readout electronic circuits.

Johnson noise A noise associated with the random motion of a carrier in a resistance.

Loss tangent A parameter that correlates the loss resistance in a ferroelectric with the impedance of its capacitive component.

Monolithic structure An IRFPA structure in which an array of pixels and readout circuits are integrated on a silicon chip.

Noise equivalent power The radiant power incident on an infrared detector that gives rise to a signal equal to the total rms noise.

Noise equivalent temperature difference (NETD) The temperature difference of a blackbody that produces a signal-to-noise ratio of one.

Pixel The unit cell of the imaging device.

Pyroelectric coefficient The gradient of the spontaneous polarization versus temperature curve.

Pyroelectric detector A ferroelectric infrared detector that uses the temperature dependence of spontaneous polarization.

Quantum infrared detector An infrared detector that detects the infrared rays by interaction of photon and electron/hole.

Resistance bolometer An infrared detector or thermometer that uses the temperature dependence of the resistance of a metal or semiconductor.

Responsivity The value that represents how sensitive a photodetector is, and is given by the output signal amplitude divided by the incident light power.

Scene temperature sensitivity The sensitivity defined as the output signal amplitude per Kelvin temperature change in the observed scene.

Seebeck coefficient The thermoelectric voltage per Kelvin temperature difference generated by the Seebeck effect.

Seebeck effect The effect in which an electromotive force is generated when two dissimilar conductors are connected and are given different temperatures at two junctions.

Spectral D^* The D^* specified for a monochromatic light source.

Shot noise A noise generated when carriers flow over some potential barrier.

SOI wafer A silicon wafer that consists of a single-crystal silicon substrate, a silicon dioxide layer, and a top single-crystal silicon layer.

Spontaneous polarization Polarization that appears in a pyroelectric material without an external applied electric field.

Temperature coefficient of resistance (TCR) The ratio of the resistance change due to 1 K temperature change to the resistance of the resistance bolometer.

Temperature fluctuation noise-limited D^* The NETD that is determined by the noise due to the fluctuation of heat conduction between the thermal infrared detector and the surroundings.

Temperature fluctuation noise-limited NETD The NETD that is determined by the noise due to the fluctuation of heat conduction between the thermal infrared detector and the surroundings.

Thermal conductance A parameter defined as the transported energy per Kelvin temperature difference.

Thermal infrared detector An infrared detector that detects the infrared rays by its change in temperature.

Thermal time constant A parameter that represents the thermal response speed.

Thermocouple A thermometer operated by the principle of the Seebeck effect.

Thermoelectric detector A thermal infrared detector that uses a thermometer based on the Seebeck effect.

Uncooled IRFPA An IFRPA that integrates thermal infrared detectors. Quantum IRFPAs operated at ambient temperature are sometimes categorized under uncooled IRFPA.

Abbreviations

Acronym	*Full spelling and explanation*
AFM	*Atomic Force microscope*. High-resolution microscope for observing material surfaces to an accuracy of atomic level.
BST	*Barium strontium titanate*. A material used for ferroelectric uncooled IRFPAs.
CCD	*Charge-coupled device*. A semiconductor device that has an array of MOS capacitors and has a function to transfer electronic charges.
CMOS	*Complementary metal oxide semiconductor*. MOS circuits or LSI having both n-channel and p-channel MOS transistors.
EDP	*Ethylenediamine pyrocatechol*. Name of an etchant for silicon anisotropic etching that contains ethylenediamine, pyrocatechol, and water.
FPA	*Focal plane array*. Imaging devices that integrate a great number of pixels and readout circuits.
FPN	*Fixed pattern noise*. A noise in FPAs that is a time-independent characteristic. The sources of this noise include pixel-by-pixel nonuniformity of responsivity and dark current, and nonuniformity in readout circuits.
IRFPA	*Infrared focal plane array*. FPAs having response in infrared spectral bands.
IVP	*Integrated vacuum package*. A configuration of vacuum package for uncooled IRFPAs that consist of an IRFPA chip and lid directly bonded to the IRFPA chip.
LSI	*Large-scale integration*. Silicon electronic devices that integrate a great number of transistors and other electronic components.
LWIR	*Long-wavelength infrared*. An infrared spectral band between 8 and 14 μm.
MOD	*Metal organic decomposition*. A thin-film deposition method that utilizes decomposition of metal organic precursors at elevated temperatures.
MOS	*Metal oxide semiconductor*. A transistor that has a source and drain diffusion region and a channel region that is formed in a metal oxide semiconductor structure.
MWIR	*Middle-wavelength infrared*. An infrared spectral band between 3 and 5 μm.
NEP	*Noise equivalent power*. A figure of merit for light detectors that gives the lowest detectable infrared radiation power for the detector and is defined as a ratio of total rms noise to responsivity.
NETD	*Noise equivalent temperature difference*. A figure of merit for infrared imaging system representing the target temperature difference that gives the output signal having the same magnitude as the rms noise.
PCT	*Lead calcium titanate*. A material used for ferroelectric uncooled IRFPAs.
PECVD	*Plasma-enhanced chemical vapor deposition*. CVD processes that utilize plasma to enhance chemical reaction rates of the precursors.
PLD	*Pulsed laser deposition*. A thin-film deposition method utilizing a technique called laser ablation.
PSG	Phosphosilicate glass.
PST	*Lead scandium tantalate*. A material used for ferroelectric uncooled IRFPAs.
PVDF	*Polyvinylidene fluoride*. A material used for ferroelectric uncooled IRFPAs.
PZT	*Lead zirconate titanate*. A material used for ferroelectric uncooled IRFPAs.
QDIP	*Quantum dot infrared photodetector*. A quantum infrared detector that has a quantum dot structure and operates based on the intraband transition.
QWIP	*Quantum well infrared photodetector*. A quantum infrared detector that consists of a multilayer of ultrathin semiconductor films and operates based on the intraband transition.
ROIC	*Readout integrated circuit*. Electronic circuits for readout operation of FPA.
SEM	*Scanning electron microscope*. A high-magnification microscope that uses a scanning electron beam.
SOI	*Silicon on insulator*. A silicon wafer having a thick single-crystal silicon substrate, a thin single-crystal silicon

	layer, and a silicon dioxide layer between them.
TCR	*Temperature coefficient of resistance*. A figure of merit for the resistance bolometer that gives a ratio of the change of resistance per Kelvin to the value of the resistance.
TFFE	*Thin-film ferroelectric*. A name expressing a monolithic ferroelectric uncooled IRFPA pixel.
TMAH	*Tetramethyl ammonium hydroxide*. An etchant for silicon anisotropic etching, the chemical formula of which is $(CH_3)_4NOH$.
Type II SLS	*Type II strained layer superlattice*. A quantum infrared detector that consists of a multilayer of ultrathin semiconductor films and operates based on the interband transition between adjacent semiconductor layers.

3.04.1 Introduction

Infrared (IR) imaging is a tool to see objects at ambient temperatures in complete darkness. It also offers temperature information. IR imaging is a passive imaging that does not require any illuminating light sources. Its usefulness has already been recognized in a number of application areas, including security, surveillance, search and rescue, fire fighting, traffic systems, law enforcement, process control, and predictive maintenance. The long-wavelength IR (LWIR; 8–14 μm) and middle-wavelength IR (MWIR; 3–5 μm) spectral bands are made available for the above-mentioned applications because of sufficient IR radiation energy and high atmospheric transmission. Both quantum and thermal IR detectors are used in IR imaging. Although the sensitivity and response speed of the quantum detectors is much higher than those of the thermal detectors, recent advances in IR focal plane arrays (IRFPAs) with thermal detectors based on microelectromechanical systems (MEMS) technology attract much attention particularly from the viewpoint of civil applications. The IRFPA with a thermal detector is called the uncooled IRFPA, because in contrast to the IRFPA with a quantum detector, it can be operated at ambient temperatures. In the thermal IR detector, the IR energy is converted to heat that changes the detector temperature, and the temperature change is measured by a thermometer in the detector. The responsivity of the thermal IR detector is inversely proportional to the thermal conductance between the detector and the substrate. Since MEMS technology makes it possible to fabricate structures with very low thermal conductance, remarkable performance improvement in uncooled IRFPAs has been accomplished by the introduction of MEMS technology. There are some books that include topics on thermal detectors and uncooled IRFPAs (Capper and Elliott 2001, Dereniak and Crowe 1984, Kruse 2001, Kruse and Skatrud 1997, Kruse *et al.* 1962).

According to Walsh and coworkers (Rai-Choudhury 2000), MEMS is the technology that enables the manufacture of products that would otherwise be impossible to produce, improves the manufacturing efficiencies by as much as an order of magnitude, improves the critical performance aspects of current products by as much as an order of magnitude, and/or improves the product quality by reducing the component size and number. Before the MEMS era, uncooled IRFPAs were manufactured in the form of a hybrid structure, in which a detector chip is mated with a Si readout integrated circuit (ROIC) using bump structures (Capper and Elliott 2001, Kruse 2001, Kruse and Skatrud 1997). The heat loss in this case was determined by the thermal conductance through the bump structure, and it was very difficult to reduce the thermal conductance because of limitation of the bump size and material. Uncooled IRFPAs based on MEMS technology have monolithic structures, in which freestanding thin-film thermometers are fabricated above or by the side of readout circuits. The freestanding structure is supported by thin and narrow legs that are made by the same technology as that for silicon large-scale integrations (LSIs), and their thermal conductance is much lower than that of the bump in the hybrid structure (Capper and Elliott 2001, Kruse 2001, Kruse and Skatrud 1997). Thus, MEMS technology has been a powerful method to achieve responsivity improvements of uncooled IRFPAs. Furthermore, the batch process by the MEMS technology promises low-cost, large-scale mass production, and it is expected to open huge markets for IR imaging systems. While the first-generation MEMS-based uncooled IRFPAs had single-level and double-level structures that were realized by the

conventional bulk and/or the surface micromachining technology, the second-generation devices having smaller pixel sizes have more complicated structures that require more sophisticated MEMS technology (Kosasayama 2004, Murphy 2002). Thus, the importance of MEMS technology is still growing for uncooled IRFPA development.

The uncooled IRFPA is one of the most successful examples of the so-called integrated MEMS device, so is the digital micromirror (DMD) device. It has a great number of tiny thermal IR detector pixels (typically from a few tens of thousands to a few hundreds of thousands) on a chip, along with readout circuits. To manufacture integrated MEMS devices, compatibility with Si-LSI processes is the most important issue to be addressed when designing the devices. The DMD is a digital device, which integrates small bistable movable mirrors and static random access memory cells to control them. On the other hand, the uncooled IRFPA has no moving components and has analog circuits that deal with minute analog signals from thermometers. Although the analog circuit technology is not a major theme of this chapter, it is important to note that the current performance of the uncooled IRFPAs would not be reached if low-noise analog circuits were not developed for them.

This chapter is devoted to uncooled IRFPA technology, including the basics and state-of-the-art technology. Before explaining individual IRFPA technologies, the classification and history of IR detectors and IRFPAs are reviewed in Section 3.04.2. Then, the basics of the thermal detectors and their fundamental performance limit are discussed along with some important formulae in Section 3.04.3. Following these introductory sections, individual uncooled IRFPA technologies, including the ferroelectric IRFPA, microbolometer IRFPA, thermoelectric IRFPA, diode IRFPA, and bimaterial and thermo-optical IRFPAs, are described in the continuing sections.

3.04.2 History and Classification

The history of IR detectors started with the discovery of IR radiation by Herschel in 1800 (Rogalski 1995). In his experiments, a thermal IR detector of a glass liquid thermometer was used. Since then, various IR detectors have been developed. The IR detectors are broadly categorized into two classes: thermal detectors and quantum detectors. **Figure 1** shows a classification of the IR detectors that are used for IRFPAs.

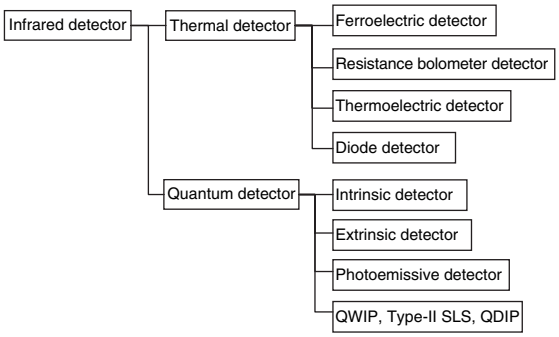

Figure 1 Classification of the infrared detectors used for infrared focal plane arrays.

The thermal detectors absorb IR radiation and change their temperature. The change in the temperature is measured by the thermometer fabricated on the detector. The thermal detectors are generally classified according to the type of thermometers, as shown in **Figure 1**. Although any physical mechanism having a temperature dependence can be applied to thermal detectors, practical thermal detectors currently used in IRFPAs are the pyroelectric detector, the dielectric bolometer, the resistance bolometer, the thermoelectric detector, and the diode bolometer.

The first thermal detector developed after Herschel's discovery was the thermoelectric detector. The thermoelectric detector utilizes the Seebeck effect that appears when two dissimilar metals and/or semiconductors are connected (Dereniak and Crowe 1984). The thermometer based on the thermoelectric effect is called the thermocouple and is used not only for IR detectors but also for contact-type thermometers. For IR detectors, serial-connected thermocouples called thermopiles are often used to enhance responsivity.

In 1881, Langley made the first resistance bolometer (Kruse and Skatrud 1997). His IR detector makes use of the temperature dependence of a Pt stripe resistance. Metals have positive temperature coefficients of resistances (TCRs), i.e., they increase their resistance as the temperature rises. The positive TCRs of metals are caused by the increased probability of scattering at higher temperatures. Both metals and semiconductors are used for resistance bolometers. In contrast to metals, semiconductors have negative TCRs. The characteristics of semiconductors reflect temperature dependences of the number of carriers and/or the mobility. Various sintered mixtures of oxides were developed for

semiconductor resistance bolometers. Typically, the sensitivity of the semiconductor bolometers is an order of magnitude larger than that of the metal bolometers.

Pyroelectric detectors and dielectric bolometers are made of ferroelectric materials. Pyroelectricity has long been known, but there were genuine efforts to understand this phenomenon only in the 19th century (Kruse and Skatrud 1997). The operation mechanism of the pyroelectric IR detector is based on the temperature dependence of the spontaneous polarization, and it is widely used as single-element IR sensors. The change in spontaneous polarization can be detected by measuring a transient current flowing through a capacitor having a pyroelectric material as an insulator. Hanel proposed the usage of the temperature-sensitive dielectric constant of ferroelectric materials in bolometers (Kruse and Skatrud 1997). Ferroelectric materials show large temperature dependence of the dielectric constant near the Curie temperature. We can apply this effect to thermometers for IR detectors. This class of ferroelectric IR detectors is called the dielectric bolometer.

The current–voltage characteristic of diodes is also temperature dependent and is used for contact-type thermometers and IR detectors. Application of the diode bolometer to the IR detector attracted attention with the progress in the development of 2D IRFPAs, because its most competitive feature when compared with other technologies is the compatibility with Si-LSI technology (Ishikawa *et al.* 1999).

Although thermal detectors have attractive features such as ambient-temperature operation and low-cost mass production, research and development of quantum detectors became the most important theme in IR technology from the mid-20th century because the first-generation IR imaging systems, which were mechanical scanning systems, required higher sensitivity and faster response for IR detectors. In the quantum detectors, the absorbed photons excite electrons in materials, changing their energy distribution. The change in the energy distribution is detected as a change in the resistance or in the current flow through an energy barrier. The operation mechanism of the photon detectors ensures a high-sensitivity and high-frequency response at the expense of the cooling requirement. While the thermal detectors for the LWIR spectral band can operate at ambient temperatures, the quantum detectors having spectral sensitivity in the MWIR and LWIR spectral bands generally have to be cooled down to cryogenic temperatures in order to reduce thermal excitation of the carriers.

Materials investigated in the early stage of quantum detector development were semiconductors of the lead salt family (PbS, PbSe, and PbTe) (Rogalski 1995). These materials were mainly used for single-element intrinsic photoconductive IR detectors. Both photoconductive and photovoltaic detectors are available with the intrinsic photodetection mechanism. The next important narrow gap semiconductor was single-crystal InSb (Capper and Elliott 2001). Extensive research on InSb during the 1950s and 1960s improved the crystal quality and purity, and thus contributed to IR detector technology. The bandgap energy of InSb is 0.23 eV at 77 K, which corresponds to a cutoff wavelength of 5.5 μm. The most important material in intrinsic IR detectors is HgCdTe, which was introduced by Lawson *et al.* in 1959 (Lawson *et al.* 1959). The bandgap energy of this alloy is adjustable, and as a result wavelength customization is possible in a very wide wavelength range between about 2 and 14 μm. In the late 1970s, and through the 1980s, HgCdTe technology was focused on developing the photovoltaic device because large-format IRFPAs needed IR detectors with low power dissipation and high impedance to interface to readout circuits. The photovoltaic HgCdTe detectors are widely used in the second-generation IR imaging systems, in which linear or 2D staring IRFPAs are incorporated. In contrast to mechanical scanning systems, every pixel in the staring IRFPA continuously stares the scene allocated for the pixel.

Si- and Ge-based extrinsic photoconductive detectors are being developed to extend the detection wavelength into the much longer wavelength in the IR region. Stressed Ge:Ga extrinsic photoconductors exhibit useful responses up to a wavelength of 200 μm (Rogalski 1995). Although extrinsic Si detectors are attractive for large-scale integration because of the compatibility with Si-LSI technology, low operation temperature restricted their applications to limited areas such as astronomy. In the early 1960s, the first real-time thermal imaging system operating in the LWIR spectral region was developed with a Hg-doped Ge extrinsic linear detector array (Rogalski 1995).

Noble proposed a metal oxide semiconductor (MOS) X–Y imaging array in 1968 (Noble 1968), and the charge-coupled device (CCD) was invented by Bole and Smith in 1970 (Boyle and Smith 1970). Such inventions triggered development of 2D staring

FPAs in IR spectral bands as well as in the visible range. Emergence of 2D staring IRFPAs changed the circumstances for IR detector development. Staring operation alleviates requirements for the sensitivity and response speed because of the long integration time in the 2D IRFPAs. In place of high sensitivity and fast response, capability of large-scale integration and high responsivity uniformity became important to realize high-performance IR imaging systems. It is important to note that nonuniformity of 2D IRFPAs sometimes limits the noise equivalent temperature difference (NETD) because IR imaging is high background imaging. This change in the circumstances sheds light on some photon detectors with low quantum efficiency, such as Si-based photoemissive detectors and GaAs-based quantum well IR photodetectors (QWIPs) (Rogalski 1995). It also revived the thermal detectors with relatively low responsivity and slow response speed.

Photoemissive detectors with Schottky barrier and heterojunction detect IR rays by using their potential barriers to measure the change in the energy distribution of carriers. Despite their relatively low quantum efficiency, PtSi Schottky-barrier IRFPAs were in the leading position in the array size race of IRFPAs for more than 10 years from the early 1980s due to their monolithic structure fabricated with a Si-LSI-compatible process and due to exceptionally high uniformity of responsivity. Nonuniformity of <1% is routinely obtained with PtSi Schottky-barrier IRFPAs. The first full-TV resolution IRFPA (Kimata *et al.* 1987) and the first megapixel IRFPA (Yutani *et al.* 1991) were developed with the PtSi Schottky-barrier technology in 1987 and 1991, respectively.

Quantum well or superlattice photodetectors are the newcomers in the quantum IRFPA field. This type of photodetector is divided into three groups:

(1) The QWIP (Rogalski 1995).
(2) The type II strained layer superlattice (SLS) (Rogalski 1995).
(3) The quantum dot IR photodetector (QDIP) (Lim *et al.* 2006).

The photodetection mechanism of QWIP is based on intersubband transition. Thanks to the mature material and process technology, GaAs-based QWIPs made significant progress in the 1990s. Compared to intrinsic detectors, QWIPs suffer from lower quantum efficiency and lower operation temperature. They, however, have found some application areas in which their advantages of large-scale and multiband integration are significant. The type II SLS uses the interband transition between the states in alternative layers. Since the type II SLS and QDIP IRFPAs offer higher performance and higher operating temperature when compared with QWIPs, research activities in this area are shifting from QWIP to them.

As explained in Section 3.04.1, the IRFPAs integrating thermal detectors are called uncooled IRFPAs. In contrast, the IRFPAs with quantum detectors are referred to as cooled IRFPAs. The term cooled IRFPA was not needed until the beginning of the 1990s because research activities and achievements in uncooled IRFPAs were limited and the term IRFPA generally meant the cooled IRFPA. In 1992, two outstanding results on the uncooled IRFPAs were disclosed. One was a hybrid IRFPA with barium strontium titanate (BST) ferroelectric detectors (Hanson *et al.* 1992) and the other was a monolithic IRFPA with VO_x resistance bolometer detectors (Wood *et al.* 1992). After these successful demonstrations, uncooled IRFPAs have made an amazing advance, and eventually, we have had to use the term, which discriminates IRFPAs with quantum detectors from those with thermal detectors.

The hybrid ferroelectric technology played an important role in the 1990s by leading commercialization of the uncooled IRFPAs. A lot of IR imaging systems, including enhanced vision systems for cars, were developed using hybrid ferroelectric IRFPAs. On the other hand, performance improvement has been proceeding in the resistance bolometer and diode bolometer, making best use of their monolithic structures manufactured with Si-LSI-like or Si-LSI-compatible processes. For resistance bolometer and diode bolometer IRFPAs, lower thermal conductance realized with advanced MEMS processes for these uncooled IRFPAs offered competitive sensitivities with the second-generation cooled IRFPAs, and monolithic structures enabled large-scale integration up to 640×480 elements (Murphy *et al.* 2005, Ueno *et al.* 2005).

Features of different kinds of IR detectors are summarized in **Table 1**.

3.04.3 Thermal Infrared Detector

This section outlines the operation and performance of thermal IR detectors and discusses the theoretical limit of thermal IR detectors and uncooled IRFPAs.

Table 1 Features of infrared detectors

Type		*Operation principle*	*Operation temperature*	*Sensitivity*	*Spectral response*	*Response time*	*FPA structure*	*Typical materials*
Thermal	Ferroelectric	Temperature dependence of spontaneous polarization (pyroelectric) Temperature dependence of dielectric constant (dielectric bolometer)	Room temperature	Low	Depending on absorber	Slow	Hybrid	BST, PST, PZT, PVDF
	Resistance bolometer	Temperature dependence of resistance						VO_x, a-Si
	Thermoelectric	Seebeck effect					Monolithic	Al/poly-Si n poly-Si/p poly-Si
	Diode	Temperature dependence of I–V characteristic						Si
Quantum	Intrinsic	Interband transition	Cryogenic temperature	High	Determined by bandgap energy	Fast		HgCdTe, InSb
	Extrinsic	Excitation from impurity level			Determined by impurity level		Hybrid	Si:In, Si:Ga, Ge:Cu, Ge:Hg
	Photoemissive	Emission over Schottky-barrier or hetero junction			Determined by barrier height			PtSi/p-Si, GeSi/p-Si
	QWIP type II SLS QDIP	Intraband or interband transition in superlattice structure		Medium	Tunable by design		Monolithic	GaAs- or InP-based compound semiconductors

3.04.3.1 Operation of Infrared Detector

Figure 2 shows the general construction of the thermal IR detector in which a thermometer is thermally and electrically linked with a substrate with a support structure. This construction assumes an electrical readout. Although there are some examples that adopt optical readout methods and do not need electrical links, we limit our discussion to the electrical readout thermal IR detectors here. The IR radiation is absorbed in an IR absorber attached to the thermometer to change the temperature of the thermometer. The support structure provides the functions of mechanical support, thermal conducting paths to the substrate, and electrically conducting paths. If the thermal conductance of the support legs is sufficiently low, a detectable temperature change is generated at the thermometer, and a change in the output from the thermometer is read out through the support legs and the signal processing circuits on the substrate.

There are three issues to be addressed while designing the thermal IR detector. One is the type of thermometer. As reviewed in Section 3.04.2, we can utilize pyroelectric thermometers, dielectric bolometers, resistance bolometers, thermopiles, diode thermometers, bimaterial thermometers, and thermo-optical thermometers. The sensitivity and noise characteristics of the thermometer are the most important factors in selecting the thermometer. In addition to that, we have to give much importance to the material and manufacturing process for the thermometer, especially in developing the uncooled IRFPAs because monolithic integration of the thermometer on Si signal-processing circuits requires stringent rules for the material and process. The maximum process temperature after the metal interconnection process is often a serious barrier to deposit thin-film detector materials with good quality onto complementary metal oxide semiconductor (CMOS) readout circuits.

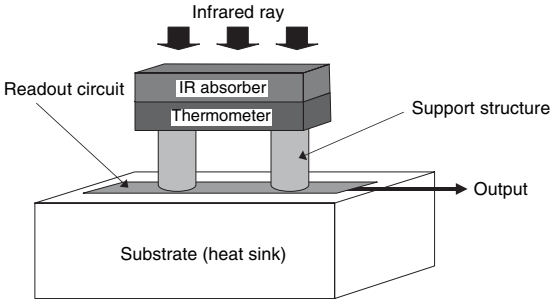

Figure 2 Schematic illustration of a thermal infrared detector, explaining the operation principle.

The second issue is related to the method of IR absorption. The design of the IR absorber influences the spectral absorptivity and heat capacity of the thermally isolated detector structure. Thermal IR detectors with higher sensitivity and faster response claim higher absorptivity and lower heat capacity. Deposition of metals such as Au at pressures of above 10^2 Pa makes flaky films called metal black with high absorptivity in a wide spectral band (Hirota and Morita 1998), and the metal black films are widely used in thermal IR detectors. Insulator films such as SiO_2 and SiN, which are used in Si-LSI processes, exhibit moderate absorption in the LWIR spectral band. Although the insulator films are not the best choice from the viewpoint of absorptivity, compatibility with Si-LSI processes is an attractive advantage of this IR absorber (Lenggenhanger *et al.* 1992). A thin metal film having a sheet resistance of 189 Ω per square can also be used for the IR absorber (Liddiard 1993). Single path through the metal film absorbs 50% of the incident IR radiation. More efficient IR absorption is possible with a 1/4 wavelength-resonant optical cavity (Capper and Elliott 2001). This resonant IR absorber consists of a metal reflector, a thin metal film having a sheet resistance of 377 Ω per square, and a dielectric film between them. The thickness of the dielectric film is tuned to be 1/4 of the wavelength of interest. Appropriate design of the resonant IR absorber achieves absorptivity more than 90% over the wavelength range of 8–14 μm. Any metal can be used for the thin metal film as resonant cavity absorber if its sheet resistance meets the requirement.

The last issue to be addressed is the structure of the thermal isolation between the detector structure and the substrate. The degree of thermal isolation is determined by the design of the support structure. Typical support structures in uncooled IRFPAs are a bump bond (Capper and Elliott 2001, Kruse 2001, Kruse and Skatrud 1997) and a microbridge (Capper and Elliott 2001, Kruse 2001, Kruse and Skatrud 1997), the details of which are discussed in Section 3.04.4 on ferroelectric IRFPAs and resistance bolometer IRFPAs. Higher thermal isolation is possible with the microbridge structure fabricated by MEMS technology (Wood 1993). Reduction of the thermal conductance has made possible recent remarkable improvements in the performance of uncooled IRFPAs.

The IRFPA is an imager that integrates a number of thermal IR detectors and has an electronic scanning capability. The pixel size of IRFPAs is from a few hundreds micrometer square to a few tens micrometer square, depending on the array size. The output from pixels is multiplexed by the vertical and horizontal scanning circuits, and is read out from a single or a few output ports. Since the output from the thermal IR detector is small, low-noise amplifiers are generally integrated on the chip. The simplest way to multiplexing is to activate only one selected pixel at a time, and scan the pixel in the X and Y directions. Application of this scanning scheme, however, is limited to relatively small-format IRFPAs with moderate sensitivity because it requires wide bandwidth for the pixel operation and has larger pixel noise when the array size becomes large. For high-performance uncooled IRFPAs, a line-addressed scheme is generally adopted. In the line-addressed IRFPA, a row having many pixels is selected simultaneously, and the output from the pixels is integrated by integrators located at the end of each column. This readout scheme makes it possible to reduce the bandwidth to a frequency corresponding to a horizontal scanning period. The CMOS technology makes it possible to integrate clock generators, bias generation/conditioning circuits, A/D converters, offset compensation circuits, on-chip device temperature monitor, and so on.

3.04.3.2 Performance of Thermal Detectors and IRFPAs

The responsivity R is defined as the output signal voltage V_S divided by the incident radiant power P_{IN} falling on the IR detector.

$$R = \frac{V_S}{P_{IN}} \qquad [1]$$

While the responsivity defined by eqn [1] is expressed in volts per watt, the unit for IR detectors that output current signals is amperes per watt. The responsivity generally depends on the wavelength, reflecting the wavelength-dependent absorptivity. As the thermal IR detector transduces the IR energy to a temperature change, and then to an electrical signal, the responsivity is broken up as given below:

$$R = \frac{\Delta T_D}{P_{IN}} \frac{V_S}{\Delta T_D} \qquad [2]$$

where ΔT_D is the temperature change at the detector due to the incident IR power P_{IN}. $\Delta T_D/P_{IN}$ in the right-hand side of eqn [2] is determined by the thermal balance consideration of the detector, which will be discussed later in this section, and $V_S/\Delta T_D$ is the sensitivity of the thermometer.

There are various noise sources in a thermal IR detector. The total noise gives the noise equivalent power (NEP) that is the lowest detectable IR radiant power for the detector. The NEP, P_N, is an important figure of merit of the photodetector, and it is given by (Hudson 1969):

$$P_N = \frac{V_{TN}}{R} \qquad [3]$$

where V_{TN} is the total root mean square (rms) noise voltage. If there are several uncorrelated noise sources, the total noise is the square root of the sum of the squares of the individual noise voltages. The NEP is the radiant power incident on an IR detector that gives rise to a signal equal to the total rms noise. The NEP is smaller for the more sensitive detector. It is, however, useful to use a figure of merit that has a large value when the detector is more sensitive, and the detectivity D is sometimes used in place of the NEP (Hudson 1969). The detectivity is simply the reciprocal of the NEP.

$$D = \frac{1}{P_N} \qquad [4]$$

The NEP and detectivity, which depend on the detector area A_D and the signal bandwidth B, are useful figures of merits in comparing specified detectors. However, further ingenuity is needed when we compare some detection mechanism and/or some material to others. Assuming that the noise is white (the noise amplitude is frequency independent), the noise voltage depends on the square root of the bandwidth. Extensive studies show that for most of the detection mechanisms, the signal-to-noise ratio depends on the square root of the detector area, and the detectivity varies inversely as the square root of the detector area. Then, a figure of merit that is independent of design parameters is defined as follows (Hudson 1969):

$$D^* = \frac{(A_D B)^{1/2} R}{V_{TN}} = \frac{(A_D B)^{1/2}}{P_N} \qquad [5]$$

where D^* (dee-star) is the normalized detectivity, the unit of which is cm $Hz^{1/2}$ W^{-1}. As the responsivity of IR detectors depends on the wavelength, we have to express D^* either in a spectral D^* (D^*_λ, where λ is the wavelength) or in a blackbody D^* ($D^*(T_B)$, where T_B is the blackbody temperature).

IR detectors and IRFPAs measure the temperature change or temperature distribution of objects. Therefore, it is worthwhile to know the sensitivity in terms of the temperature change of the observed objects. **Figure 3** shows a concept of IR imaging. The IR radiation from a scene segment, which has a one-to-one correspondence with a pixel on the IRFPA, passes through the atmosphere and is focused on the pixel by a lens. What we are interested in is the scene temperature sensitivity S, which is defined as follows:

$$S = \frac{V_S}{\Delta T_{SC}} \qquad [6]$$

where ΔT_{SC} is the scene temperature change. The scene temperature sensitivity is obtained by multiplying terms of a spectral integration of the thermal derivative of Planck's law in a spectral range of interest ($\Delta P_{SC}/\Delta T_{SC}$) and the energy transfer ratio between the scene and IFFPA ($\Delta P_{IN}/\Delta P_{SC}$) to eqn [2], namely:

$$S = \frac{\Delta P_{SC}}{\Delta T_{SC}} \frac{\Delta P_{IN}}{\Delta P_{SC}} \cdot \frac{\Delta T_D}{\Delta P_{IN}} \cdot \frac{\Delta V_S}{\Delta T_D} \qquad [7]$$

where ΔP_{IN} is the change in power falling on the detector due to the change in the object temperature. The scene temperature sensitivity means the output signal voltage due to 1 K temperature change at the observed object, and has the unit of volts per kelvin. As is evident in the above discussion, the scene temperature sensitivity is not defined for the detector itself, but for a detector module or imaging system, including optics. A useful figure of merit, the NETD is derived from consideration of the signal-to-noise ratio of the IR system (Kruse and Skatrud 1997):

$$\mathrm{NETD} = \frac{4F^2 V_{TN}}{\tau_O A_D R(\Delta P_{SC}/\Delta T_{SC})} = \frac{V_{TN}}{S} \qquad [8]$$

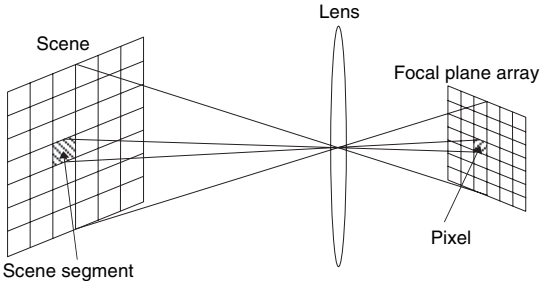

Figure 3 Concept of infrared imaging with focal plane array.

where F is F-number of optics and τ_O is the transmittance of optics. The NETD is the temperature difference of a blackbody that produces a signal-to-rms noise ratio of one.

3.04.3.3 Heat Balance in Thermal Detector

In order to understand the importance of thermal isolation, we will give a simple analysis for the heat balance in a thermal infrared detector here. The rate of energy accumulated at the thermally isolated detector structure equals the difference between the heat input and the heat loss. Although Joule heating is involved in some cases, the IR energy absorbed by the detector is the only source of heat input. An analysis including the Joule heating will be given in the section for resistance bolometer IRFPAs, in which the Joule heating restricts the operation condition.

There are three heat loss mechanisms: conduction, convection, and radiation. Conduction occurs in the way of heat flow from the thermally isolated detector structure to the substrate through the support structure. Heat conduction through the surrounding atmosphere is also an important heat loss mechanism if the IR detector is not mounted in an evacuated package. Assuming that the substrate temperature T_S equals the temperature T_A of the surroundings, the heat loss due to conduction E_{COND} is expressed as follows:

$$E_{COND} = (G_S + G_A)(T_D - T_S) \qquad [9]$$

where G_S is the thermal conductance of the support structure, G_A is the thermal conductance of the surrounding atmosphere, and T_D is the temperature of the thermally isolated detector structure.

The convection also takes place in nonevacuated packages. It is, however, a minor heat loss mechanism when compared with other heat loss mechanisms, and therefore it is neglected in the following analysis (Kruse and Skatrud 1997).

The thermally isolated detector structure radiates IR energy to its surroundings, and the surroundings radiate IR energy to the thermally isolated detector structure. If $T_D > T_S$, the radiation transfers energy from the thermally isolated detector structure to the surroundings. This radiation heat loss E_{RAD} is given by the following equation (Dereniak and Crowe 1984):

$$E_{RAD} = A_D \eta \sigma (T_D{}^4 - T_S{}^4) \qquad [10]$$

where A_D is the detector area, σ is the Stefan–Boltzmann constant, and η is the emissivity. As the temperature difference between the thermally isolated detector structure and the surroundings is very small in thermal IR detectors, we can treat the radiation mechanism like the conduction mechanisms with a thermal conductance G_{RAD} (Kruse 2002).

$$G_{RAD} = 4A_D\eta\sigma T_D^3 \quad [11]$$

Thus, the total heat loss E_{TOT} is given by

$$E_{TOT} = G_T(T_D - T_S) = G_T\Delta T_D \quad [12]$$

where

$$G_T = G_S + G_A + G_{RAD} \quad [13]$$

Eventually, we obtain the following heat balance equation.

$$C_H\frac{d(\Delta T_D)}{dt} = \eta P_{IN} - G_T \Delta T_D \quad [14]$$

where C_H is the heat capacity of the thermally isolated detector structure, and t is the time.

Assuming the incident IR energy to be a sinusoidal function,

$$P_{IN} = P_0 e^{j\omega t} = P_0 e^{j(2\pi f)t} \quad [15]$$

where P_0 is the amplitude of the sinusoidal incident IR energy, ω is the angular frequency, and f is the frequency. Then, the solution to the heat balance equation is as given below:

$$\Delta T_D = \frac{\eta P_0 e^{j\omega t}}{G_T + j\omega C_H} \quad [16]$$

The detector temperature also changes with time in a sinusoidal function, the amplitude of which is given by:

$$|\Delta T_D| = \frac{\eta P_0}{G_T(1+\omega^2\tau_T{}^2)^{1/2}} \quad [17]$$

where τ_T is the thermal time constant, defined as

$$\tau_T = \frac{C_H}{G_T} \quad [18]$$

At low frequencies for which $\omega t << 1$, ΔT_D is approximated as

$$|\Delta T_D| = \frac{\eta P_0}{G_T} \quad [19]$$

It is important to note that ΔT_D is inversely proportional to G_T. This is the reason why considerable efforts have been undertaken to fabricate a high thermal isolation structure in uncooled IRFPA development. G_{RAD} for a 50-μm-square pixel is $1.5 \times 10^{-8}\,W\,K^{-1}$ when the emissivity of the IR absorber and the fill factor is unity. The radiation sets the fundamental limitation of the heat loss. As the thermal conductivity of air is $2.5 \times 10^{-4}\,W\,cm^{-1}\,K^{-1}$, the thermal conductance through air is about $2.5 \times 10^{-5}\,W\,K^{-1}$ for a 50-μm-square pixel having an interference IR absorber suspended 2.5 μm above the substrate (Capper and Elliott 2001). The state-of-the-art technology has achieved a thermal conductance of the support structure of $1 \times 10^{-7}\,W^{-1}\,K^{-1}$ or less (Kruse and Skatrud 1997). Therefore, the dominant thermal loss mechanism in a nonevacuated package is the conduction through the surrounding air. The thermal loss through the surrounding air can be eliminated by encapsulating the IRFPA in a vacuum package having a pressure of <6.7 Pa (Capper and Elliott 2001). Then, the limiting factor for the heat loss is the conduction through the support structure in current vacuum packaged uncooled IRFPAs.

At high frequencies for which $\omega t >> 1$, ΔT_D falls off inversely with the frequency and is given by:

$$|\Delta T_D| = \frac{\eta P_0}{\omega C_H} \quad [20]$$

This means that the responsivity decreases as the modulation frequency of the incident IR power increases. At a frequency corresponding to the thermal time constant ($f_c = 1/2\pi\tau_T$), the responsivity becomes $\sqrt{1/2}$ of that in the low frequency region. Furthermore, for uncooled IRFPAs, image lag is observed in such a high-frequency region. IRFPAs operating at a TV frame rate (30 frames s^{-1}) typically have thermal time constants from 10 to 20 ms.

3.04.3.4 Fundamental Performance Limit

Here, we analyze the fundamental limit of the performance of uncooled IRFPAs according to Kruse (Kruse and Skatrud 1997). In addition to the electrical noise, heat exchange with the surroundings exhibits random fluctuation caused by the statistical nature of the mechanism. If the detector temperature is the same as the surroundings, the mean square temperature fluctuations $\overline{\Delta T_D{}^2}$ of the thermal IR detector over all frequencies is given by (Kruse and Skatrud 1997):

$$\overline{\Delta T_D{}^2} = \frac{kT_D{}^2}{C} \quad [21]$$

where k is the Boltzmann's constant and C is the harmonic average of the heat capacity, which is reduced to the heat capacity of the thermally isolated detector structure in the thermal IR detector. Assuming that fluctuations in the power interchange with the surroundings are independent of frequency, and the heat balance equation is valid for fluctuations in the detector temperature and interchanged power, we obtain the following (Kruse and Skatrud 1997):

$$\overline{P_F{}^2} = 4kT_D{}^2 G_T B \qquad [22]$$

where $\overline{P_F{}^2}$ is the mean square fluctuations in interchanged power and B is the bandwidth. $\overline{P_F^2}$ gives the fundamental limit for NEP P_{NFL} (Kruse and Skatrud 1997).

$$P_{NFL} = \left(\frac{\overline{P_F{}^2}}{\eta^2}\right)^{1/2} \qquad [23]$$

According to the definition of normalized detectivity, the temperature fluctuation noise-limited D^* becomes (Kruse and Skatrud 1997):

$$D^*{}_{TF} = \left(\frac{\eta^2 A_D}{4kT_D{}^2 G_T}\right)^{1/2} \qquad [24]$$

Using R/V_{TN} obtained from eqn [24], the temperature fluctuation noise-limited NETD is expressed as follows (Kruse and Skatrud 1997):

$$NETD_{TF} = \frac{8F^2 T_D (kBG_T)^{1/2}}{\eta \tau_O A_D (\Delta P_{SC}/\Delta T_{SC})} \qquad [25]$$

As discussed above, G_T is the sum of G_S, G_A, and G_{RAD}. G_S is the dominant component in the total thermal conductance in current uncooled IRFPAs fabricated by the MEMS technology that is mounted in a vacuum package. If we can make a support structure having a much lower thermal conductance than the radiation thermal conductance, the fluctuation in the radiation heat loss limits the performance. This situation gives the fundamental performance limit of the uncooled IRFPA, called the background fluctuation noise limit. Substituting the radiation thermal conductance into eqn [24], the background noise-limited D^* is given by (Kruse and Skatrud 1997):

$$D^*{}_{BF} = \left(\frac{\eta}{16k\sigma T_D{}^5}\right)^{1/2} \qquad [26]$$

Therefore, the background noise-limited NETD is expressed as (Kruse and Skatrud 1997):

$$NETD_{BF} = \frac{16F^2 (k\sigma B T_D{}^5)^{1/2}}{\tau_O (\eta A_D)^{1/2} (\Delta P_{SC}/\Delta T_{SC})} \qquad [27]$$

The detector temperature and the temperature of the surroundings are assumed to be the same in eqns [26] and [27]. When the detector temperature differs from that of surroundings, the background noise-limited D^* becomes (Kruse and Skatrud 1997):

$$D^*{}_{BF} = \left(\frac{\eta}{8k\sigma (T_D{}^5 + T_A{}^5)}\right)^{1/2} \qquad [28]$$

and the background noise-limited NETD is expressed as (Kruse and Skatrud 1997):

$$NETD_{BF} = \frac{8F^2 (2k\sigma B (T_D{}^5 + T_A{}^5))^{1/2}}{\tau_O (\eta A_D)^{1/2} (\Delta P_{SC}/\Delta T_{SC})} \qquad [29]$$

Figure 4 shows the temperature fluctuation noise-limited and background fluctuation noise-limited NETD for an uncooled IRFPA with a 50-μm-square pixel, calculated by eqns [25] and [27] (Kruse 1995). This graph is obtained assuming the parameters shown in the figure. The hatched area indicates the attainable NETD region. The temperature fluctuation noise-limited NETD decreases as $G_T^{1/2}$ by lowering the thermal conductance, and finally reaches the background fluctuation noise-limited NETD.

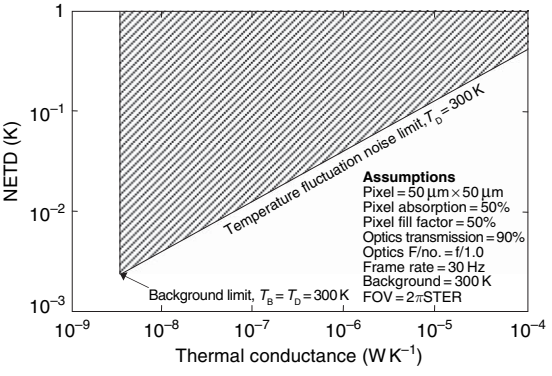

Figure 4 Temperature fluctuation noise limit and background fluctuation noise limit to noise equivalent temperature difference (NETD). NETDs in a hatched area is feasible. (Source: Kruse P W 1995 Uncooled IR focal plane array. *Proc. SPIE* **2552**, 556–63.)

3.04.4 Ferroelectric IRFPAs

3.04.4.1 Operation of Ferroelectric Infrared Detector

Figure 5 shows temperature dependences of the spontaneous polarization P_S, pyroelectric coefficient p, and dielectric constant ε of a ferroelectric (Capper and Elliott 2001). The spontaneous polarization becomes smaller with the increase in temperature. At the Curie temperature T_C, a phase transition occurs due to heating, and the ferroelectric is no longer polarized. The pyroelectric coefficient p is a measure of the rate of change of electric polarization with respect to temperature change, and is defined as follows:

$$p = \frac{\partial P_S}{\partial T} \qquad [30]$$

As depicted in **Figure 5**, the pyroelectric coefficient increases when the temperature becomes higher.

The pyroelectric IR detector uses the temperature dependence of spontaneous polarization with no applied bias voltage. A ferroelectric with higher pyroelectric coefficient has higher sensitivity for temperature. Although ferroelectrics have higher pyroelectric coefficients near T_C, most pyroelectric IR detectors are operated well below their T_C because the dielectric loss increases near T_C, degrading the performance. The dielectric bolometer uses both the temperature dependence of spontaneous polarization and the temperature dependence of dielectric constant near T_C. In this mode, an electric field is applied to the ferroelectrics, and the polarization and the pyroelectric effect are stabilized in the region of and above T_C (Capper and Elliott 2001). The electric field enhances the effective pyroelectric coefficient. The field-enhanced pyroelectric coefficient p_{FE} is given by (Hanson *et al.* 1992):

$$p_{FE} = p + \int_0^E \frac{\partial \varepsilon}{\partial T} dE \qquad [31]$$

where E is the applied electric field.

Consider a capacitor with a ferroelectric as an insulator. A change in temperature ΔT_D produces a transient current I_S to flow through an external circuit connected to the capacitor. The magnitude of I_S is given by:

$$I_S = pA_D \frac{d(\Delta T_D)}{dt} \qquad [32]$$

Using the heat balance equation, eqn [14], given in Section 3.04.3, we obtain the signal current as:

$$I_S = \frac{\eta p \omega A_D P_0}{G_T (1 + \omega^2 \tau_T{}^2)^{1/2}} \qquad [33]$$

For the pyroelectric IR detector and ferroelectric bolometer, the incident IR radiation is modulated, for example, with a light chopper, and the rms amplitude is given as:

$$I_S = \frac{\eta p \omega A_D P_0}{\sqrt{2} G_T (1 + \omega^2 \tau_T{}^2)^{1/2}} \qquad [34]$$

The capacitance has a loss resistance R_L that has a relationship with the pixel capacitor C_E, expressed as:

$$R_L = \frac{1}{\omega C_E \tan\delta} \qquad [35]$$

where $\tan\delta$ is the loss tangent, which means the angle between the resistance and the capacitive reactance. Then, the signal voltage V_S is given by the following equation (Kruse 2001):

$$\begin{aligned} V_S &= \frac{I_S R_L}{(1 + \omega^2 \tau_E{}^2)^{1/2}} \\ &= \frac{\eta p \omega A_D R_L P_0}{\sqrt{2}\, G_T (1 + \omega^2 \tau_E{}^2)^{1/2} (1 + \omega^2 \tau_T{}^2)^{1/2}} \end{aligned} \qquad [36]$$

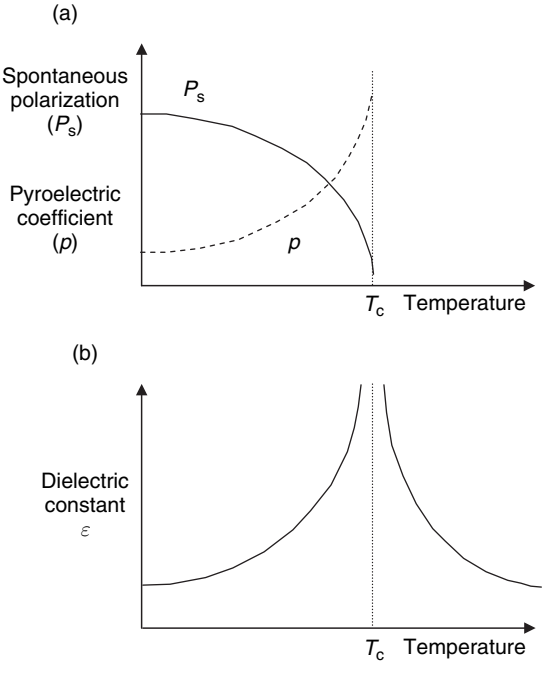

Figure 5 Temperature dependence of spontaneous polarization, pyroelectric coefficient, and dielectric constant of ferroelectric material, explaining the operation of ferroelectric infrared detector. (Source: Capper P, Elliott C T 2001 *Infrared Detectors and Emitters: Materials and Devices*. Kluwer Academic Publishers, Norwell, MA.)

where τ_E is the electrical response time defined as:

$$\tau_E = R_E C_E = \frac{1}{\omega \tan \delta} \quad [37]$$

Therefore, the responsivity is expressed as:

$$R = \frac{\eta p \omega A_D R_L}{\sqrt{2}\, G_T (1 + \omega^2 \tau_E^2)^{1/2} (1 + \omega^2 \tau_T^2)^{1/2}} \quad [38]$$

Assume that $\tau_E > \tau_T$, the responsivity rises with frequency at low modulation frequencies, reflecting the electrical response, then reaches a plateau, and finally decreases, being inversely proportional to the frequency at higher frequencies, influenced by the thermal response.

The electrical noise V_{EN} in the ferroelectric IR detector is associated with the loss resistance.

$$V_{EN} = \sqrt{\frac{kT_D}{\omega C_E \tan \delta}} \quad [39]$$

In the case of the ferroelectric IR detector, the noise is not white, but depends on the frequency according to the equivalent circuit consisting of the pixel capacitance and loss resistance.

3.04.4.2 Hybrid Ferroelectric IRFPAs

The development of ferroelectric uncooled IRFPAs started with hybrid structures in the mid-1970s. It took a long time for the ferroelectric technology to be recognized as a useful IRFPA technology. In 1992, Hanson and coworkers reported an impressive result with a 245 × 328-element hybrid ferroelectric uncooled IRFPA having a pixel structure as shown in **Figure 6** (Beratan *et al.* 1994, Hanson 1993, Hanson *et al.* 1992, Owen *et al.* 1992). The ferroelectric material used in their device is a BST ceramic. The first step of the ferroelectric wafer process is laser reticulation that makes grooves with a width of 10 μm between pixels in order to minimize the lateral thermal diffusion. The pixel pitch is 48.5 μm. After laser reticulation, a parylene backfill is deposited to replanarize the reticulated surface, and a common electrode and resonant cavity IR absorber is formed on the top of the BST wafer. Then, the BST wafer is thinned and polished to the final thickness of about 25 μm. The final step for the BST wafer is the formation of metal contacts to the Si ROIC and removal of the parylene backfill. On the Si ROIC, miniature organic mesas with over-the-edge metallization are fabricated for hybridization. This organic mesa structure reduces the thermal conductance from the BST detector to the Si ROIC, when compared with metal bump structures.

Figure 7 shows the temperature dependence for spontaneous polarization and the dielectric constant for BST ceramic (Hanson *et al.* 1992). As can be understood from this figure, this material is suitable for operating in a dielectric bolometer mode at ambient temperatures. **Figure 8** is a scanning electron microscope (SEM) photograph of pixels, showing reticulated BST detectors and organic mesa structures on the Si ROIC (Owen *et al.* 1992). The readout architecture for the BST ferroelectric uncooled IRFPA is shown in **Figure 9** (Hanson *et al.* 1992). The unit cell contains a high-pass filter, a gain stage, a tunable low-pass filter, a buffer, and an address switch. An NETD of 80 mK at *f*/1.0 was achieved with this IRFPA.

The hybrid structure shown in **Figure 10** was developed in the United Kingdom (Watton *et al.* 1996), which used lead scandium tantalate (PST) as a ferroelectric material. Like in the case of the

BST uncooled IRFPA, the ferroelectric wafer is cut from a hot-pressed ceramic block and polished to around 10–15 μm thickness and is reticulated by a laser-assisted etching process. In this pixel structure, the solder bond is isolated from the Si substrate by a thick polymer layer and a narrow metal interconnection track and a small diameter of solder bond. They developed 100-μm pitch 100 × 100-element, 56-μm pitch 256 × 128-element, and 40-μm pitch 384 × 288-element ferroelectric uncooled IRFPAs (McEwen and Manning 1999, Watton and Manning 1998). Along with the device development, a three-point image-difference processing algorithm (Watton *et al.* 1996) and microscan chopper (McEwen and Manning 1999) were also implemented. The three-point image-difference processing algorithm removes errors from ramping due to leakage at the element node and eliminates thermal drift effects. The microscan chopper enhances the spatial resolution by scanning images with Ge plates on the chopper blade.

3.04.4.3 Monolithic IRFPAs with Thin-Film Ferroelectrics

Although hybrid ferroelectric uncooled IRFPAs played an important role in commercialization of IR imaging technology in the 1990s, there were serious problems when considering performance improvement and cost reduction. As can be understood from the discussion in Section 3.04.3, reduction in the thermal conductance is one of the most effective methods to enhance responsivity. By introducing the organic mesa bump structure, the thermal conductance of the hybrid uncooled IRFPA has reached a level of $4 \times 10^{-6}\,\mathrm{W/K^{-1}}$, which is sufficient to achieve an NETD of <100 mK at $f/1.0$. It is expected that extending this technology will bring further reduction in the thermal conductance to $1 \times 10^{-6}\,\mathrm{W/K^{-1}}$(Belcher *et al.* 1998). Nevertheless, this thermal conductance is still an order of magnitude larger than that of structures realized by MEMS technology. Furthermore, the hybrid process is less cost-effective than processes for monolithic structures. Reflecting these circumstances, considerable efforts have been made to realize monolithic uncooled IRFPAs with thin-film ferroelectric (TFFE) detectors (Belcher *et al.* 1998, Hanson and Beratan 2002, Hanson *et al.* 2001) or an integrated ferroelectric bolometer array (Todd *et al.* 2001, Watton and Manning 1998, Watton *et al.* 1996). The monolithic ferroelectric uncooled IRFPA offers attractive advantages over the hybrid one, such as no ferroelectric ceramic wafer preparation (cutting, thinning, and polishing), no solder bonding process, no reticulation for reducing the lateral thermal diffusion, wafer-scale processing for fully completed devices, and increased performance from superior thermal isolation provided by the microbridge (Watton *et al.* 1996).

Figure 11 illustrates a TFFE pixel structure developed by Hanson *et al.* (2001). This pixel has split top electrodes with a bottom electrode (equipotential plane), making the capacitance to be 1/4 the value of a similar capacitor whose connections are full-face electrodes on the top and the bottom. The two electrodes are transparent and together form a resonant cavity for IR absorption with a mirror on the Si ROIC. The

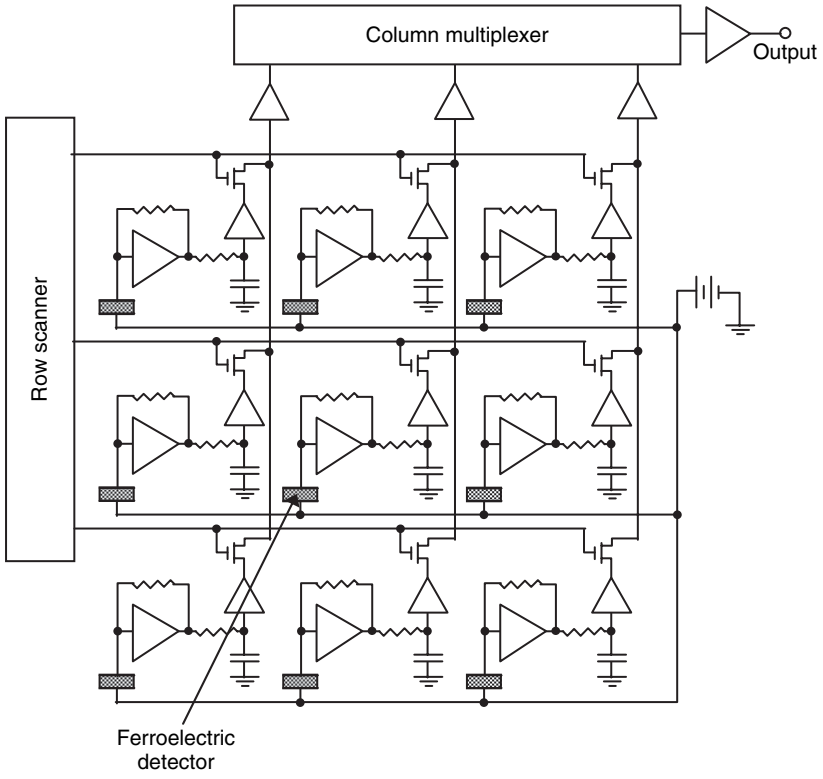

Figure 9 Readout circuit for hybrid barium strontium titanate (BST) uncooled infrared focal plane array (IRFPA). (Source: Hanson C, Beratan H, Owen R 1992 Uncooled thermal imaging at Texas Instruments. *Proc. SPIE* **1735**, 17–26.)

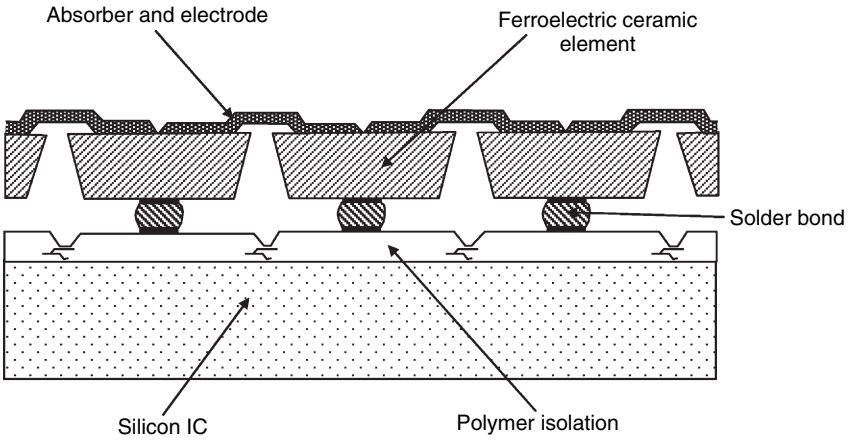

Figure 10 Hybrid pixel structure for lead scandium tantalate (PST) pyroelectric uncooled infrared focal plane array (IRFPA). (Source: Watton R, Manning P A, Perkins M J C, Gillham J P, Todd M A 1996 Uncooled IR imaging: Hybrid and integrated bolometer arrays. *Proc. SPIE* **2744**, 486–99.)

ferroelectric material is lead calcium titanate (PCT), deposited by the metal organic decomposition (MOD) of spun-on solution. They chose a pyroelectric mode rather than the dielectric bolometer mode used in their hybrid uncooled IRFPA because of its less stringent temperature control requirement.

A group in the United Kingdom also developed a monolithic ferroelectric pixel structure having full-face electrodes on the top and the bottom (Todd *et al.* 2001, Watton and Manning 1998, Watton *et al.* 1996). They tried two deposition methods with two materials: sol–gel deposited lead zirconate titanate (PZT)

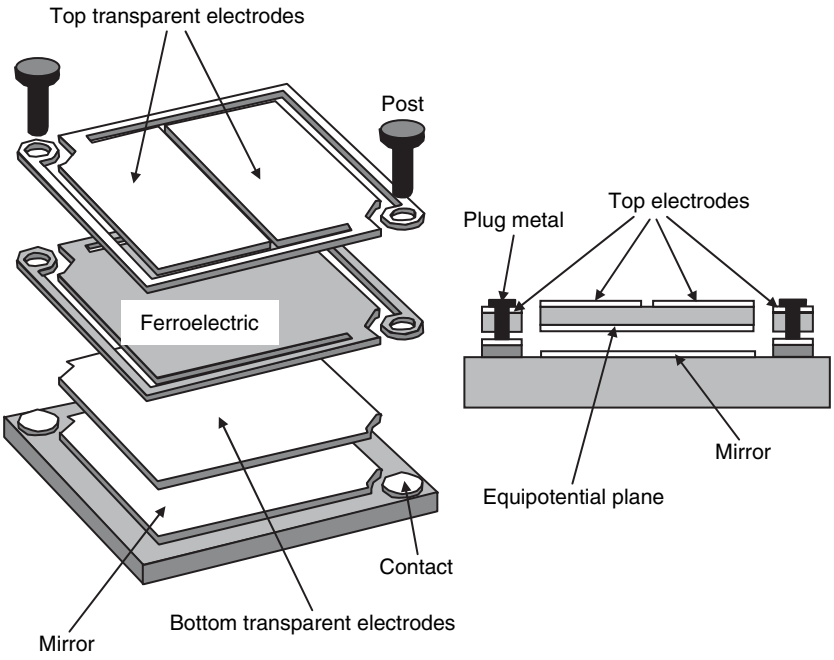

Figure 11 Monolithic thin-film ferroelectric pixel. (Source: Hanson C M, Beratan H R, Belcher J F 2001 Uncooled infrared imaging using thin-film ferroelectrics. *Proc. SPIE* **4288**, 298–303, Hanson *et al*. 2001.)

and sputtered PST, which are operated in the pyroelectric mode as well. Sol–gel is a wet chemical deposition process using the thermal decomposition of suitable metal organic precursors in solution. After several spin coating steps of the precursor solution to obtain an appropriate thickness, the film is fired just above 500°C to obtain columnar perovskite phase on a Ti/Pt electrode. Sputtered PST film was prepared from all metal targets in a dual magnetron system at 525°C. Since the figure of merit is improved by annealing at higher temperatures, rapid thermal annealing and laser annealing were studied, considering the thermal budget for the Si ROIC (Todd *et al.* 2000). Although annealing in less O_2 atmosphere increases the thermal budget, it is not sufficient to obtain a high-quality thin film suitable for high-performance uncooled IRFPAs. They, therefore, proposed a composite uncooled IRFPA structure, a cross section of which is depicted in **Figure 12** (Todd *et al.* 2000). In this structure, microbridge pixels are

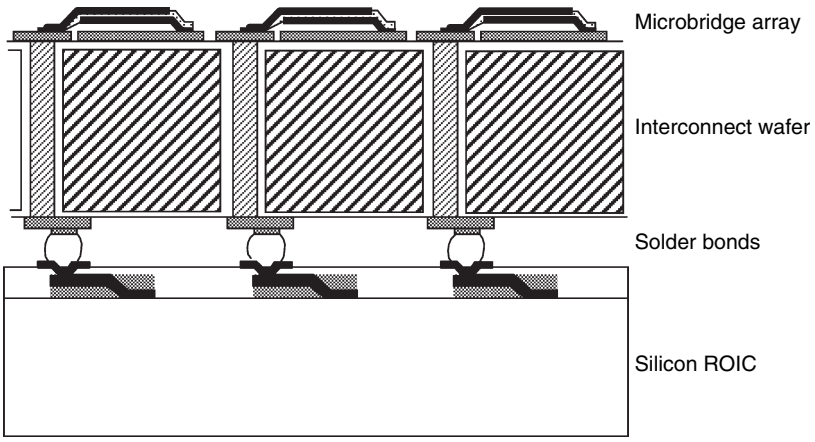

Figure 12 Composite uncooled infrared focal plane array (IRFPA) structure having microbridge pixels and interconnections through wafer. (Source: Todd M A, Manning P A, Donohue P P, Brown A G, Watton R 2000 Thin film ferroelectric materials for microbolometer arrays. *Proc. SPIE* **4130**, 128–39.)

fabricated on the front surface of a wafer, in which high-density interconnections are formed through the Si wafer. Bumps on the back surface of the wafer connect the microbridge pixels with readout circuits on the other Si wafer. Higher annealing of the detector wafer is possible before the hybridization process.

Figure 13 shows an example of a monolithic pixel structure made of BST (Xu *et al.* 1999). Anisotropic etching of a (110) Si wafer by tetramethyl ammonium hydroxide (TMAH) etchant produces the detector membrane having perpendicular cavity walls. The pulsed laser deposition (PLD) and MOD methods were employed to obtain thin BST films on Si readout circuits (Xu *et al.* 2000). By using the PLD method, BST films with good crystallographic quality are grown at relatively low temperature (520°C). This method, however, has disadvantages of poor uniformity and difficulty in enlarging the deposition area. On the other hand, larger area deposition is possible with the MOD. But, crystallizing of the spin-coated film requires a higher process temperature between 600 and 800°C. Evaluation of small linear dielectric bolometer IRFPA fabricated by the PLD and MOD methods showed a temperature coefficient of dielectric constant of around 0.5% per Kelvin, and a resulting responsivity of $100\,\mathrm{V\,W^{-1}}$ for a 200-μm-square pixel. This IRFPA uses a pixel circuit that consists of two serially connected capacitors driven by two opposite polar pulses.

Another monolithic ferroelectric uncooled IRFPA was developed using an electrospray deposited polyvinylidene fluoride (PVDF) thin film. This IRFPA also operates in a pyroelectric mode (Fujitsuka *et al.* 1997). In electrospray deposition, a PVDF solution in an organic solvent is charged by applying a high electric voltage between a needle and an electrode of the substrate, and the charged droplets of the PVDF solution are transported from the needle to the substrate by the electric field. Most solvent is vaporized during the transport process and the PVDF is deposited on the electrode, arranging its dipole due to the presence of a strong electric field. **Figure 14** shows the pixel structure of the PVDF pyroelectric uncooled IRFPA. The detector membrane is supported by four beams made of a 700-nm undoped silicate glass film. A Ti/TiN composite film, which is a LSI-compatible material, was selected for the lower electrode. After a bulk micromachining process with an ethylenediamine pyrocatechol (EDP) etchant, the PVDF film and Au-black upper electrode are deposited using a metal mask. The upper electrode also works as an IR absorber. A 16×16-element uncooled IRFPA having a pixel size of $75\,\mu\mathrm{m} \times 75\,\mu\mathrm{m}$ was fabricated by this technology. This IRFPA achieved a responsivity of $6600\,\mathrm{V\,K^{-1}}$, D^* of $1.6 \times 10^7\,\mathrm{cm\,Hz^{1/2}\,W^{-1}}$, and NETD of 0.15 K at $f/1.0$ with a 1-Hz bandwidth.

3.04.5 Resistance Bolometer IRFPAs

3.04.5.1 Operation of Resistance Bolometer Infrared Detector

The resistance bolometers detect IR radiation by their resistance change. The most important figure

Solid-State Sensors and Actuators (Transducers)*, Chicago, IL, USA, pp. 1237–1240; reproduced with permission from IEEE.)

of merit for the resistance bolometer is the TCR α, defined as:

$$\alpha = \frac{1}{R_B}\frac{dR_B}{dT} \quad [40]$$

where R_B is the resistance of the bolometer. Both metals and semiconductors are used for resistance bolometer uncooled IRFPAs. The resistance of metals increases with temperature rise, reflecting increased carrier scattering (decreased mobility) in higher temperatures. For metals near room temperatures, R_B is expressed as:

$$R_B = R_{B0}\{1 + \gamma(T - T_0)\} \quad [41]$$

where R_{B0} is the resistance at a temperature T_0 and γ is a constant. From the definition, the TCR of metals is given by:

$$\alpha = \frac{\gamma}{1 + \gamma(T - T_0)} \quad [42]$$

Metals typically have TCR values on the order of $10^{-3}\,K^{-1}$.

In contrast to metals, semiconductors exhibit negative TCRs, which means that the resistance becomes low when the temperature rises. The effect is caused by the temperature dependence of the carrier density and/or mobility. Mobile carriers in the semiconductors are generated by thermal excitation, and as a result the number of carriers increases exponentially with inverse temperature. The mobilities of some semiconductors, in which hopping over barriers at grain boundaries is the major carrier transport mechanism, also have exponential dependences on the temperature. Therefore, a resistance bolometer made of a semiconductor has characteristic represented as:

$$R_B = R_{B0}\exp\left\{\beta\left(\frac{1}{T} - \frac{1}{T_0}\right)\right\} \quad [43]$$

where β is a constant. Substituting eqn [43] into eqn [40], we obtain the TCR for a semiconductor as:

$$\alpha = -\frac{\beta}{T^2} \quad [44]$$

The TCRs of semiconductors are an order of magnitude higher than that of metals. Although eqns [42] and [44] show temperature-dependent TCRs, in designing uncooled IRFPAs we generally regard the TCR as a constant because the temperature change of the detector is very small.

When a resistance bolometer is driven with a constant bias current, then we can measure the resistance from the voltage drop across the bolometer. Assume that the IR radiation changes the detector temperature by ΔT_D, and as a consequence changes the resistance of the bolometer by ΔR_B, then the significant signal output V_S is given by:

$$V_S = I_B\ \Delta R_B = I_B \alpha R_B\ \Delta T_D \quad [45]$$

where I_B is the bias current flowing through the bolometer.

Besides the temperature fluctuation noise and background fluctuation noise, the resistance bolometer has two noise sources: Johnson noise and $1/f$

noise. The Johnson noise is associated with the random motion of carriers in a conductor, and is given by the following equation:

$$V_{JN} = (4kT_D R_B B)^{1/2} \quad [46]$$

and the $1/f$ noise V_{fN} is approximated by the following equation (Kruse 2001):

$$V_{fN} = \sqrt{\frac{(I_B R_B)^2 n}{f}} \quad [47]$$

where n is the $1/f$ noise parameter.

Referring to the discussion of the heat balance in Section 3.04.3, we obtain a frequency-dependent responsivity for the resistance bolometer as:

$$R = \frac{I_B \alpha R_B \eta}{G_T (1 + \omega^2 \tau_T^2)^{1/2}} \quad [48]$$

Responsivity is directly proportional to the bias current, the TCR, and the resistance. In the uncooled IRFPAs, the readout circuits determine the range for the acceptable resistance. Since improvement of the TCR involves time-consuming material research and it is very difficult to find higher TCR materials having appropriate resistivity and low $1/f$ noise, the TCR of bolometers used in uncooled IRFPAs has been limited to 0.02–0.03 K^{-1} for more than a decade. Although a method readily adopted to enhance the sensitivity is to increase the bias current, we have to consider the self-burnout problem and the increase in the $1/f$ noise. Here, we will discuss the self-burnout problem according to Kruse (Kruse *et al.* 1962). He analyzed the self-burnout problem with a series circuit of a bolometer and photo-insensitive load resistor with a constant voltage power supply.

We start with the condition where the only heat generation source is the Joule heating and there is no incident radiation. Then the heat balance equation is written as (Kruse *et al.* 1962):

$$C_H \frac{dT_D}{dt} = I_B^2 R_B - G_{T0}(T_{DJ} - T_S) \quad [49]$$

where G_{T0} is the thermal conductance and T_{DJ} is the temperature of the bolometer when the bias current is flowing. The first term in the right-hand side represents the heat generation by Joule heating. In the presence of an incident IR power of magnitude P_{IN}, the temperature of the bolometer rises from T_{DJ} to T_D, and the temperature difference $\Delta T_D = (T_D - T_{DJ})$ fulfills the heat balance equation (Kruse *et al.* 1962).

$$C_H \frac{d\Delta T_D}{dt} = \frac{d\left(I_B^2 R_B\right)}{dT} \Delta T_D - G_T \ \Delta T_D + P_{IN} \quad [50]$$

where the first term in the right-hand side is the increase in the Joule heating energy due to the rise in temperature. Considering the definition of the TCR and the steady-state condition for eqn [49], eqn [50] can be rewritten as (Kruse *et al.* 1962):

$$C_H \frac{d\Delta T_D}{dt} = P_{IN} - G_E \ \Delta T_D \quad [51]$$

where

$$G_E = G_T - G_{T0}(T_{DJ} - T_S)\alpha\left(\frac{R_L - R_B}{R_L + R_B}\right) \quad [52]$$

where R_L is the resistance of the load resistor. The solution of eqn [50] for a sinusoidal incident IR energy of $P_0 \exp(j\omega t)$ is given by the following equation:

$$\Delta T_D = \Delta T_{D0} \ \exp\left(-\frac{G_E}{C_H} t\right) + \frac{P_0 \ \exp(j\omega t)}{G_E + j\omega C_H} \quad [53]$$

The second term in the right-hand side is the same as that of the solution for the heat balance equation without the Joule heating that is given in Section 3.04.3. The first term represents a transient phenomenon and causes the self-burnout problem. If G_E is positive, then the transient term becomes zero with time. In this instance, the self-burnout problem never occurs. However, if G_E is negative, it increases exponentially with time, and the temperature of the bolometer rises beyond the acceptable level. It is shown that the critical temperature for self-burnout is about 50 K (Kruse *et al.* 1962) above the ambient temperature for semiconductors having a TCR of 0.02 K^{-1}. Taking this self-burnout problem into account, current high-performance resistance bolometer uncooled IRFPAs make use of a pulse-biased scheme, in which high bias current, which causes the self-burnout if continuously biased, is applied to the bolometer in a short period so as to not reach the critical temperature.

There are many possible readout architectures for resistance bolometer uncooled IRFPAs. **Figure 15** shows a typical readout architecture used in current high-performance microbolometer uncooled IRFPAs (Kruse and Skatrud 1997). In this architecture, pixels

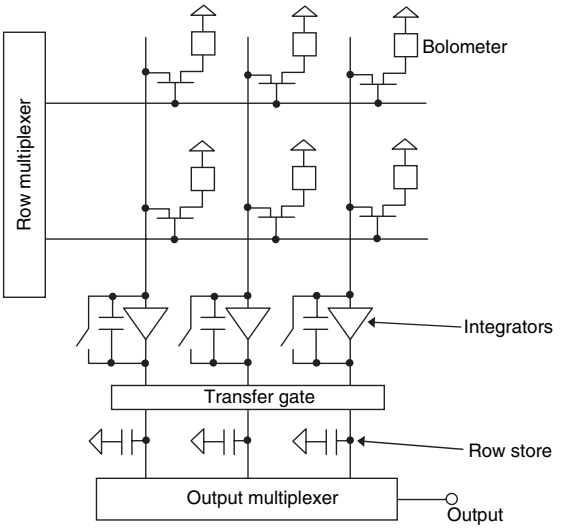

Figure 15 Typical readout architecture for resistance bolometer infrared focal plane array (IRFPA). (Source: Reprinted from *Semiconductor and Semimetals*, 47, Kruse P W, Skatrud D D, Uncooled Infrared Imaging Arrays and Systems, 94, Copyright (1997), with permission from Elsevier.)

in a row are biased simultaneously by turning on pixel selection transistors in the pixels, and outputs from the pixels are integrated by a column integrator. The integration operation not only amplifies the output signal but also restricts the bandwidth, and thus improves the signal-to-noise ratio. Therefore, a longer integration time offers a better signal-to-noise ratio. The maximum integration time for this readout architecture is a horizontal period, which equals the frame time divided by the number of rows. Integrated output signals are transferred to the sample-and-hold capacitances in the successive horizontal blanking period, and finally are read out serially.

3.04.5.2 VO_x Microbolometer IRFPAs

Wood reviewed the early works on the resistance bolometer uncooled IRFPAs (Kruse and Skatrud 1997). The development of resistance bolometer uncooled IRFPAs began with single-level pixel structures in the early 1980s. The concept and an example of the single-level pixel are shown in **Figure 16** (Kruse and Skatrud 1997). In this pixel structure, the resistance bolometer IR detector and readout electronics for the detector are arranged side by side. The bolometer film is formed in the SiN microbridge structure that is supported over an etched pit fabricated by bulk micromachining. Removal of underlying Si reduces thermal conductance and enhances sensitivity. They developed 1×16-element linear and 64×128-element 2D resistance bolometer uncooled IRFPAs with 75-μm-square single-level pixel (Kruse and Skatrud 1997). The material used in their IRFPAs was a thin-film Ni–Fe having a TCR of $+0.0023\,K^{-1}$. Other single-layer resistance bolometer detectors are also reported (Liddiard 1983). These early single-level resistance bolometer uncooled IRFPAs did not attract much attention because of their limited sensitivities caused by low TCRs of the metal bolometers and small fill factors.

Advances in surface micromachining technology made it possible to fabricate a double-level pixel structure where the bolometer film structure is supported over the readout circuits. Using the double-level structure and a semiconductor bolometer, Wood and coworkers succeeded in improving the sensitivity of resistance bolometer uncooled IRFPAs to a level better than that of ferroelectric IRFPAs (Capper and Elliott 2001, Kruse and Skatrud 1997, Wood 1993a,b, Wood *et al.* 1992). **Figure 17** shows the pixel structure of their uncooled IRFPA. A thin bolometer film of

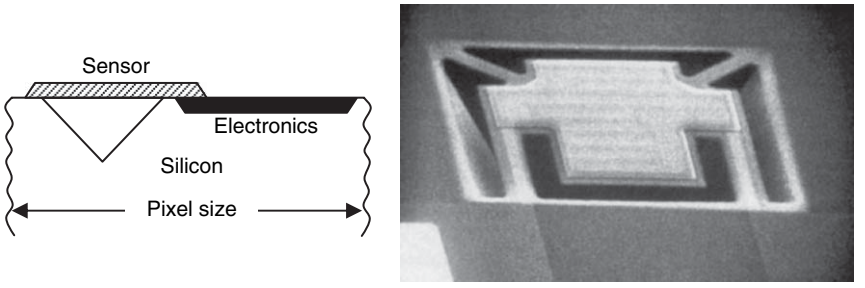

Figure 16 Single-level resistance bolometer pixel: Example of pixel photograph (*left*) and pixel layout (*right*). (Source: Reprinted from *Semiconductor and Semimetals*, 47, Kruse P W, Skatrud D D, Uncooled Infrared Imaging Arrays and Systems, 99,100, Copyright (1997), with permission from Elsevier.)

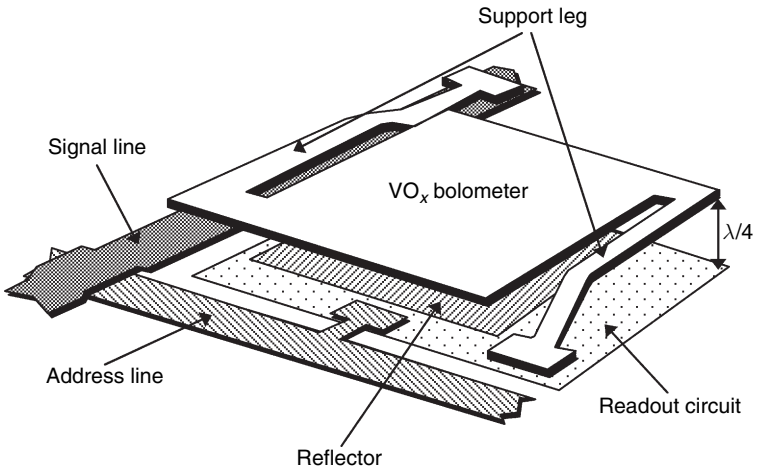

Figure 17 VO_x double-level resistance bolometer pixel. (Source: Wood R A 1993a High-performance infrared thermal imaging with monolithic silicon focal planes operating at room temperature. *Proc. IEEE IEDM*, Washington, DC, USA, pp. 175–7; reproduced with permission from IEEE.)

mixed vanadium oxide (VO_x) is deposited onto a microbridge structure that is supported by two long narrow legs. The microbridge is made of 0.5-μm-thick SiN. The supporting legs contain interconnections between the bolometer resistor and the readout circuit, which are made of 0.05-μm Ni–Cr conductive films. IR absorption is performed by a 1/4 wavelength-resonant optical cavity, consisting of an IR reflector on the substrate, IR-absorbing thin metal film on the bolometer resistor, and dielectric layer (dielectric thin films and the gap) between them.

A VO_x film can be deposited on the microbridge structure by sputtering at temperatures lower than the critical temperature for Si readout circuits. The TCR and resistivity of typical VO_x films for uncooled IRFPAs are 0.02 K^{-1} and 0.1 Ω cm, respectively. It was reported that VO_x films show no phase transition near room temperature. **Figures 18** and **19** show the characteristics of VO_x bolometers (Kruse and Skatrud 1997).

Figure 20 shows a typical fabrication sequence of a VO_x microbolometer uncooled IRFPA (Capper and Elliott 2001). After fabricating Si readout circuits, a sacrificial layer is deposited and patterned by photolithography technique. In the next step, the bottom structure of the microbridge made of SiN and VO_x film is deposited. Then, contact holes to the readout circuits are opened, and the bolometer film and readout circuits are connected by thin metal interconnections, which is covered by a SiN passivation film. The final step is a release process. After parts of the SiN layers are removed in order for an etchant to

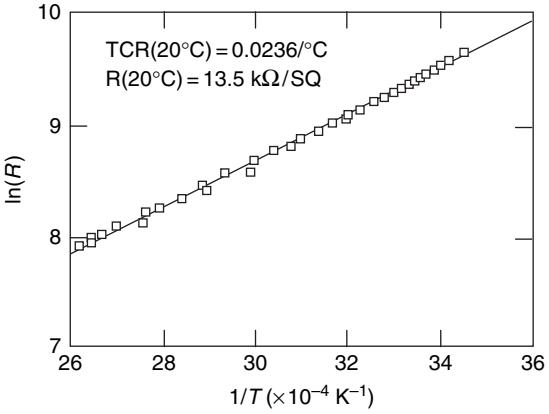

Figure 18 Temperature dependence of the resistance of typical VO_x bolometer. (Source: Reprinted from *Semiconductor and Semimetals*, 47, Kruse P W, Skatrud D D, Uncooled Infrared Imaging Arrays and Systems, 54, Copyright (1997), with permission from Elsevier.)

access the sacrificial layer, the microbridge structure is released by a selective etching process. The sacrificial layer is selected in combination with the material for the microbridge. Since the etching rate of SiO_2 to HF solution is much higher that that of SiN, SiO_2 was used as a sacrificial layer for the microbridge structure shown here in the beginning. The wet process, however, brings the sticking problem during drying, resulting in low production yield. This problem becomes serious when we reduce the thermal conductance to improve the sensitivity. Therefore, current manufacturing processes for high-performance IRFPAs use organic materials

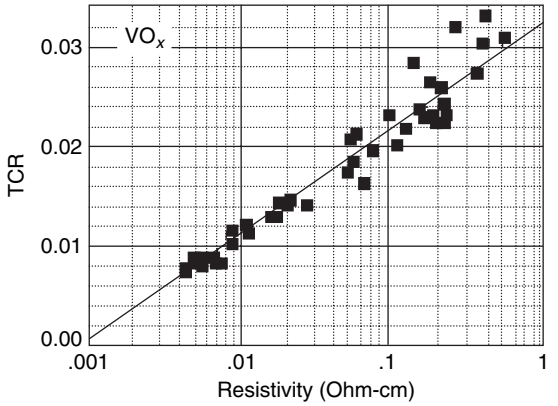

Figure 19 Temperature coefficients of resistance (TCR) versus resistivity of VO_x resistance bolometer. (Source: Reprinted from *Semiconductor and Semimetals*, 47, Kruse P W, Skatrud D D, Uncooled Infrared Imaging Arrays and Systems, 55, Copyright (1997), with permission from Elsevier.)

such as spun-on polyimides as sacrificial layers. Some organic materials for the sacrificial layer are photosensitive, and can be directly patterned by photolithography.

Using the VO_x resistance bolometer technology explained above, a 240×336-element uncooled IRFPA was developed (Wood *et al.* 1992). Thanks to the double-level structure, a fill factor of 70% and a thermal conductance of $2 \times 10^{-7}\,\mathrm{W\,K^{-1}}$ were achieved with a 50-μm-square pixel. **Figure 21** shows a SEM photograph of the pixels. The IRFPA employed a pulse-biased operation with a 5-μs pulse width and 250-μA pulse amplitude. An impressive NETD of 39 mK was reported with $f/1.0$ optics and a 30-Hz frame rate. Inspired by the success of their double-level VO_x microbolometer uncooled IRFPA, a number of IRFPAs were developed based on this technology (Herring and Howard 1996, Howard and Clarke 1999, Jerominek *et al.* 1998, Marshall *et al.* 1996, Radford *et al.* 1996, Terre *et al.* 2003, Wada *et al.* 1998). These IRFPAs have pixel sizes of around 50 μm square and array sizes from 128 μm × 128 μm to 320 μm × 240 μm.

3.04.5.3 Microbolometer IRFPAs with Other Materials

VO_x is not the only material that can be used for resistance bolometers. Si-based resistance bolometers including amorphous Si, amorphous and polycrystalline SiGe, and single-crystal Si have been studied for use in uncooled IRFPAs.

Amorphous Si is a successful example among the materials investigated for this application (Brady *et al.* 1999, Francisco 2001, Mottin *et al.* 2002, Tissot *et al.* 1998, 2000, Unewisse *et al.* 1995, Vedel *et al.* 1999). Early work on amorphous Si was done by a group in Australia (Unewisse *et al.* 1995). One of the issues in applying amorphous Si to uncooled IRFPAs is large $1/f$ noise. They prepared amorphous Si with sputtering and plasma-enhanced chemical vapor deposition

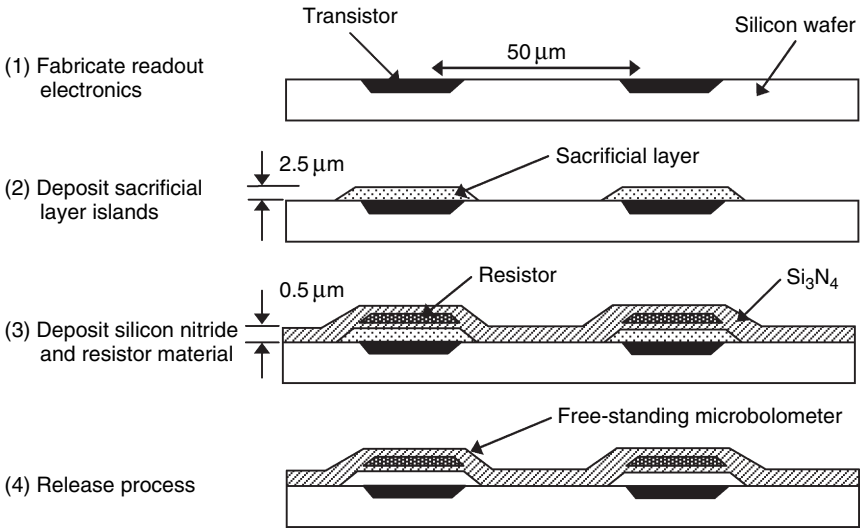

Figure 20 Fabrication sequence of double-level microbolometer pixel. (Source: Wood R A 1993a High-performance infrared thermal imaging with monolithic silicon focal planes operating at room temperature. *Proc. IEEE IEDM*, Washington, DC, USA, pp. 175–7; reproduced with permission from IEEE.)

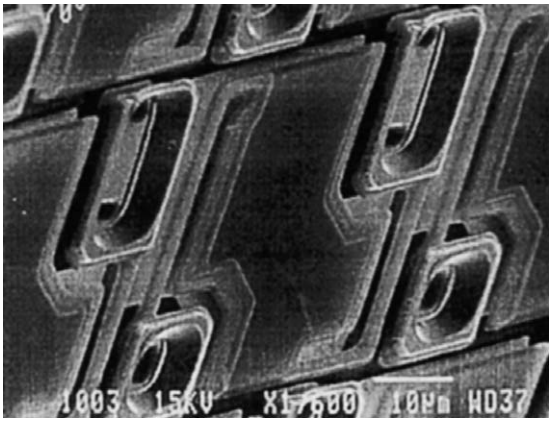

Figure 21 Scanning electron microscope (SEM) photograph of double-level microbolometer pixel. (Source: Capper P, Elliott C T 2001 *Infrared Detectors and Emitters: Materials and Devices*. Kluwer Academic Publishers, Norwell, MA.)

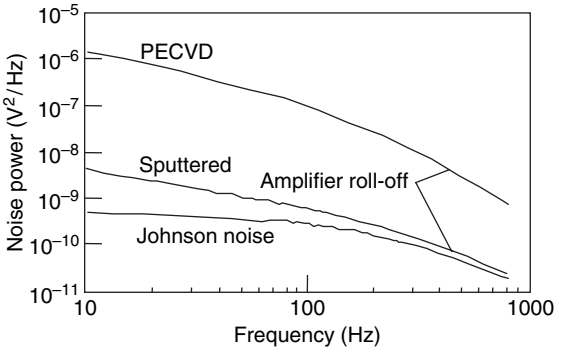

Figure 22 1/*f* noise of amorphous Si resistance bolometers prepared with plasma-enhanced chemical vapor deposition (PECVD) and sputtering. (Source: Unewisse M H, Craig B I, Watson R J, Reinholed O, Liddiard K C 1995 The growth and properties of semiconductor bolometers for infrared detection. *Proc. SPIE* **2554**, 43–54.)

(PECVD), and compared the noise characteristics of films with a similar resistivity. They found that the level of $1/f$ noise is highly dependent on the film preparation method, and amorphous Si deposited with PECVD exhibited a very high value of $1/f$ noise, as shown in **Figure 22**. They also found that amorphous silicon prepared by PECVD has a random telegraph signal noise cause by current transported along a narrow filament through the barrier of a wide-bandgap material.

Tissot *et al.* (1998) developed 256×64-element amorphous Si resistance bolometer uncooled IRFPAs with 50-μm-square pixels for a laboratory model. Their pixel has essentially the same microbridge structure as the VO_x microbolometers, but it comprises only a very thin layer (0.1 μm) of doped amorphous Si with no extra supporting layer or membrane. This makes the heat capacity of the structure very low, and offers possibility of higher frame rate operation and/or lower thermal conductance design. **Figure 23** shows the dependence of TCR on the resistivity for amorphous Si thin films (Tissot *et al.* 1998). Although a $0.05\,K^{-1}$ TCR is feasible for lightly doped films, heavily doped films with TCRs around $0.025\,K^{-1}$ are generally used for uncooled IRFPAs.

Figure 24 shows a pixel structure and a close-up photograph of the pixel near a metal stud (Mottin *et al.* 2002, Tissot *et al.* 1998). The fabrication process for this structure is depicted in **Figure 25** (Mottin *et al.* 2002). Their 256×64-element uncooled IRFPA exhibited an NETD of <50 mK with $f/1.0$ optics and high frame rate up to 100 Hz (Vedel *et al.* 1999). This technology has blossomed to a commercial product of a 320×240-element uncooled IRFPA with 45-μm pixels, which have an NETD of 70 mK at $f/1.0$ and 50 Hz (Tissot *et al.* 2000). Before the launch of the commercial product, they had to solve a reliability problem associated with the amorphous Si material. The metastable effect of amorphous Si may cause change in resistance of the bolometer after high-temperature acceleration tests if no measures against it are taken. Tissot *et al.* (2000) overcame this problem by using an original heat treatment and reported that

(Source: Mottin E, Bain A, Martin J L, Ouvrier-Buffet J L, Yon J J, Chatard J P, Tissot J L 2002 Uncooled amorphous silicon technology: High performance achievement and feature trends. *Proc. SPIE* **4721**, 56–63.)

no significant resistance change was observed at a storage temperature of 125°C after 1000 h.

Brady and coworkers reported a 160 × 120-element amorphous Si resistance bolometer uncooled IRFPA with a pixel size of 46.8 µm square (Brady *et al.* 1999, Francisco 2001). The high amorphous Si pixel resistance of 30 MΩ of this IRFPA allows the use of a DC detector bias. They adopted the full-frame time integration operation, which becomes possible with the high pixel resistance and a switched capacitor integrating amplifiers in a pixel.

Although the single-crystal Si has relatively low TCRs of 0.5–0.7% per Kelvin, it is attractive because of its compatibility with Si-LSI technology. Tezcan and coworkers reported results on a single-crystal Si resistance microbolometer uncooled

IRFPA (Eminoglu *et al.* 2001, Tezcan *et al.* 2001). The whole structure of the single-crystal microbolometer is fabricated using a standard CMOS process technology in a Si foundry, and the only additional process is the final release process to make a freestanding structure by anisotropic etching of the bulk Si using TMAH solution.

Polycrystalline SiGe has low tensile stress, low thermal conductivity, and TCR comparable with VO_x, and therefore it is suitable for self-supporting microbolometer uncooled IRFPAs (Henini and Razeghi 2002, Leonov *et al.* 2003, Moor *et al.* 2000, Sedky *et al.* 1998). As in the case of amorphous Si uncooled IRFPAs, the self-supported structure of polycrystalline SiGe offers possibility of lower thermal conductance and lower heat capacity than do multilayer structures. In order to make a very thin freestanding structure, Moor *et al.* (2000) developed a vapor HF surface micromachining at an elevated wafer temperature and a U-shape structure for stiffness enhancement. They noticed that water created during the reaction of the vapor HF etching process leads to sticking and it can be avoided by heating a wafer to a temperature between 30°C and 50°C. The U-shaped structure has a U-profile cross section, the idea of which is based on high stiffness of I-shape steel in the construction mechanics. The polycrystalline SiGe film is deposited by atmospheric pressure or reduced pressure chemical vapor deposition at 600°C (Henini and Razeghi 2002). The TCR of polycrystalline SiGe is $-0.015\,K^{-1}$, including the TCRs of the interconnection metals, and evaluation of a 128-element linear IRFPA with 50-μm-square pixels showed an NETD of 65 mK at $f/1.0$ (Leonov *et al.* 2003). Amorphous GeSi and GeSiO thin films are also investigated for the use of microbolometers (Rana and Butler 2005). As for amorphous GeSi, increased Si concentration gives higher resistivity and lower TCR. For GeSiO, the addition of O_2 to SiGe increases the resistivity and TCR.

High-T_c superconducting materials and colossal magneto resistance materials are expected to have high TCRs, and some of them are investigated for uncooled IRFPAs. Among several candidates, semiconducting amorphous YBaCuO has exhibited promising results (Almasri *et al.* 2000, Jahanzeb *et al.* 1997, Wada *et al.* 2000). Semiconducting YBaCuO is prepared by RF magnetron sputtering from a composite target. Monolithic structures are readily realized with this material because thin films having characteristics suitable for uncooled IRFPAs are prepared by deposition at room temperature. Almasri *et al.* (2000) produced 40-μm-square self-supported YBaCuO microbolometer pixels. The self-supporting structure was fabricated by a surface micromachining technology with a polyimide sacrificial layer. A 400-nm YBaCuO film is supported by two 10-nm Ti interconnection electrodes. Since Ti is not a good material to make a good ohmic contact to YBaCuO, Au contact pads were inserted between YBaCuO and Ti. TCR and D^* for a broadband (2.5–13 μm) radiation of their microbolometers are reported to be $-0.035\,K^{-1}$ and $10^8\,cm\,Hz^{1/2}\,W^{-1}$, respectively. Wada *et al.* (2000) developed a 320×240-element YBaCuO resistance bolometer uncooled IRFPA with 40-μm-square pixels. Their YBaCuO bolometer had a TCR of $-0.032\,K^{-1}$ and a $1/f$ noise comparable with the VO_x bolometers. The IRFPA has an NETD of 80 mK with $f/1.0$ optics, and an excellent thermal image was demonstrated. Good YBaCuO films can be deposited on various substrates, including flexible substrates such as polyimide and Kapton. A smart skin that incorporates flexible microsensors is expected using this feature of YBaCuO (Celik-Butler *et al.* 2002).

Although the TCR of metal bolometers is about an order of magnitude lower than that of semiconductor bolometers, some attempts were made with Ti bolometers (Manning *et al.* 2004, Tanaka *et al.* 1996). Ti is selected because of its full compatibility with the Si-LSI process, low thermal conductivity, and low $1/f$ noise. Tanaka and coworkers developed a 128×128-element Ti bolometer with 50-μm-square pixels. The TCR of a Ti thin film was $0.0025\,K^{-1}$, which is smaller than a bulk Ti TCR of $0.0042\,K^{-1}$. They demonstrated an NETD of 90 mK at $f/1.0$ with a 2.5-mA bias current and 5.3-μs integration time.

3.04.5.4 Small Pixel Microbolometer IRFPAs

The pixel structure of the resistance bolometer uncooled IRFPA made progress from the single level to the double level in order to enlarge the fill factor and thus to enhance the sensitivity. During the 1990s, the technology for the double-level structure was fully mastered, and many products manufactured by this technology became commercially available. Those products had pixel sizes around 50 μm square. The double-level structure worked well for relatively large pixels. Pixel size reduction, however, is mandatory in imaging device development to realize higher spatial resolution and smaller imaging systems. Further pixel size reduction from 50 μm square imposes a serious

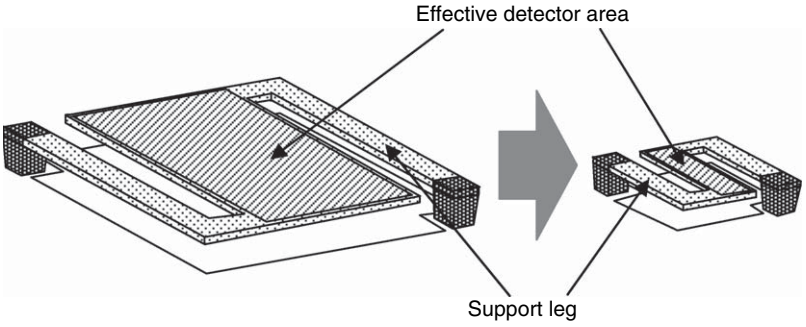

Figure 26 Difficulties in pixel size reduction for microbolometer.

problem, as illustrated in **Figure 26**. Smaller pixels collect less IR energy to elevate their temperature, and as a result have lower sensitivity. Radford *et al.* (1999) showed that lengthening the support legs is one of the most effective methods to improve sensitivity. They achieved an NETD of 8 mK at $f/1.0$ with a 50-μm-square pixel having long multibending legs. Unfortunately, the trade-off between the fill factor and the thermal conductance becomes more serious when reducing the pixel size, and therefore, their approach cannot be applied to smaller pixels. There are two approaches to overcome this problem. One is to develop new pixel structures that ensure high fill factor and low thermal conductance simultaneously. The other is to move to manufacturing processes that allow tighter design rules.

Murphy *et al.* (2002) implemented several improvements to the VO_x microbolometer pixels such as the reduction of the leg width and the introduction of dry etching micromachining process and low-density SiN film having low thermal conductivity and low specific heat. They, however, found that conventional micromachining processes suffer severe performance degradation as the unit cell size is reduced below 40 μm, and even if micromachining design rules are improved by a factor of 2, the performance of a 25-μm pixel is very poor compared with a 50-μm pixel. In order to overcome this problem, they developed a multilevel microbolometer pixel, in which the thermal isolation legs and VO_x bolometer are in different levels as shown in **Figure 27** (Murphy *et al.* 2002, 2003, 2005). This structure is fabricated by a surface micromachining process with double sacrificial layers. Using this pixel structure, 320×240 and 640×480-element uncooled IRFPAs with 25-μm-square pixels have been developed. A recent report showed that the former IRFPA has an NETD of 22 mK at $f/1.0$ and the latter IRFPA an NETD of 35 mK at $f/1.0$ (Murphy *et al.* 2005). Furthermore, a

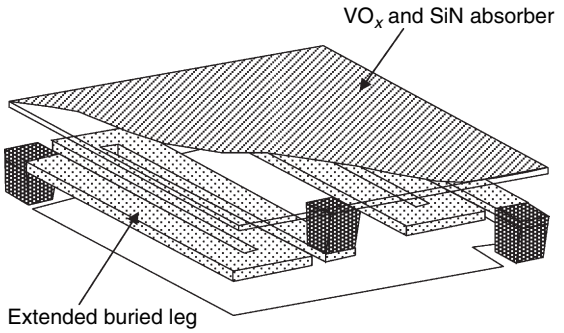

Figure 27 Multilevel VO_x microbolometer pixel having hidden support legs. (Source: Murphy D, Ray M, Wyles R, Asbrock J, Lum N, Wyles J, Hewitt C, Kennedy A, Lue D V, Anderson J, Bradley D, Chin R, Kostzewa T 2002 High sensitivity 25 μm microbolometer FPAs. *Proc. SPIE* **4721**, 99–110.)

program is progressing to develop 640×480-element uncooled IRFPAs with 20-μm-square multilevel pixels (Murphy *et al.* 2005). SEM photographs of the 20-μm multilevel microbolometer pixels are shown in **Figure 28**. Current performance of the 20-μm IRFPA was reported to be 27 mK at $f/1.0$ with a 30-Hz frame rate (Murphy *et al.* 2006). Multilevel resistance bolometer pixel structures were also reported from other organizations (Jerominek *et al.* 2000, Lee *et al.* 1998).

Another pixel structure categorized as the first approach is illustrated in **Figure 29** (Tohyama *et al.* 2004). This structure has an eaves sticking out from the freestanding bolometer that absorbs the IR radiation falling on the leg and interconnection areas. The eaves are made of SiN. Tohoyma *et al.* (2004) reported that the responsivity of a 23.5-μm-square pixel with the eaves was improved by a factor 1.3 compared with the conventional double-level pixel. Extra IR-absorbing structures are also adopted in other resistance bolometer uncooled IRFPAs (Han *et al.* 2005, Hay and Deusen 2005, Wada *et al.* 2000).

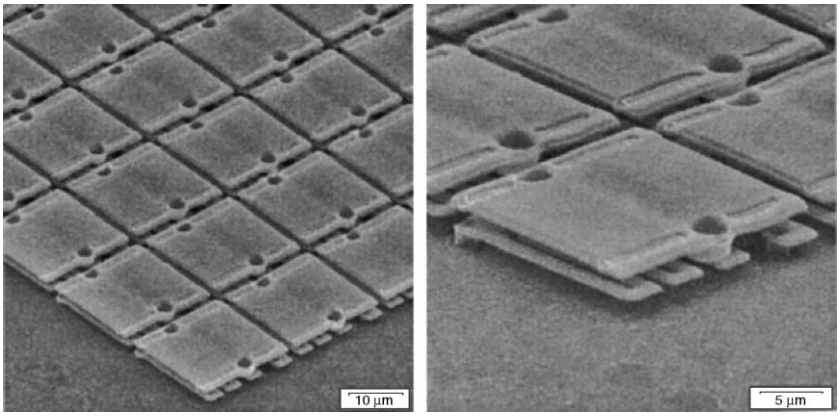

Figure 28 Scanning electron microscope (SEM) photograph of multilevel VO_x microbolometer pixel having hidden support legs. (Source: Murphy D, Ray M, Kennedy A, Wyles J, Hewit C, Wyles R, Gordon E, Sessler T, Baur S, Lue D V, Anderson S, Chin R, Gonzalez H, Pere C L, Ton S, Kostrzewa T 2005 Expand applications for high performance VO_x microbolometer FPAs. *Proc. SPIE* **5783**, 448–59.)

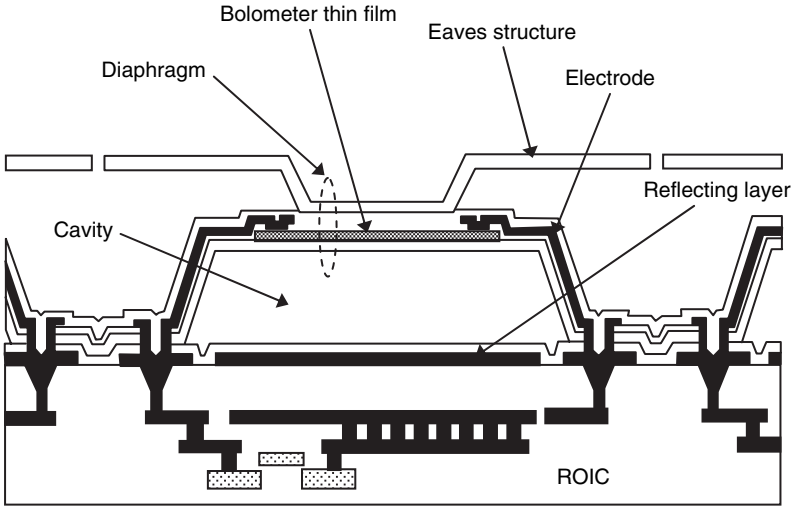

Figure 29 Microbolometer pixel with eaves structure for enhanced infrared absorption. (Source: Tohyama S, Miyoshi M, Kurashina S, Ito N, Sasaki T, Ajisawa A, Oda N 2004 New thermal isolation pixel structure for high-resolution uncooled infrared FPAs. *Proc. SPIE* **5406**, 428–36.)

The conventional VO_x double-level pixel structure is still being used in the pixel sizes from 28 to 25 μm by reducing minimum design rules (Altman *et al.* 1999, Mizrahi *et al.* 2005, Norton and Kohin 2005, Norton *et al.* 2006). An example is a 28-μm pixel designed with 0.8-μm fine pattern design rules for a 640 × 480-element IRFPA (Altman *et al.* 1999). This pixel achieved a thermal conductance of $5 \times 10^{-8}\,\mathrm{W\,K^{-1}}$ and a fill factor of 64%. In addition to the tighter design rules, a single-contact-per-pixel design contributes to fill factor improvement of IRFPAs with the smaller double-level pixel (Norton *et al.* 2006).

The amorphous Si resistance bolometer pixel is also being miniaturized while preserving the double-level pixel structure (Mottin *et al.* 2001, Tissot *et al.* 2006, Yon *et al.* 2005). In order to fabricate a 35-μm pixel and a 25-μm pixel, enhanced amorphous Si technology has been developed, which includes an improvement of thermal resistance by more than a factor of 3, reduction in the $1/f$ noise by increasing the bolometer thickness and improved process for the bolometer, and advanced design rules for stud formation (Mottin *et al.* 2001, Yon *et al.* 2005). Utilizing the enhanced amorphous Si technology, a 320 × 240-element IRFPA with a 35-μm pixel pitch achieved an NETD of 35 mK at $f/1.0$

(Mottin *et al.* 2001), and a 640 × 480-element IRFPA with a 25-μm pixel pitch 48 mK at *f*/1.0 (Tissot *et al.* 2006).

3.04.5.5 MWIR Response

In the quantum IRFPA field, multiband integration including IR detectors for LWIR and MWIR spectral bands is one of the most important themes for the third-generation thermal imager. On the other hand, until recently, uncooled IRFPAs have not been used for the detection of the MWIR spectral band because of their lower responsivity. But, recent progress in the uncooled IRFPA has made the responsivity comparable with that of quantum IRFPAs categorized in the second generation, and thus has made it possible to expand applications of the uncooled IRFPA to the MWIR spectral region. Tissot *et al.* (2004) showed that a 160 × 120-element amorphous Si uncooled IRFPA optimized for LWIR detection had a useful response (NETD = 170 mK at *f*/1.0) in the MWIR spectral band while its LWIR NETD was 30 mK at *f*/1.0. Simulations of IR absorption were performed to optimize the thickness of the bolometer bridge and the gap between the bolometer and the reflector for dual-band detection (Murphy *et al.* 2005, Norton and Kohin 2005). **Figure 30** shows an example of a simulated IR absorption that enables a MWIR NETD better than 100 mK at *f*/1.0 (Norton and Kohin 2005).

3.04.5.6 Packaging

As discussed in Section 3.04.3, the microbolometer uncooled IRFPA is encapsulated in a vacuum package because the thermal conductance of the support legs in the microbolometer is much lower than that of the air around the pixel. **Figure 31** explains how the surrounding pressure has an influence on the responsivity (Liddiard 1983). **Figure 32** shows a vacuum package for the first VO_x microbolometer uncooled IRFPA with 240 × 336 pixels (Capper and Elliott 2001). The package is constructed of brazed and soldered materials, which are carefully cleaned and baked before sealing to produce low outgassing. It has getters to absorb outgassing and a thermoelectric temperature stabilizer that controls the IRFPA temperature in order to eliminate the drift of output due to the temperature change.

Packaging using the package shown in **Figure 32** is a costly process and is not suitable for mass production. Mottin *et al.* (2001) reported a packaging concept that allows the simultaneous assembling of four IRFPAs. The package is made of 4inch Si wafer with cavities and low-temperature nonevaporable getters. Cole *et al.* (2001) developed a wafer-level packaging technology named integrated vacuum package (IVP) process. The IVP process consists of bonding a Si cap wafer to the IRFPA wafer to produce a 4inch bonded double wafer having multiple arrays. A low-oxygen floating-zone Si wafer having a thickness of 250 μm is used for a cap wafer. Sealing is performed by a PbSn solder. Since the vacuum cavity of the IVP is very small, a small amount of outgassing during wafer bonding degrades the

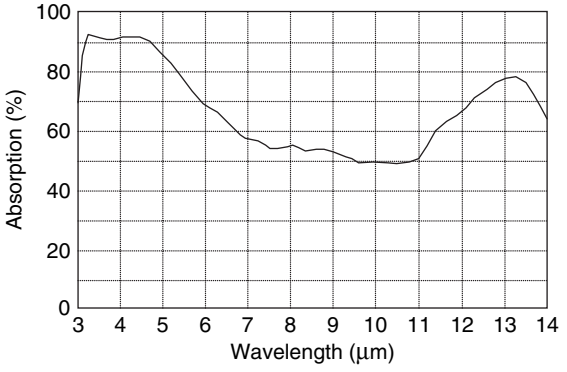

Figure 30 Simulated infrared absorption of resonant cavity absorber optimized for middle-wavelength infrared (MWIR) detection. (Source: Norton P W, Kohin M 2005 Technology and applications advancements of uncooled imagers. *Proc. SPIE* **5783**, 524–30.)

vacuum level. They were able to solve this problem by using an etched pumping port in the IRFPA wafer, which is sealed by an evaporated thin metal film after a baking process. Microstructured antireflection coating is adopted for the cap. **Figure 33** illustrates a part of the IVP structure. While the wafer-level packaging technology is still under development, pixel-level packaging was also proposed for uncooled IRFPAs (Astier *et al.* 2004).

3.04.6 Thermoelectric IRFPAs

3.04.6.1 Operation of Thermoelectric Infrared Detector

When two dissimilar metals or semiconductors are connected at both ends, making a closed circuit (**Figure 34(a)**), and a temperature difference is given between the two connected points, a current flows in the circuit. If one of the conductors is cut in the middle (**Figure 34(b)**) or the circuit is cut at junction B (**Figure 34(c)**), a thermoelectric voltage appears in the opened circuit. This effect is called the Seebeck effect after its discoverer.

The thermoelectric voltage V_S is proportional to the temperature difference ΔT_D ($= T_A - T_B$), or

$$V_S = \alpha \ \Delta T_D \qquad [54]$$

where α is the Seebeck coefficient. Practically, the Seebeck coefficient is measured for a pair of materials. The Seebeck coefficient, however, can be defined as a material-inherent value. Let the Seebeck coefficient of conductor 1 and conductor 2 in **Figure 34** be α_1 and α_2, respectively, then the Seebeck coefficient of this pair is expressed as:

$$\alpha = \alpha_1 - \alpha_2 \qquad [55]$$

The thermocouple has configurations shown in **Figure 34(b)** or **34(c)**. **Figure 35** shows an example

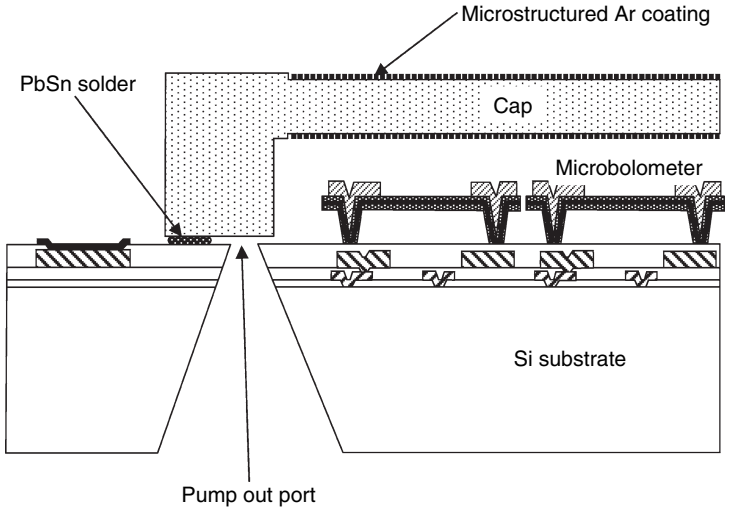

Figure 33 Integrated vacuum package for microbolometer uncooled infrared focal plane array (IRFPA). (Source: Cole B E, Higashi R E, Ridely J A, Wood R A 2001 Integrated vacuum packaging for low-cost light-weight uncooled microbolometer arrays. *Proc. SPIE* **4369**, 235–9.)

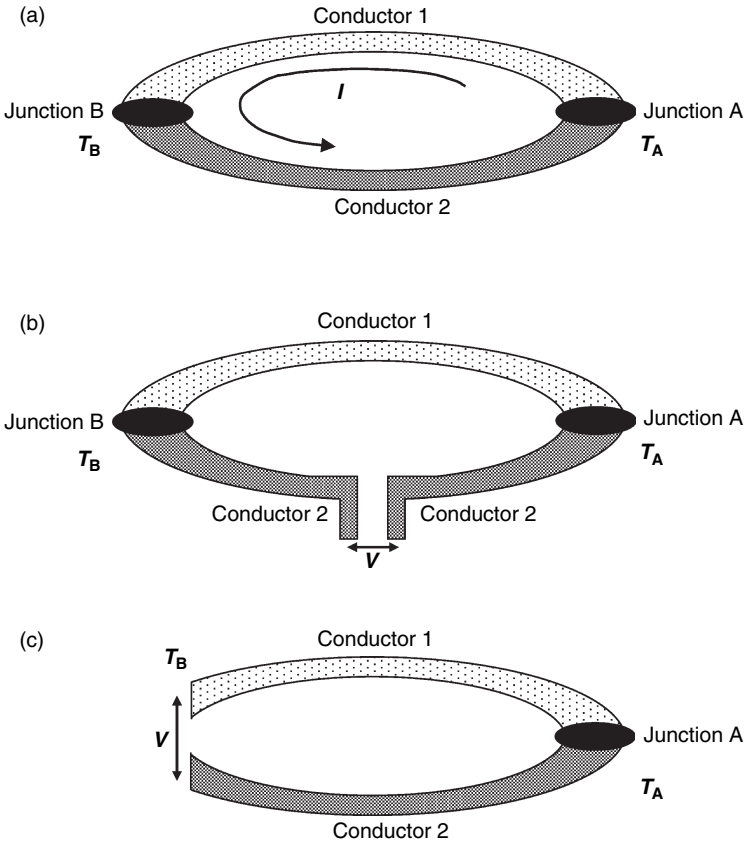

Figure 34 Generation of thermoelectric current and voltage by Seebeck effect.

of a thermoelectric IR detector, which corresponds to the configuration shown in **Figure 34(b)**. The substrate acts as a heat sink. While a cold junction is located on the substrate, a hot junction is fabricated on the thin membrane, under which the substrate is removed. IR radiation on the detector is absorbed in an IR absorber and raises the temperature at the hot junction because the membrane has a low thermal

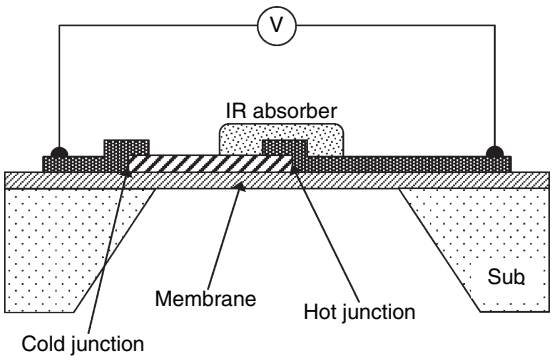

Figure 35 Structure of thermoelectric infrared detector.

conductance to the substrate. On the other hand, the temperature at the cold junction remains unchanged because it is just on the heat sink. Thus, a temperature difference between the hot and the cold junctions appears in response to IR radiation.

Since the thermoelectric voltage is additive, serial connection of hot and cold junctions of the thermocouples enhances the sensitivity. The serially connected thermocouple is called the thermopile. The thermoelectric voltage of a thermopile with m hot/cold junction pairs is given by the following equation:

$$V_S = m\alpha\Delta T_D \quad [56]$$

The electrical noise in thermoelectric IR detectors is the Johnson noise associated with the resistance of the thermocouple or thermopile R_D.

$$V_{JN} = (4kT_D R_D B)^{1/2} \quad [57]$$

Referring to the discussion in Section 3.04.4.3, one obtained the Johnson noise-limited normalized detectivity D^* of the thermoelectric IR detector as (Kruse 2001):

$$D^* = \frac{\eta m\alpha\sqrt{A_D}}{2G_T\sqrt{kT_D R_D}\sqrt{1+\omega^2\tau_T^2}} \quad [58]$$

and the NETD as (Kruse 2001):

$$\mathrm{NETD} = \frac{8F^2 G_T\sqrt{kT_D R_D B}\sqrt{1+\omega^2\tau_T^2}}{\tau_0 A_D \eta m\alpha(\Delta P_{SC}/\Delta T_{SC})} \quad [59]$$

Higher responsivity is obtained with larger Seebeck coefficient and smaller thermal conductance, and lower electrical noise is attained with smaller resistance. Considering these dependences, it is convenient to use a figure of merit for thermoelectric materials, which is defined as (Kruse 2001):

$$Z = \frac{\alpha_1 - \alpha_2}{\sqrt{\rho_1\sigma_1} + \sqrt{\rho_2\sigma_2}} \quad [60]$$

where σ_1 and σ_2 are thermal conductivity, and ρ_1 and ρ_2 are the electrical resistivity of materials 1 and 2, respectively.

3.04.6.2 Thermopile IRFPAs

Before the introduction of MEMS technology, thermoelectric IR detectors were made on thin plastic or alumina substrates. The Si-LSI-compatible MEMS technology had a great impact also on thermoelectric IR detectors from the viewpoint of sensitivity, productivity, and array integration.

The first thermopile detector fabricated by the micromachining process was reported in 1982 (Lahiji and Wise 1982). **Figure 36** shows the structure of the monolithic silicon thermopile detector. Hot junctions are formed on a thin membrane, and cold junctions on the thick silicon rim. The membrane consists of a thin dielectric film and a highly boron-diffused silicon layer. The fabrication process for this thermopile IR

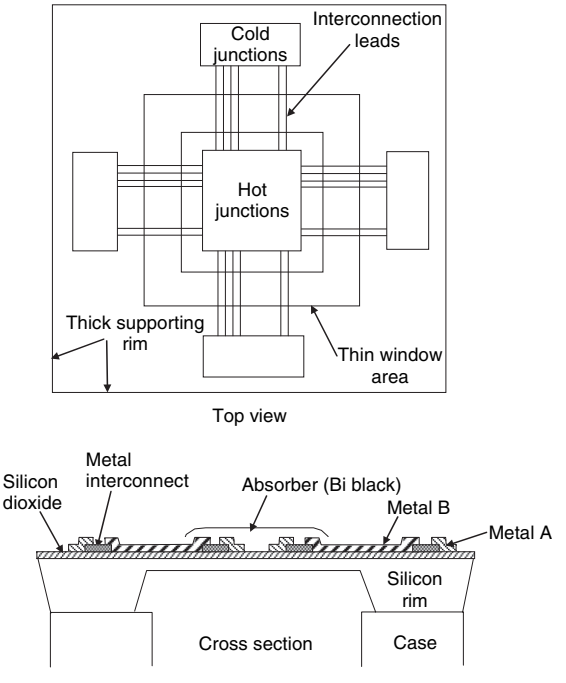

Figure 36 Structure of monolithic thermopile infrared detector. (Source: Lahiji G R, Wise K D 1982 A batch-fabricated silicon thermopile infrared detector. *IEEE Trans. Electron Devices* **ED-29**, 14–22; reproduced with permission from IEEE.)

detector is shown in **Figure 37**. The membrane is formed using an EDP etchant. As this is an anisotropic etching, and the etching rate of highly doped silicon is virtually zero, the planar shape and thickness of the membrane are precisely controlled. Bismuth black was used as an IR absorber. Using this technology, detectivities of mid-10^7 cm $Hz^{1/2}$ W^{-1} for 15-ms response times were achieved with Bi/Te, p-polysilicon/Au, and n-polysilicon/Au thermopiles. This technology for a single detector was extended to fabricate a 16×2-element staggered array with p-type polysilicon-Au thermopiles (Choi and Wise 1986).

High compatibility with commercial CMOS LSI processes is one of the most important features of thermopile uncooled IRFPAs. A group from ETH Zürich extensively made researches to develop CMOS-based thermopile uncooled IRFPAs, including the Si-LSI-compatible IR absorber. The thermopiles investigated were an aluminum/p-doped polysilicon junction and an n-doped/p-doped polysilicon junction. They started with single-element IR sensors that were fabricated by a front-accessed bulk micromachining technology (Lenggenhager *et al.* 1993). The IR sensors have IR absorbers made of dielectric films. **Figure 38** shows spectral reflectance data of dielectric films of SiN and SiO_2. Since the value of 1 minus reflectance gives the absorptivity, these data indicate that SiN and SiO_2 have useful absorption in an 8- to 14-μm spectral band. The absorptivity is enhanced by placing an aluminum reflector for double-pass absorption under the dielectric absorber and/or by using structuring absorbers (Schneeberger *et al.* 1995).

There are several possible pixel structures in realizing 2D thermopile uncooled IRFPAs (Oliver and Wise 1999). Among these pixels, IRFPAs having a single membrane by back-etched processes require pixel thermal isolation structures by which the cold junctions keep a constant temperature. Fabricating all pixels on a single membrane, the back-etched bulk micromachining process enables us to pack pixels as close as possible. **Figure 39** shows an

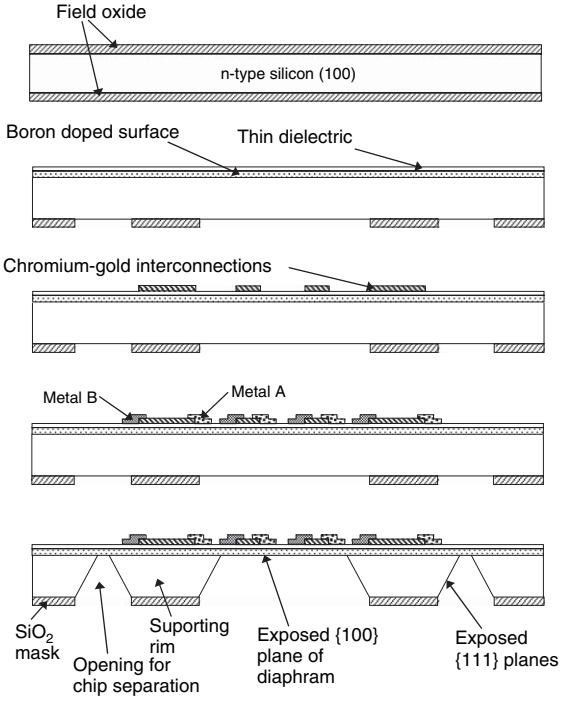

Figure 37 Process sequence for monolithic thermopile infrared detector. (Source: Lahiji G R, Wise K D 1982 A batch-fabricated silicon thermopile infrared detector. *IEEE Trans. Electron Devices* **ED-29**, 14–22; reproduced with permission from IEEE.)

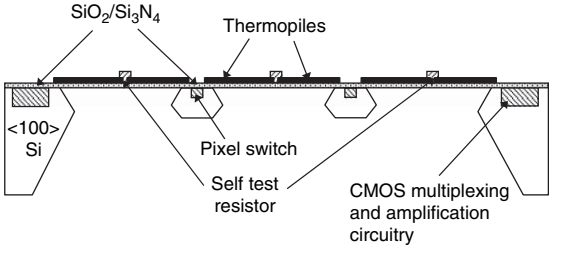

Figure 39 Thermopile uncooled infrared focal plane array (IRFPA) structure fabricated by combination of front-undercut and back-etched micromachining process. (Source: Oliver A D, Wise K D 1999 A 1024-element bulk-micromachined thermopile infrared imaging array. *Sens. Actuators* **73**, 222–31.)

example of such a structure (Oliver and Wise 1999). This structure is fabricated by the combination of a front-undercut and a back-etched micromachining technology. Etching with EDP from both sides forms the structure having heat sinks between pixels. This heat sink is made of lightly doped single-crystal silicon on which pixel switches are located. A 32×32-element IRFPA was developed with this structure. The thermopile of 32-pair p-type and n-type polysilicon thermocouples is arranged in a 375-μm-square pixel.

The other structure made by a back-etched process is shown in **Figure 40** (Münch *et al.* 1997). The pixels are thermally separated by gold lines, which are made by a tape automated bonding technology with gold bumps. A wafer-level bulk micromachining process from the back with KOH solution was developed in order to fabricate this structure. Using this technology, a 10×10-element thermoelectric uncooled IRFPA was developed (Schaufelbühl *et al.* 2001). This device integrated a low-noise chopper-stabilized amplifier. A 250-μm-square pixel has 12 thermocouples made of n-doped polysilicon and aluminum with a relative Seebeck coefficient of $108\,\mu V\,K^{-1}$. The separation gold line with 25 μm thickness and 80 μm width successfully reduces the crosstalk of <3.6%. An imaging module built with this IRFPA and an $f/1.0$ polyethylene Fresnel lens exhibited an NETD of 530 mK at a frame rate of 0.5 Hz. The sensitivity was improved by a factor of 3.3 for a successively developed 16×16-element IRFPA by employing a new pixel design and thermopile geometry optimized considering the thermal resistance and electrical resistance (Schaufelbüehl *et al.* 2001).

Front-accessed bulk-undercut processes have also been adopted to 2D thermoelectric uncooled IRFPAs. **Figure 41** shows an example of a pixel photograph fabricated by such a process (Hirota *et al.* 2001, 2003). The thermopile is made of p-doped polysilicon/n-doped polysilicon. The polysilicon layers for thermopile are doped with a boron dose of $1 \times 10^{16}\,cm^{-2}$ for p-type area and a phosphorous dose of $1 \times 10^{16}\,cm^{-2}$ for n-type area, and the junction between them is shunted by aluminum. A Au-black IR absorber is formed on the freestanding structure by lift-off process using a phosphosilicate glass (PSG) sacrificial layer (Hirota and Morita 1998). The Au-black films with thicknesses of 2–3 μm have absorptivity of >90% in a wavelength range of 8–13 μm. The developed devices are a 48×32-element IRFPA with 190-μm-square pixels and a 120×190-element IRFPA with 100-μm-square pixels. These devices are intended to operate in vacuum. When operated under atmospheric pressure, the responsivity is improved by increasing the number of thermopile pairs. The responsivity in vacuum, however, is a complicated function of the pixel structure, the materials used for support legs, the design rules for pattern layout, and the number of thermopile pairs because the dominant thermal loss mechanism is thermal conduction through the support legs. In designing pixels, they optimized the number of thermopile pairs, considering the responsivity and thermal time constant. Although the thermal time constant becomes shorter as the number of thermopile pairs increases, the dependence of the responsivity on the number of

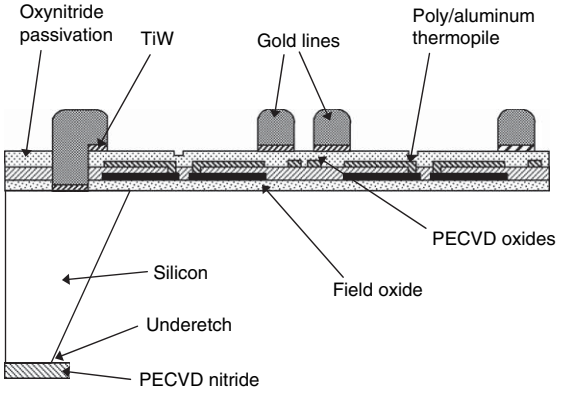

Figure 40 Thermopile uncooled infrared focal plane array (IRFPA) structure with gold bump for heat sink. Figure 41 Scanning electron microscope (SEM) photograph of p-polysilicon/n-polysilicon thermopile pixel fabricated by front-accessed bulk-undercut process. (Source: Hirota M, Satou F, Saito M, Kishi Y, Nakajima Y, Uchiyama M 2001 Thermoelectric infrared imager and automotive applications. *Proc. SPIE* **4369**, 312–21.)

thermopile pairs generally has a peak, indicating that there is an optimum number. According to their design, the optimum numbers for the 190-μm and 100-μm-square pixels are six pairs and two pairs, respectively. For 48 × 32-element IRFPAs, the measured responsivity is 2100 V W^{-1} and an NETD of 0.4 K was obtained with *f*/0.7 optics (Hirota *et al.* 2001).

Using a surface micromachining technology, the thermopile layer can be stacked over the readout circuits. Kanno *et al.* (1994) developed a 128 × 128-element thermoelectric uncooled IRFPA with a stacked pixel. The thermopile of this IRFPA consists of p-type boron-doped polysilicon and n-type phosphorous-doped polysilicon. Doping with the impurity concentration of 10^{19} to 10^{20} cm^{-3}, the thermocouple has a Seebeck coefficient of 300–400 μV K^{-1}. The voltage generated by 32-pair thermocouples is applied to the gate electrode of an input circuit and modifies the electron injection into the accumulation capacitor. The accumulated signal charges are read out through CCDs. The stacked structure and a fine pattern of 0.6 μm width make it possible to achieve a high fill factor of 67% with a 100-μm-square pixel. An NETD of 0.5 K was reported with *f*/1.0 optics and a 120 Hz frame rate.

Although compatibility with silicon technology is one of the most important features of the thermopile uncooled IRFPA, the best performance of the thermopile uncooled IRFPA is obtained using materials impermissible in Si-LSI facilities. Compounds in the $(Bi_{1-x}Sb_x)_2(Te_{1-y}Se)_3$ family have the highest figure of merit at room temperature. Since these materials are difficult to fabricate into thin films and to be incorporated into Si-LSI processes, there are few reports on thermopile uncooled IRFPA with them. Foote *et al.* (1998) succeeded in improving the performance of thermopile uncooled IRFPAs by combining Bi–Te and Bi–Sb–Te thermoelectric materials. They fabricated uncooled linear IRFPAs with several types of pixels and achieved D^* values as high as 2.2×10^9 cm $Hz^{1/2}$ W^{-1} for 83 ms response times at a 1000 K blackbody (Foote and Jones 1998). They also developed an upheld pixel structure that is suitable for 2D IRFPAs (Foote and Gaalema 2001). **Figure 42** shows a top view and cross section of two pixels. The detectors are constructed on a silicon substrate and are fabricated by a surface micromachining process using two polyimide sacrificial layers. The IR absorber, which is connected to the isolated thermocouple junctions, is made of a silicon nitride film with a thin platinum-absorbing layer. This structure offers nearly 100% fill factor while still accommodating many thermocouples per pixel, high thermal isolation, and possibility of integrating CMOS readout circuits below the thermopile structure.

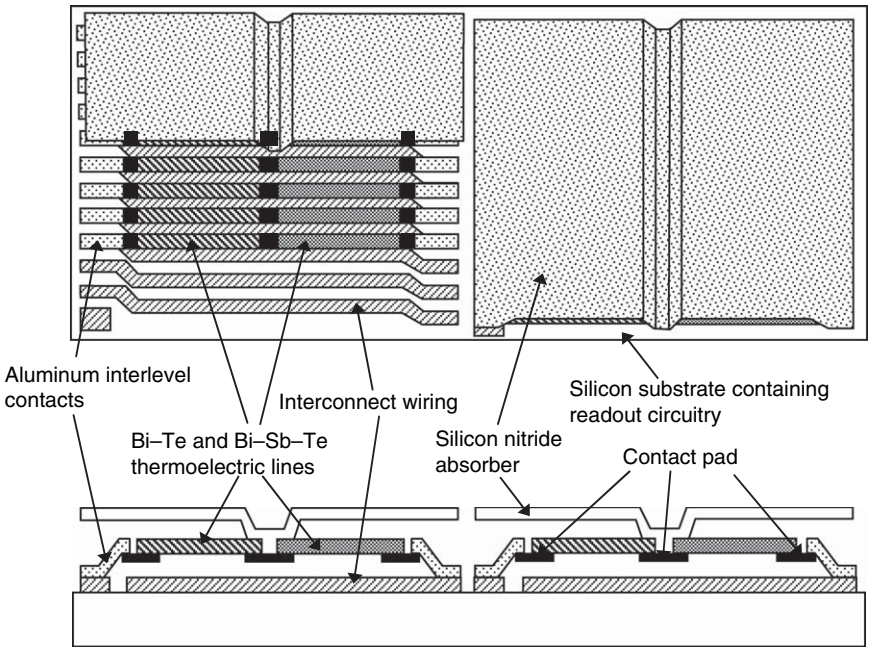

Figure 42 Upheld thermopile pixel structure having nearly 100% fill factor. (Source: Foote M C, Gaalema S 2001 Progress towards high-performance thermopile imaging arrays. *Proc. SPIE* **4369**, 350–5.)

Pursuing larger thermoelectric figure of merit, AlGaAs (Dehe *et al.* 1995) and InGaAs (Dehe *et al.* 1997) thermopiles were also investigated. Thin thermocouple membranes of AlGaAs on GaAs and InGaAs on InP were obtained by etchants with high selectivities.

3.04.7 Diode IRFPAs

Temperature-dependent characteristics of semiconductor devices sometimes bother circuit designers. They, however, can be used for temperature sensing and can be applied to uncooled IRFPAs. In fact, uncooled IRFPAs with diode temperature sensors have been successfully developed and IR cameras with some of these devices are commercially available now. We will discuss uncooled IRFPA technology with diode temperature sensors in this section.

3.04.7.1 Operation of Diode Thermal Infrared Detector

The forward-biased pn-junction diode has long been used as a temperature sensor. Assuming an ideal diffusion-limited characteristic and a sufficiently large forward-bias voltage V_F, the current I_F flowing in the diode is given by the following equation (Sze 1969):

$$I_F = A_J \mathcal{J}_S \exp\left(\frac{qV_F}{kT_D}\right) \quad [61]$$

$$\mathcal{J}_S = KT_D^{(3+\kappa/2)} \exp\left(-\frac{E_G}{kT_D}\right) \quad [62]$$

where A_J is the junction area, $\mathcal{J}_S$ is the saturation current, q is the magnitude of electronic charge, E_G is the bandgap energy, κ is a constant determined by the temperature dependence of the diffusion constant and carrier lifetime, and K is a temperature-independent constant.

When the diode is driven in a constant-current mode, the temperature sensitivity of V_F is expressed as follows.

$$\left.\frac{dV_F}{dT_D}\right|_{I_F=\text{const.}} = \frac{V_F}{T_D} - \left(3+\frac{\kappa}{2}\right)\frac{k}{q} - \frac{E_G}{qT_D} \quad [63]$$

dV_F/dT is insensitive to the process fluctuations because κ, a process-sensitive parameter, is included only in the second term of the right-hand side of eqn [63] and this term is negligible when compared with the other two terms. This feature ensures stable mass production of the diode uncooled IRFPAs. A typical forward bias condition of 0.6 V for a silicon diode gives a temperature sensitivity of about 2 mV K^{-1} at 300 K.

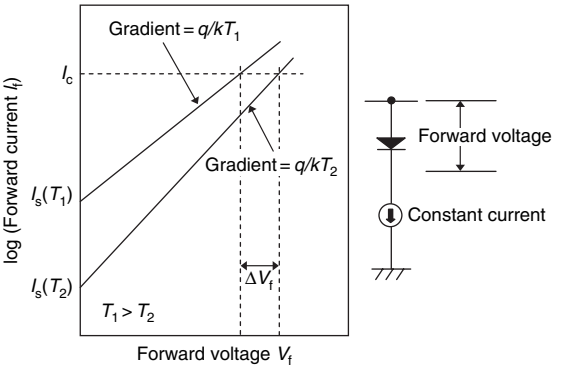

Figure 43 Operation of forward-biased diode thermometer. (Source: Kimata M, Ueno M, Takeda M, Seto T 2006 SOI diode uncooled infrared focal plane arrays. *Proc. SPIE* **6127**, 61270X-1–11.)

Figure 43 shows current–voltage characteristics of a diode for two different temperatures, explaining the operation of a diode thermometer. When the diode is operated in a constant-current mode, the forward voltage measured across the diode reflects the absolute temperature of the device. From this figure, the forward voltage is determined by $\mathcal{J}_S$, the intersection with the current axis, and the gradient q/kT_D. The dominant temperature dependence of $\mathcal{J}_S$ is derived from the exponential term in eqn [62]. The forward voltage becomes smaller as the temperature rises. In diode uncooled IRFPAs, the pixel-by-pixel difference of the forward voltage is displayed as the temperature difference.

The shot noise V_{SN} is a source of noise in the diode. It appears in statistical processes where electrical carriers flow over a potential barrier, and is given by the following equation (Ishikawa *et al.* 1999):

$$V_{SN} = \sqrt{2qI_F}\frac{dV_F}{dI_F} \quad [64]$$

In addition to the shot noise, we have to take into account the Johnson noise associated with the resistive component in the diode. In some cases, the $1/f$ noise might be one of the important noise sources.

3.04.7.2 Si Diode IRFPAs

A single-element IR detector with a polysilicon diode was reported in 1990 (Suzuki *et al.* 1990). This research is connected to the development of 16-element linear (Tanaka *et al.* 1992) and 16 × 16-element

2D (Asahi *et al.* 1992) uncooled IRFPAs with 400 μm × 400 μm pixels. **Figure 44** shows the schematic cross section of the polysilicon diode uncooled IRFPA. The diodes are made on a SiN membrane under which a cavity is formed by bulk micromachining with a polysilicon sacrificial layer. The IRFPAs integrate NMOS readout circuits, including pixel switches and shift registers. Although an image taken with 2D IRFPAs was demonstrated, preliminary results of these uncooled IRFPAs show a relatively low normalized detectivity of 6×10^5 cm $Hz^{1/2}$ W^{-1} and large fixed pattern noise (FPN) of ±20%.

Although the pixel structure with the polysilicon diodes can be fabricated with relatively simple process technology, this technology did not evolve further because of their poor performance. In its place, IR detectors with silicon single-crystal diodes were developed using back-accessed (Xu *et al.* 1993) and front-accessed (Reay *et al.* 1994) bulk micromachining processes.

Ishikawa *et al.* (1999) proposed another diode uncooled IRFPA. By using a silicon-on-insulator (SOI) wafer, they developed three freestanding pixel structures that contained single-crystal temperature-sensing diodes. **Figure 45(a)** shows a cross section of the original SOI diode pixel structure (type I) (Ishikawa *et al.* 1999, Kimata *et al.* 2006). As the figure illustrates, the pn-junction diodes are held over a cavity by two thin support legs. The thermal conductance of the support legs is designed to be as small as possible to obtain higher sensitivity. The support legs include electrical interconnections between the diodes and the readout circuits. Since the diode temperature sensor, the support legs, and the other components in the pixel have to be placed on the same level, only a small fraction of the area can be allocated to the freestanding effective IR-absorbing area if a single-level structure is employed. To overcome this problem, they devised a novel IR-absorbing structure that covers almost the entire pixel area. This IR-absorbing structure is an interference IR absorber that is used in other IRFPAs. It consists of a metal reflector, a dielectric film having a thickness that is 1/4 of the wavelength of interest, and an ultrathin metal film IR absorber. The IR-absorbing structure is thermally connected only to the freestanding diode structure with a high thermal conductance, and thus the temperature of the IR-absorbing structure is essentially the same as that of the diode structure. While conventional two-level microbolometer pixels have fill factors of around 60%, a 90% fill factor is feasible with this structure.

Although a useful sensitivity was obtained with the type I SOI diode pixel, it had a serious problem in the thermal time constant. Since the IR absorber of the type I pixel requires a thick dielectric layer to meet the tuning condition, this structure has a relatively long thermal time constant. An improved pixel structure shown in **Figure 45(b)** (type II) (Ishikawa *et al.* 2000, Kimata *et al.* 2006) was developed in order to reduce the thermal time constant. In this structure, the reflector is removed from the IR-absorbing structure, and moves to the lower level, and a vacuum gap between the thermal absorber and the reflector is used as a part of the dielectric layer in the interference IR-absorbing structure. This structure makes it possible to thin the thermal absorber to a thickness suitable for mechanical considerations.

The type II SOI diode pixel works well for relatively large pixels around 40–50 μm square, though a serious problem arises with this pixel structure when we reduce the pixel size. IR energy falling on a pixel

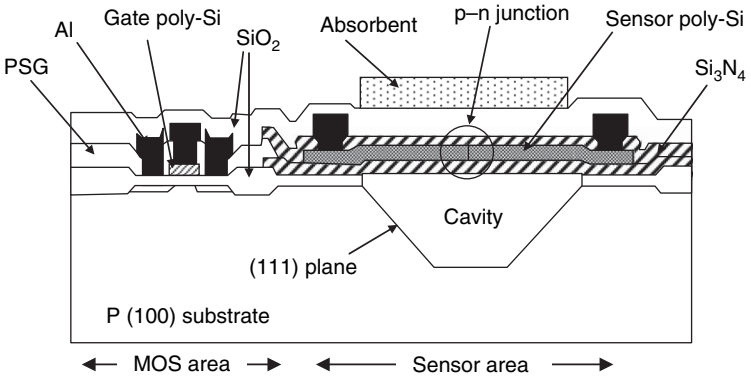

Figure 44 Polysilicon diode uncooled infrared focal plane array (IRFPA) pixel. (Source: Reprinted from *Infrared Phys.*, **33**, Tanaka A *et al.*, Infrared linear image sensor using a poly Si pn junction diode array, 229–36, Copyright (1992), with permission from Elsevier.)

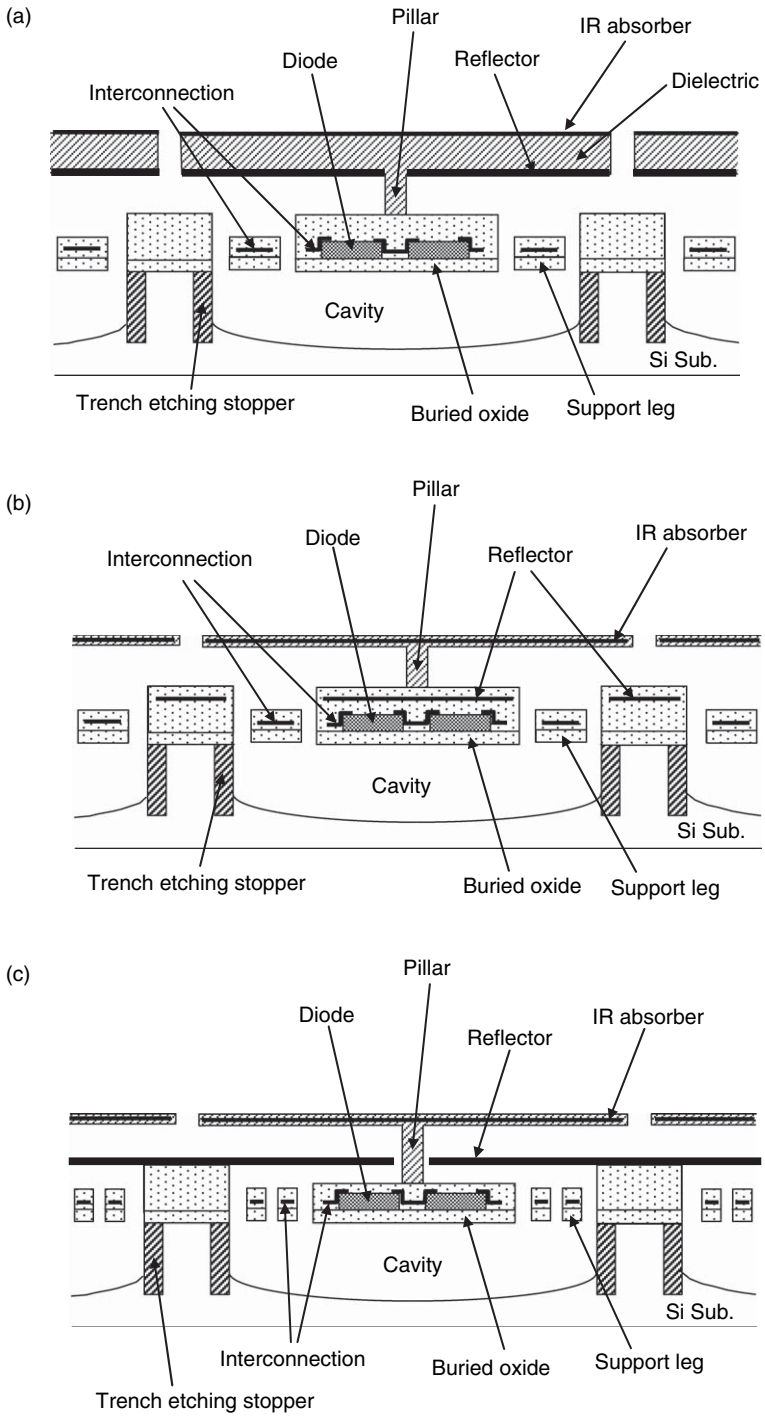

Figure 45 Three types of silicon-on-insulator (SOI) diode uncooled infrared focal plane array (IRFPA) pixels. (Source: Kimata M, Ueno M, Takeda M, Seto T 2006 SOI diode uncooled infrared focal plane arrays. *Proc. SPIE* **6127**, 61270X-1–11.)

is proportional to the pixel size, as discussed in Section 3.04.5. We, therefore, have to reduce the thermal conductance in designing small pixels if the sensitivity degradation is not acceptable. Lower thermal conductance claims more area in a pixel due to the need for longer support legs. As can be expected, the support leg area does not work as a perfect reflect or because of the slits around the

support legs, and thus reduces IR absorption. Together, these make it difficult for us to design smaller pixels with high sensitivity. Thus, a third SOI diode pixel structure shown in **Figure 45(c)** (type III) (Kimata *et al.* 2006, Kosasayama *et al.* 2004) was proposed. This pixel has an independent metal reflector between the IR absorber and the lower structure that includes the diode structure. The thermal properties of the pixel are not affected by adding this reflector structure because the reflector does not thermally connect with the IR absorber or diode structure. Since removing the reflector from the diode structure reduces the heat capacity, the type III SOI diode pixel structure offers a shorter thermal time constant than does the type II pixel structure if the thermal conductance of the two structures is the same.

The fabrication process for the SOI diode uncooled IRFPA includes bulk and surface micromachining processes (Kimata *et al.* 2006, Nakaki *et al.* 2003). It is clear that the full dry MEMS process is indispensable for fabricating the fragile structures discussed in Section 3.04.6 because the sticking problem drastically reduces the production yield if wet MEMS processes are employed. Two full dry MEMS processes have been developed for the SOI diode uncooled IRFPA. One is a single sacrificial layer process for the pixel structures of types I and II, the other a double sacrificial layer process for the pixel structures of type III.

Figure 46 illustrates a MEMS process for the type III SOI diode pixel. After completion of the process for CMOS circuits and temperature-sensing diodes, the first organic sacrificial layer is spin-coated and

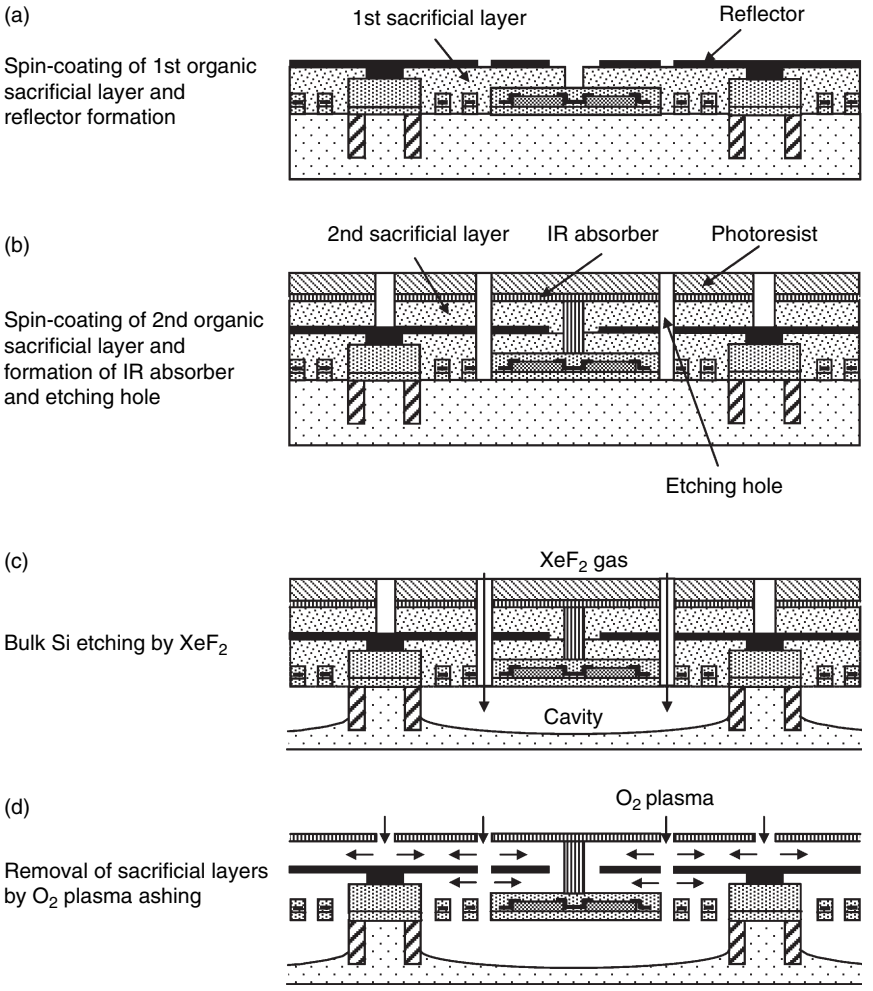

Figure 46 Fabrication process for multilevel silicon-on-insulator (SOI) diode uncooled infrared focal plane array (IRFPA) pixel. (Source: Kimata M, Ueno M, Takeda M, Seto T 2006 SOI diode uncooled infrared focal plane arrays. *Proc. SPIE* **6127**, 61270X-1–11.)

hardened by baking. A very flat surface is obtained with spin coating if we choose proper materials and suitable process conditions. A part of the sacrificial layer is removed in order to form anchors of the reflector to the substrate structure. **Figure 46(a)** shows the structure just after patterning of the metal reflector on the first organic sacrificial layer. The second sacrificial layer is then spin-coated, and the IR absorber is formed on it. Following IR absorber formation, etching holes for the bulk silicon etching are opened through the IR absorber and two sacrificial layers (**Figure 46(b)**). After that, bulk silicon etching by XeF_2 is performed (**Figure 46(c)**). XeF_2 etching is a dry etching process in which the etching proceeds isotropically. Therefore, a deep trench-etching stopper surrounding the pixel cavity is needed to avoid the connection between neighboring cavities. In this case the buried oxide of the SOI substrate plays the role of etching stopper to protect the SOI diodes during the XeF_2 etching process. Finally, as shown in **Figure 46(d)**, all organic layers, including the two sacrificial layers and the photoresist for etched-hole formation, are removed by the final O_2 plasma ashing process. It is important to note that the XeF_2 etching process is not the final process, but is done before the sacrificial layer etching. By this process flow, XeF_2 gas enters from only the central area of the cavity, enlarging the etching margin.

Figure 47 shows a SEM photograph of a type II SOI diode pixel array fabricated by the single sacrificial layer process, in which both surface and cross-sectional structures can be observed. The pixel size is 40 μm square, and the IR absorber covers 90% of the pixel area. A 25-μm-square pixel has successfully been fabricated with the double sacrificial layer process. An example of the lower part of the three-level structure is shown in **Figure 48(a)**. Two long meandering support legs effectively reduce the thermal conductance down to $1 \times 10^{-8}\,\mathrm{W\,K^{-1}}$. **Figure 48(b)** shows a close-up photograph near the IR absorber pillar.

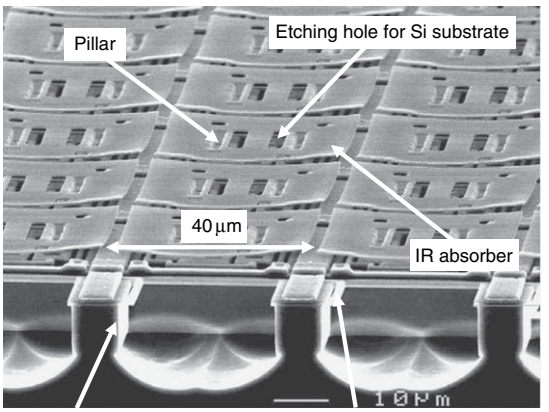

Figure 47 Scanning electron microscope (SEM) photograph of double-level silicon-on-insulator (SOI) diode uncooled infrared focal plane array (IRFPA) pixels, showing cross-sectional structure and infrared absorber covering pixel. (Source: Kimata M, Ueno M, Takeda M, Seto T 2006 SOI diode uncooled infrared focal plane arrays. *Proc. SPIE* **6127**, 61270X-1–11.)

Figure 49 shows a block diagram of the SOI diode uncooled IRFPA. The temperature-sensing diodes are active in a forward-biased condition. This design eliminates the selection switch in the pixel because unselected diodes are reverse-biased and are automatically cut off from the signal line. Each column has a gate modulation integrator for signal amplification and bandwidth restriction. The output from a pixel connects to the gate of an integration MOS transistor, which discharges the charge at an integration capacitor. The pixel diodes are biased row by row during a horizontal period. One integration time starts from a horizontal blanking period and ends at the next blanking period. After integration during one horizontal period, the voltages at the integration capacitors are transferred to sample-and-hold capacitors and are read out through an on-chip amplifier. Since the circuits for readout operation need a relatively high voltage, they are fabricated not on the SOI layer but on the bulk silicon.

Several SOI diode uncooled IRFPAs listed in **Table 2** have been reported. While the first two 320×240-element IRFPAs with 40-μm and 28-μm-square pixels employ the type II pixel structure, the type III pixel structure is applied to the IRFPAs with 25-μm-square pixels. Despite pixel size reduction, the sensitivity has been drastically improved in two IRFPAs with 25-μm-square pixels. The NETD achieved with 25-μm-square SOI diode pixels is better than 50 mK with $f/1.0$ optics (Ueno *et al.* 2005). The sensitivity improvement became possible mainly due to the reduction in the thermal conductance. Examples of thermal images taken with a 25-μm 640×480 SOI diode uncooled IRFPA are shown in **Figure 50**.

The other uncooled IRFPA with single-crystal silicon diodes was developed using the electrochemical etch-stop process technology (Eminoglu *et al.* 2002). While the SOI diode uncooled IRFPA requires some dedicated processes in the pre-MEMS process, the pixel of this uncooled IRFPA is realized

by a standard CMOS process and post-CMOS etching steps. A maskless post-CMOS process becomes possible by making required etch openings to reach the silicon substrate with dry etching process while CMOS metal layers are used as protection mask. A 128×128-element uncooled IRFPA with 40-μm-square pixels was reported with the CMOS-compatible single-crystal diode technology. Using a

Figure 50 Examples of thermal images with 640 × 480 silicon-on-insulator (SOI) diode uncooled infrared focal plane array (IRFPA). (Source: Kimata M, Ueno M, Takeda M, Seto T 2006 SOI diode uncooled infrared focal plane arrays. *Proc. SPIE* **6127**, 61270X-1–11.)

0.35-μm CMOS foundry process, a fill factor of 44% and thermal conductance of 1.8×10^{-7} W K^{-1} were achieved (Eminoglu *et al.* 2003). As a single-diode pixel design yields a relatively low sensitivity, an NETD of 1 K is expected for the current design of these IRFPAs.

Murguia *et al.* (1999) proposed a Schottky-barrier diode bolometer named the thermoionic thermal detector. The sensing mechanism of their device is the modulation of Schottky diode dark current (the reverse current) with temperature. The operating temperature depends on the barrier height, and thus this detector needs some cooling if a Schottky diode having lower barrier height is used. Although there are no operating thermoionic thermal detector devices reported so far, a simulation shows that the thermoionic thermal detectors optimized for operation at room temperature have a 6% per Kelvin temperature coefficient and have a potential of achieving an NETD of 6 mK (Murguia *et al.* 1999).

3.04.8 Bimaterial and Thermo-Optical IRFPAs

All the thermal detectors discussed above are based on operation mechanisms that convert the change in temperature to some electrical outputs. Old technology, however, teaches us that we can use mechanisms in which some mechanical displacements occur due to the temperature change. Microcantilever structures constructed from materials exhibiting dissimilar thermal expansion properties can be used to detect visible and IR radiation. A feasibility study of this concept was performed by Oden *et al.* (1996). They made use of commercially available piezolever for electrical deflection monitoring and atomic force microscope (AFM) probe tips for optical deflection monitoring, and found that the former microcantilever has an NETD of 90 mK and the latter has a D^* of 3.6×10^7 cm Hz$^{1/2}$ W^{-1}.

Amantea *et al.* (1997) and Wang *et al.* (2006) extended the microcantilever optical detector concept and proposed a bimaterial uncooled IRFPA in which mechanical displacement of a freestanding structure due to temperature change is detected as capacitance change. **Figure 51** explains the operation

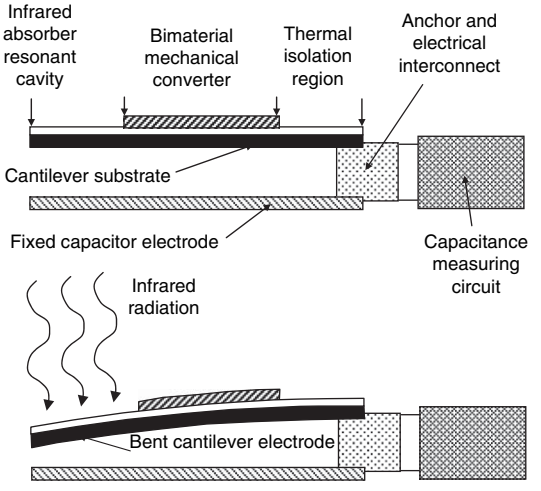

Figure 51 Operation of bimaterial uncooled infrared focal plane array (IRFPA) with electrical readout. (Source: Hunter S R, Amante R A, Goodman L A, Kharas D B, Gershtein S, Matey J R, Perna S N, Yu Y, Maley N, White L K 2003 High sensitivity uncooled microcantilever infrared imaging arrays. *Proc. SPIE* **5074**, 469–80.)

mechanism of the bimaterial thermal IR detector with capacitive readout (Hunter *et al.* 2003). The detector consists of three elements: the IR-absorbing element, the bimaterial element, and the thermal isolation support element. The bimaterial element is made of two thin films that have different thermal expansion coefficients. The IR-absorbing element absorbs the IR radiation and coverts it to heat, raising the temperature of the IR-absorbing element and the bimaterial element. Since two layers in the bimaterial element adhere to one another, they must expand by equal amounts, and tensile stress builds up in one film having a smaller thermal expansion coefficient while compressive stress builds up in the other film with a larger thermal expansion coefficient. Thus, the stress gradient across the bimaterial element developed by IR radiation causes the bimaterial element to bend, and as a result, causes the change in the electrical capacity between the cantilever electrode and the fixed electrode. They tried two bimaterial pairs; one is a SiC/Al pair and the other is a SiC/Au pair. In both case, amorphous hydrogenated SiC was used because it has a low thermal expansion coefficient (4×10^{-6} per Kelvin) when compared to Al and Au, and has a lower thermal conductivity ($0.35\ \mathrm{W\,m^{-1}\,K^{-1}}$) when compared to other dielectric materials used in Si-LSI processes.

Figure 52 shows a cross-sectional structure and pattern layout of the pixel that uses the SiC/Al bimaterial structure. A simulation shows that the SiC/Al bimaterial with a thickness of 0.2 μm and length of 50 μm exhibits a mechanical sensitivity of $0.18\ \mu\mathrm{m\,K^{-1}}$, resulting in an electrical (capacitance) sensitivity of 36% per Kelvin if the initial gap is 0.5 μm. Since the electrical sensitivity in this device corresponds to TCR for the resistance bolometer, the typical value of which is a few percent per Kelvin for semiconductor bolometers, the bimaterial uncooled IRFPA is expected to have higher sensitivity than the resistance bolometer uncooled IRFPAs. The NETD of the bimaterial uncooled IRFPA with 50-μm-square pixels was estimated as 5 mK with $f/1.0$ optics. After proposal of the bimaterial uncooled IRFPA, considerable efforts were made to overcome various problems, such as material stress control, anchor formation, sacrificial materials and release process, IR absorber design, vibration caused by a pulse readout operation (Amantea *et al.* 1998). Although the predicted performance was appealing, the best NETD measured with a 320×240-element bimaterial uncooled IRFPA with 50-μm-square pixels was 1.8 K, and the NETD and its distribution depend on the operating temperature (Amantea *et al.* 1997). Despite the disappointing results obtained until now, the development of uncooled IRFPAs based on this bimaterial concept is being continued by another group (Hunter *et al.* 2006).

The bimaterial deflection can also be measured optically. Several optical techniques to measure the individual pixel deflection have been proposed (Datskos *et al.* 2000, Ishizuya *et al.* 2001, Zhao *et al.* 2003). Ishizuya *et al.* (2001) developed a

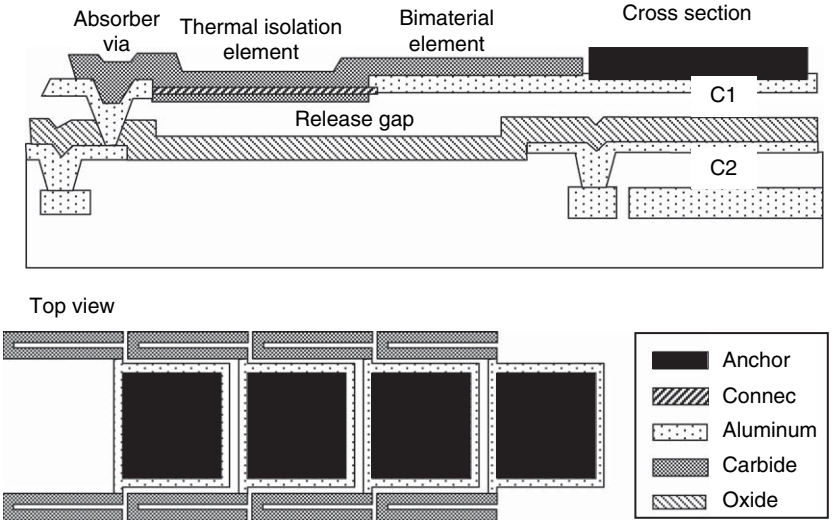

Figure 52 Pixel of bimaterial uncooled infrared focal plane arrays (IRFPAs). (Source: Amantea R, Knoedler C M, Pantuso F P, Patel V K, Sauer D J, Tower J R 1997 An uncooled IR imager with 5 mK NETD. *Proc. SPIE* **3061**, 210–22.)

266 × 194-element optical readout bimaterial uncooled IRFPA with 55-μm-square pixels. The pixel structure and schematic diagram of the optical readout system are depicted in **Figure 53**. The optical readout eliminates the metal interconnection between the freestanding thermometer and the readout circuit on the substrate, and simplifies the pixel structure and manufacturing process. In this IRFPA, IR rays are irradiated from the back of the IRFPA. The backside illumination is possible because silicon is almost transparent in the wavelength range of interest. IR energy absorbed in the IR absorber elevates the temperature of the IR absorber and the bimaterial beam, and deflects the bimaterial beam in the same way as bimaterial uncooled IRFPA with capacitance readout. To measure the deflecting angle of the bimaterial structure, a probe visible light beam is irradiated from the front side. The probe light is reflected back by the bimaterial pixels, passes through a pinhole, and is eventually imaged on a visible CCD. If the IRFPA is exposed to a uniform background, the fraction of reflected light that passes through the pinhole is the same for all the pixels. On the other hand, when the intensity of the incident IR radiation is not uniform across the IRFPA, the reflected light intensity passing through the pinhole becomes different pixel by pixel, reflecting the deflecting angle of the bimaterial structure. Thus, CCD reproduces the IR image falling on the IRFPA as visible light gray-scale image. If the CCD is replaced by a human eye, direct viewing of IR images is possible with this type of IRFPA.

Zhao *et al.* (2003) also developed an optical readout bimaterial uncooled IRFPA. Although the IRFPA has basically the same structure as that developed by Ishizuya and coworkers, they devised a different readout technique. Their readout technique requires a laser probe light source, and relies on the local interference between light scattered by the pixel edge and that scattered by the substrate. They reported that a 300 × 300-element optical readout bimaterial IRFPA with 65-μm-square pixels exhibited an NETD of 200 mK with $f/1.0$ optices and a 10-Hz frame rate.

Optical readout for uncooled IRFPAs without mechanical movement is also possible. Examples of such IRFPAs are devices that use a temperature-sensitive Fabry–Perot tunable optical filter (Flusberg and Deliwala 2006, Wu *et al.* 2005) and an electrooptical crystal operated in the paraelectric phase (Secundo *et al.* 2005). The former (Wu *et al.*

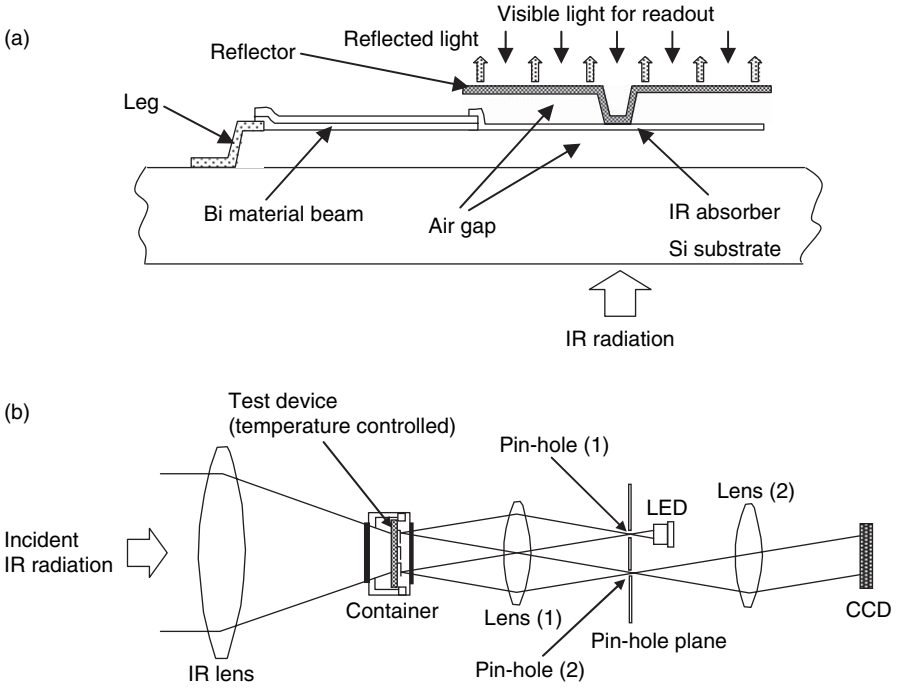

Figure 53 Bimaterial uncooled infrared focal plane array (IRFPA) with optical readout. (a) Shows the pixel structure; and (b) illustrates the readout scheme. (Source: Ishizuya T, Suzuki J, Akagawa K, Kazama T 2001 Optically readable bi-materials infrared detector. *Proc. SPIE* **4369**, 342–9.)

2005) is explained in detail here. Changing the index of refraction of filter materials with temperature gives the narrow band optical filter wavelength tunability. They developed a temperature-sensitive tunable filter using amorphous silicon and silicon nitride, and found that it has a thermo-optical coefficient (the differential temperature dependence of the refraction index) of $2.3 \times 10^{-4}\,\mathrm{K}^{-1}$ at 300 K and a tunability of $0.06\,\mathrm{nm\,K}^{-1}$. The FPA is simply constructed by arranging thermally isolated small filters on a substrate that is transparent in the near-IR wavelength region. **Figure 54** is a schematic illustration of an IR camera system with this optical readout uncooled IRFPA. IR image focused on the IRFPA produces a temperature distribution in the pixel array, depending on the intensity distribution of the IR image. A CCD or CMOS image sensor captures near-IR images through the IRFPA that is generated by a near-IR probe light introduced by a beam. The sensitivity is maximized when the emission spectrum of the probe light is narrower than the filter transmission spectrum and its peak wavelength is located at the wavelength at which the transmission spectrum has the largest gradient. A hexagonal-arranged 160×120-element IRFPA was developed with 50-μm pitch tunable filters supported by hollow post structures. This IRFPA exhibited an NETD of 280 mK at $f/0.86$ optics and 20-Hz frame rate.

3.04.9 Conclusions

IR imaging started with mechanical scanning systems, in which single-element detectors or small-format linear arrays cover all the field of view by moving the line of sight in X and Y directions. Such systems required IR detectors having a high responsivity and a fast response speed. Therefore, thermal IR detectors did not find their place in mechanical scanning IR imaging systems. Quantum IR detectors were the inevitable choice. Evolution from mechanical scanning systems to electrical scanning systems enabled the full-frame integration operation for IRFPAs, and thus alleviated the requirements for responsivity and response speed. This shift shed light on quantum IR detectors with low quantum efficiencies, such as Si-based and GaAs-based IR detectors, for their capability of large-scale

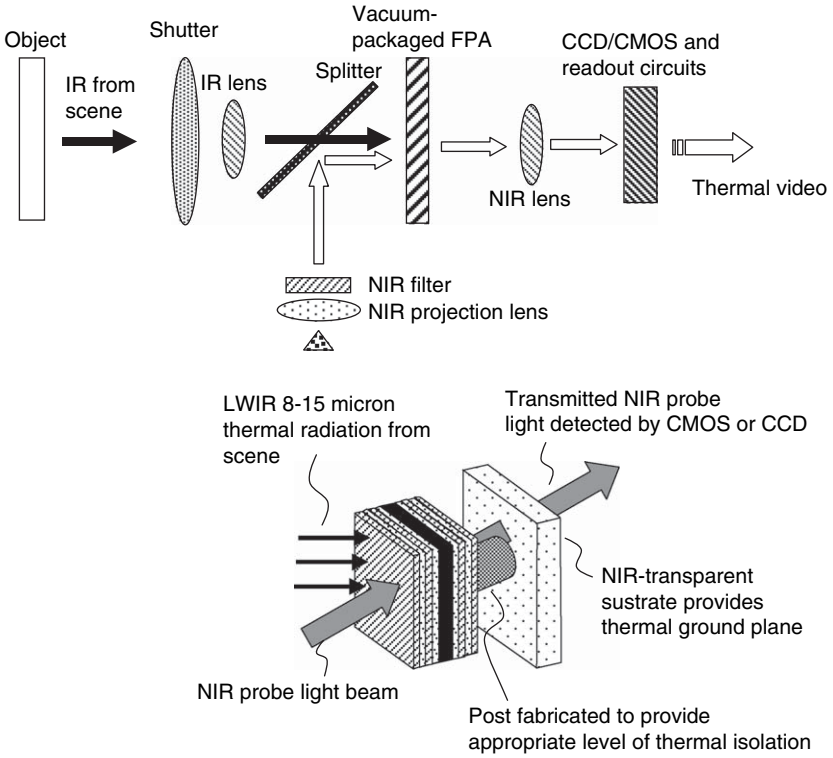

Figure 54 Thermo-optical uncooled infrared focal plane array (IRFPA) based on temperature-sensitive narrowband near-infrared (IR) filter. (Source: Wu M, Cook J, Vito R D, Li J, Ma E, Murano R, Nemchuk N, Tabasky M, Wagner M 2005 Novel low-cost uncooled infrared camera. *Proc. SPIE* **5783**, 496–505.)

integration and high uniformity. It also activated development of uncooled IRFPAs with thermal detectors.

MEMS technology, which made remarkable progress in the 1980s and in the beginning of the 1990s, accelerated performance improvement of the uncooled IRFPAs and made it possible to manufacture microbolometer uncooled IRFPAs with an NETD of <100 mK at $f/1.0$. In the uncooled IRFPAs, the MEMS technology has played an important role to break through the limitation of the thermal conductance in the hybrid structure based on the bump-bonding technology that had been used before the MEMS era. The thermal conductance achievable by the MEMS technology is one to two orders of magnitude smaller than those by the hybrid technology. The first-generation uncooled IRFPAs had pixel sizes around 50 μm square and array sizes from 160 μm × 120 μm to 320 μm × 240 μm. Currently, advanced technology for uncooled IRFPAs has reached a level that achieves NETDs of <50 mK at $f/1.0$ with pixel sizes from 25 μm square to 20 μm square. Such technology has also enabled large-scale integration up to 640 × 480 pixels. Those second-generation uncooled IRFPAs have more complicated pixel structures and/or finer design rules that require more sophisticated MEMS fabrication technology, and importance of MEMS technology is growing.

Although more than 10 years have passed since uncooled IRFPA development became active, various types, including resistance bolometer, pyroelectric, ferroelectric bolometer, thermoelectric, and diode uncooled IRFPAs, are still being used with distinct advantages. The next high-end target seems to be megapixel uncooled IRFPAs with pixels smaller than 20 μm square that have NETDs of around 10 mK at $f/1.0$. On the other hand, low-end markets need uncooled IR cameras whose prices are less than $1000. It is difficult to forecast the future of uncooled IRFPAs, but several technologies will survive in response to diverse demands from various application sectors.

Biography

Masafumi Kimata received his BS and MS degrees in electronic engineering from Nagoya University in 1974 and 1976, respectively, and received his Ph.D. degree in faculty of engineering science from Osaka University in 1992. He joined Mitsubishi Electric Corporation in 1976, where he was involved in the research and development of silicon-based infrared focal plane arrays, including Schottky-barrier cooled infrared focal plane arrays and SOI diode uncooled focal plane arrays. In 2004, he retired from Mistubishi Electric, and presently, he is a professor of Ristumeikai University, where he continues his research on MEMS-based uncooled infrared focal plane arrays. He was awarded the Prime Minister Prize of the Japan National Invention Awards in 1993 for the invention of high-resolution Schottky-barrier infrared focal plane arrays. He has been serving as a program committee member of SPIE's conference on Infrared Technology and Applications since 1992. He is a fellow member of SPIE.

Nomenclature

a_{TE}, a_{TM}	Asymmetry parameters	**D**	Electric flux density of optical wave
$A(z)$, $B(z)$	Amplitudes of coupled waves	**E**	Electric field of optical wave
b	Normalized propagation constant	E^e_z	External electric field amplitude
c	Light velocity in vacuum	f	Surface acoustic wave frequency
		$g(z)$	Output field profile function

$h(z)$	Input field profile function	V	Normalized waveguide thickness (normalized frequency)
H	Magnetic field of optical wave	W	Waveguide width
h	Grating groove depth	α_r, $\alpha_q^{(i)}$	Radiation decay factors
$I(g,h)$	Overlap integral	β	Propagation constant
j	Imaginary unit	β	Optical wave vector
k	Wave number of optical wave	γ_a, γ_c	Evanescent factors
K	Wave number of periodic structures	$\delta_{mm'}$	Cronecker's delta
K	Grating vector of periodic structures	$\delta(x)$	Dirac's delta function
L	Device length or coupling (interaction) length	$\delta\lambda$	Wavelength deviation
		Δ	Phase mismatch parameter
L_c	Complete coupling length	$\Delta\beta$	Propagation constant deviation
m	Mode number	ε_0	Dielectric permittivity of vacuum
N	Effective index of refraction (mode index)	$[\varepsilon]$	Dielectric tensor
		$\varepsilon(x,y)$	Relative dielectric permittivity profile
N_I, N_{II}	Effective indexes	θ	Incidence angle
$n(x,y)$	Refractive index profile	θ_B	Bragg angle
n_e	Extraordinary refractive index	η	Coupling efficiency or diffraction efficiency
n_o	Ordinary refractive index		
$P_q^{(i)}$	Power distribution ratio	κ	Coupling coefficient
[p]	Photoelastic tensor	κ_c	Lateral wave number
P_s	Surface acoustic wave power	κ_{SHG}	Nonlinear optic coupling coefficient (SHG coupling coefficient)
q	Order of coupling or diffraction		
Q	Grating thickness parameter	λ	Optical wavelength in vacuum
[r]	Electrooptic (Pockels) tensor	Λ	Period of periodic structures
S	Complex Poynting vector	μ_0	Magnetic permittivity of vacuum
[S]	Strain tensor	Φ_a,Φ_s	Phase shifts associated with the total internal reflection
T	Waveguide of thickness		
[T]	Stress tensor	$\Phi(y,z)$	Phase distribution function
v	Velocity of surface acoustic wave	ω	Angular frequency of optical wave

3.05.1 Introduction

Optical techniques using coherent laser light combined with electronic techniques offer tremendous possibilities for applications in wide-ranging areas of storing, transmitting, processing, and sensing of information. Although optical setups and instruments consisting of conventional optical elements may be used in laboratories, they are not suitable for practical use in industries, offices, and consumers' lives. Compact optical systems can be developed by miniaturizing conventional elements such as lenses, prisms, and mirrors and assembling them to construct a module for a specific application. An example of such systems, called microoptics, is optical disk pickup heads, which are now widely used in CD and DVD systems. It is hoped that further integration of optical components, or realization of optical analog of electronic integrated circuits (ICs) and large-scale integrations (LSIs), would significantly enhance the possibilities of applications.

The concept of integrated optics (IO) was proposed based on such an idea (Miller 1969, Shubert and Harris 1968). IO uses optical waveguides as the fundamental structure to confine coherent optical waves. Various active and passive optical components are realized in the waveguide, and they are integrated to construct a device of higher function for a specific application (Coldren and Corzine 1995, Lifante 2003, Murphy 1999, Nishihara *et al.* 1989, Tamir 1975, 1988). The resultant devices are called IO devices, integrated photonic (IP) devices, optical integrated circuits (optical ICs), and photonic integrated circuits (photonic ICs). Devices consisting of optical and electronic components are called optoelectronic integrated circuits (OEICs). Although these terms are used with selection often being based

on the features to be emphasized, the nomenclature is not necessarily clear. They may be classified under microoptics in a broader sense.

The IO technologies has several advantages and outstanding features:

(1) Properties of guided waves can be used to realize components and devices based on new working principles different from those of bulk devices and to achieve higher performances.
(2) High performances, in terms of a high conversion efficiency, a low driving power (voltage), or a high speed, can be obtained for each component, as optical field is confined in narrow waveguides, and the electric (or other) fields for control are concentrated in a narrow space.
(3) The devices are compact and robust and are of low weight, and they do not require critical alignments, as these devices are rugged solid-state structures.
(4) Advanced functions can be achieved by integrating large number of components or different functions of components.
(5) The devices can be mass-produced by the cost-effective planar lithographic fabrication technologies.

Although it took rather a long time, various IO devices were developed in several areas of applications, and many IO devices have been commercialized and put into practical use. The application of IO covers almost all areas of information technology, i.e., optical signal processing, optical communications, optical memories, optical interconnection, and displays. Another important area is optical sensing. A number of components, devices, modules, and systems have been developed. Practical devices include integrated laser light sources, optical modulators, switches, attenuators, filters, wavelength multi/demultiplexers, and integrated receivers for optical network; IO disk pickup heads; and IO interferometer displacement sensors.

This chapter presents an outline of the IO technologies. After discussing theoretically the fundamental characteristics of optical waveguides and coupling of guided waves, passive and active components in waveguides are presented. Then examples of IO devices and their applications are presented to highlight the IO technology including the recent R&D activities.

3.05.2 Optical Waveguides

Optical waveguides are the fundamental structure for the implementation of IO devices. This section describes the concept and the basic characteristics of the waveguides by using simple models (Marcuse 1974, Snyder and Love 1983). Although many waveguides used for IO are prepared in anisotropic crystals, isotropic materials are assumed for simplicity in the theoretical discussions.

3.05.2.1 Waveguide Structures and Optical Waves

Optical waveguides are structures to confine and guide optical waves by the total internal reflection (TIR) at dielectric interfaces. They are classified into planar waveguides (slab waveguides) (**Figure 1(a)**) and channel waveguides (**Figure 1(b)**). Planar waveguides for confinement of optical field in a guiding layer can easily be fabricated and are used as a simple model for discussing the waveguide characteristics. Channel waveguides for 3D confinement are more suitable for implementation of many IO devices. It is required that the refractive index of the guiding (core) region be higher than that of the surrounding (cladding) region. In ray optics, the waveguiding can simply be interpreted in terms of the zigzag pass of the ray at an angle greater than the critical angle, representing successive TIRs at the core/cladding interfaces (**Figure 2**). However, wave optics analysis is required to clarify the important waveguide characteristics.

The wave optics analysis can be made based on the electromagnetic theory using Maxwell's equations (Marcuse 1974, Nishihara *et al.* 1989, Snyder and Love 1983). We consider optical waves of angular

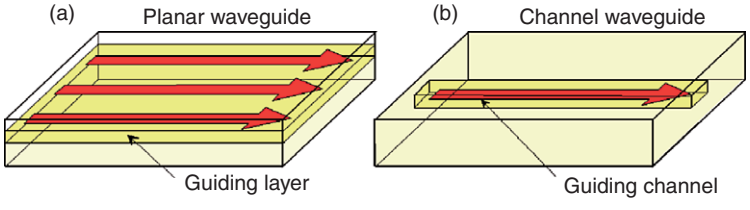

Figure 1 Schematic of optical waveguides.

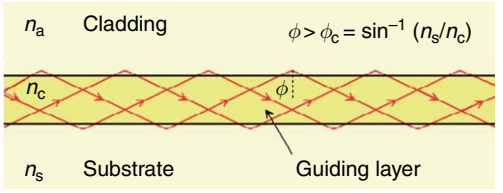

Figure 2 Ray optics presentation of optical waveguiding.

frequency ω. The complex descriptions $\mathbf{E}$ and $\mathbf{H}$ are used for the electric and the magnetic field, respectively, and the time-dependent factor $\exp(j\omega t)$ is omitted.

A lossless waveguide structure, in general, can be described by the distribution of relative permittivity ε over the cross-section. Taking the z-axis of the coordinate system along the waveguide (propagation) axis, the distribution can be written as $\varepsilon = \varepsilon(x,y) = [n(x,y)]^2$, where $n(x,y)$ is the refractive index profile. The fields of optical waves in the structure may be written as

$$\begin{aligned}\mathbf{E}(x,y,z) &= \mathbf{E}(x,y)\exp(-j\beta z),\ \mathbf{H}(x,y,z)\\ &= \mathbf{H}(x,y)\exp(-j\beta z)\end{aligned} \quad [1]$$

where β denotes the propagation constant, and β is often displayed as a wave vector β along the propagation axis. Substituting eqn [1] into Maxwell's equations and eliminating H yield a wave equation:

$$\left[\nabla_t^2 + \left\{k^2 n^2(x,y) - \beta^2\right\}\right]\mathbf{E}(x,y) = 0 \quad [2]$$

where $\nabla_t = (\partial/\partial x, \partial/\partial y, 0)$ is a transverse differential operator, $k = \omega(\varepsilon_0\mu_0)^{1/2} = \omega/c = 2\pi/\lambda$ is the wave number, c the velocity of light, and λ the wavelength in vacuum. The above equation is valid for cases where the medium is homogeneous ($\nabla\varepsilon = 0$) in sections and is valid approximately under an assumption of $\nabla\varepsilon \cong \mathrm{O}$ The propagation constant can be written as

$$\beta = Nk \quad [3]$$

where N is the effective index of refraction or mode index.

Among many solutions of eqn [2] with appropriate boundary conditions are those such that $\mathbf{E}(x, y)$ is large near the waveguide axis and decays to 0 away from it, called guided modes, as they give optical waves that are confined in the waveguide and propagate along the axis. There are a limited number of guided modes, and they are characterized by discrete mode profiles $\mathbf{E}(x, y)$ and $\mathbf{H}(x, y)$ with discrete propagation constants. Solutions such that $\mathbf{E}(x, y)$ does not decay with the distance from the axis are called radiation modes, as the optical wave radiates far away from the axis. There are an infinite number of radiation modes, and they are characterized by continuous mode profiles and propagation constants.

An important property of optical waves in a waveguide is mode orthogonality, which can be deduced from Maxwell's equations. Let the two modes in a waveguide be $\{\mathbf{E}_m, \mathbf{H}_m\}$ and $\{\mathbf{E}_{m'}, \mathbf{H}_{m'}\}$. The power flow of a mode is given by the integral over the cross section of the real part of the z component of the complex Poynting vector $\mathbf{S} = (1/2)\mathbf{E} \times \mathbf{H}^*$. It is convenient to normalize the field so as to have unity power flow. Then the orthonormal relation for guided modes is given by

$$\iint \mathrm{Re}\left(\frac{\mathbf{E}_{tm} \times \mathbf{H}^*_{tm'}}{2}\right)\mathrm{d}x\,\mathrm{d}y = \pm\delta_{mm'} \quad [4]$$

where $\delta_{mm'} = 0$ for $m \neq m'$, $\delta_{mm'} = 1$ for $m = m'$, and the plus and minus signs in the RHS represent the forward ($\beta_m > 0$) and backward ($\beta_m < 0$) modes, respectively. For radiation modes, the Cronecker's δ in the RHS of eqn [4] should be replaced by Dirac's δ function. The modal fields also possess the completeness, which means that an arbitrary field can be expressed in the form of a series expansion using modal fields.

3.05.2.2 Planar Waveguides

The simplest model of waveguides is a planar waveguide of thickness T with a step index profile as shown in **Figure 3(a)**. The index distribution is given by

$$n(x,y) = n(x) = \begin{cases} n_a, & (0 < x) \\ n_c, & (-T < x < 0)\ (n_c > n_s > n_a) \\ n_s, & (x < -T) \end{cases} \quad [5]$$

where n_a, n_c, and n_s are the refractive indexes of the (upper) cladding layer, guiding (core) layer, and lower cladding layer (substrate), respectively. It can be shown from Maxwell's equations that the modes in the planar waveguide structure can be classified into two polarization modes.

3.05.2.2.1 Transverse electric modes

One of the polarization modes is transverse electric (TE) modes, where the electric field has the transverse component E_y only and $E_x = E_z = 0$. The

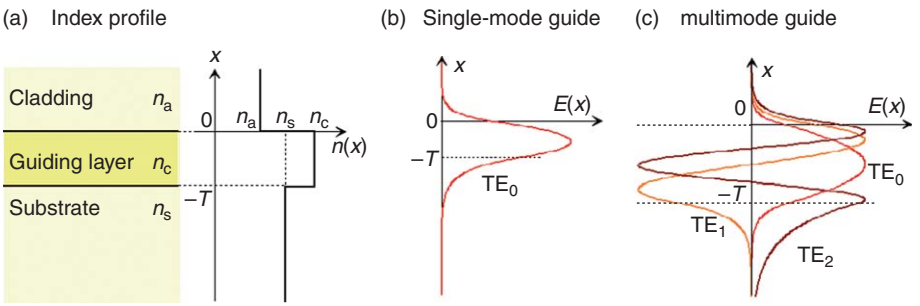

Figure 3 Planar waveguide of step index distribution and the mode field profiles. TE, transverse electric.

dominant field components $E_y(x)$ satisfies a wave equation

$$\left[\frac{d^2}{dx^2} + \left\{k^2 n^2(x) - \beta^2\right\}\right] E_y(x) = 0 \qquad [6]$$

and the magnetic field is given by $H_x = (-\beta/\omega\mu_0)E_y$, $H_z = (\mathrm{j}/\omega\mu_0)\,(dE_y/dx)$, and $H_y = 0$.

The guided mode solution of eqn [6] can be written as

$$E^y(x) = \begin{cases} E_a \exp\{-\gamma_a x\} & (0 < x) \\ E_c \cos\{\kappa_c x + \Phi_a\} & (-T < x < 0) \\ E_s \exp\{+\gamma_s(x+T)\} & (x < -T) \end{cases} \qquad [7]$$

where E_a, E_c, and E_s are constants and

$$\gamma_a = k\sqrt{N^2 - n_a^2}, \gamma_s = k\sqrt{N^2 - n_s^2}, \kappa_c = k\sqrt{n_c^2 - N^2} \qquad [8]$$

It should be noted that for guided modes the mode index N is in $n_s < N < n_c$. Using the continuity of $E_y(x)$ and $H_z(x)$, required by the boundary conditions at $x = 0$, T, we obtain a characteristic equation:

$$\begin{aligned} &\kappa_c T - \Phi_a - \Phi_s = m\pi \,(m = 0, 1, 2, \cdots) \\ &\Phi_a = \tan^{-1}\left(\frac{\gamma_a}{\kappa_c}\right), \Phi_s = \tan^{-1}\left(\frac{\gamma_s}{\kappa_c}\right) \end{aligned} \qquad [9]$$

which determines the mode index N. The integer m is the mode order number, and Φ_a and Φ_s are the phase shifts associated with the TIR. The constants E_a, E_c, and E_s are correlated by $E_a = E_c \cos\Phi_a$ and $E_s = E_c(-1)^m \cos\Phi_s$.

3.05.2.2.2 Transverse magnetic modes

Another polarization mode is transverse magnetic (TM) modes, where the magnetic field has the transverse component H_y only and $H_x = H_z = 0$. The dominant field component $H_y(x)$ satisfies the same wave equation as eqn [6], and the electric field is given by $E_x = (\beta/\omega\varepsilon_0 n^2)H_y$, $E_z = (-\mathrm{j}/\omega\varepsilon_0 n^2)$ $(\mathrm{d}H_y/\mathrm{d}x)$ and E_y=0. The guided mode solution for $H_y(x)$ can be written as

$$H_y(x) = \begin{cases} H_a \exp\{-\gamma_a x\} & (0 < x) \\ H_c \cos\{\kappa_c x + \Phi_a\} & (-T < x < 0) \\ H_s \exp\{+\gamma_s(x+T)\} & (x < -T) \end{cases} \qquad [10]$$

Using the continuity of $H_y(x)$ and $E_z(x)$, required by the boundary conditions at $x = 0$, T, we obtain a characteristic equation:

$$\begin{aligned} &\kappa_c T - \Phi_a - \Phi_s = m\pi \,(m = 0, 1, 2, \cdots) \\ &\Phi_a = \tan^{-1}\left\{\left(\frac{n_c}{n_a}\right)^2 \left(\frac{\gamma_a}{\kappa_c}\right)\right\} \\ &\Phi_s = \tan^{-1}\left\{\left(\frac{n_c}{n_s}\right)^2 \left(\frac{\gamma_s}{\kappa_c}\right)\right\} \end{aligned} \qquad [11]$$

The constants H_a, H_c,and H_s are correlated by $H_a = H_c \cos\Phi_a$ and $H_s = H_c(-1)^m \cos\Phi_s$.

The dominant field components are described by the same formula for the TE and TM modes. The field profiles of the fundamental ($m = 0$) mode and a few higher-order modes are illustrated in **Figure 3(b)** and **3(c)**, respectively. They are characterized by a sinusoidal variation in the core and the exponential decay in the cladding. The propagation constant and the mode index depend on the index profile, optical wavelength, polarization, and mode order. Although an explicit expression for N cannot be derived, it can be given in a convenient graphic form using normalized parameters. We define a normalized guide thickness (normalized frequency) by

$$V = kT\sqrt{n_c^2 - n_s^2} = \left(\frac{\omega}{c}\right) T\sqrt{n_c^2 - n_s^2} \qquad [12]$$

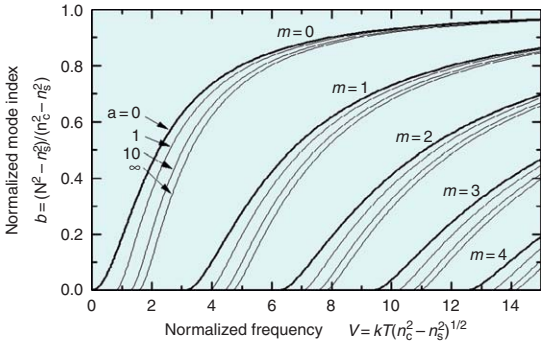

Figure 4 Mode dispersion curves of planar waveguides of step index distribution.

and an asymmetry parameter by $\alpha_{TE} = \left(n_s^2 - n_a^2\right)/\left(n_c^2 - n_a^2\right)$. The mode index N is represented by

$$b = \frac{N^2 - n_s^2}{n_c^2 - n_s^2} \qquad [13]$$

Then the characteristic equation [9] can be expressed by using V, α_{TE}, and b only. **Figure 4** shows the mode dispersion curves obtained by solving the characteristic equation. The mode number increases with V. The mode index N increases monotonously with increasing V and approaches n_f. With decreasing V, N decreases to n_s at the cutoff point. Waveguides that support only the fundamental ($m = 0$) mode are single-mode (monomode) waveguides, and those that support higher-order modes are multimode waveguides. For many applications, single-mode waveguides with small V (small index difference and small core thickness) are advantageous, as conversion and interference between modes may give rise to complication and deterioration of the device performances. By putting $N \rightarrow n_s$ in eqn [9], the cutoff condition for the mth mode is obtained as $V_{cm} = m\pi + \tan^{-1}(\alpha_{TE})^{1/2}$. For symmetrical waveguides ($\alpha_{TE} = 0$), there is no cutoff for the fundamental ($m = 0$) mode, and the single-mode condition is given by $V < \pi$. Similar treatment can be made for TM modes with an asymmetry parameter $\alpha_{TM} = (n_c/n_a^4)\left(n_s^2 - n_a^2\right)/\left(n_c^2 - n_a^2\right)$, and in many cases the expressions for TE modes can be used as a good approximation for TM modes.

Radiation modes can also be expressed in the form of eqn [1]. They are classified into substrate radiation modes and substrate–air radiation modes. The former is the superposition of two plane waves in the core and substrate regions with evanescent tail in the air (upper cladding) region, and $n_a < |N| < n_s$. The latter has propagating plane wave component(s) in all core, substrate, and air regions, and the effective index $|N|$ is $< n_a$. They are of continuous spectrum. The spectrum of the propagation constants of guided and radiation modes are illustrated in **Figure 5**.

Waveguides having a graded index profile can also be used for IO device implementation. For example, the index profiles of metal-indiffused $LiNbO_3$ waveguides and annealed proton-exchanged (APE) $LiNbO_3$ waveguides can be expressed approximately by a half Gauss function or a complementary error function. Exact analysis of such waveguides requires numerical calculations. The Wentzel–Kramers–Brillouin (WKB) method (Coldren and Corzine 1995, Nishihara *et al.* 1989, Snyder and Love 1983, Tamir 1975) and multilayer decomposition method (Nishihara *et al.* 1989, Snyder and Love 1983) are used. The characteristics, however, can be illustrated well with the above results, and the step index model can be used for design with reasonable accuracy, if appropriate values are used for refractive indexes and thickness to represent the graded index profile.

3.05.2.3 Channel Waveguides

Figure 6 illustrates various types of channel waveguides, and **Figure 7** shows the cross section of a channel waveguide with step index profile. The core thickness and width are T and W, respectively. The wave equation is given by eqn [2]. Although the exact field expressions for channel waveguides cannot be obtained in an analytical form, approximate but analytical solutions can be used to illustrate the characteristics and design the structure.

One of the methods is the effective index method (Coldren and Corzine 1995, Nishihara *et al.* 1989,

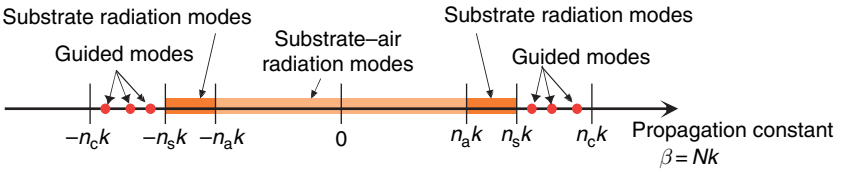

Figure 5 Spectrum of optical wave modes in a planar waveguide.

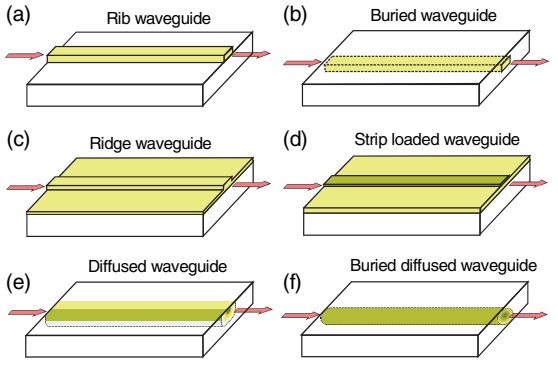

Figure 6 Various types of channel waveguides.

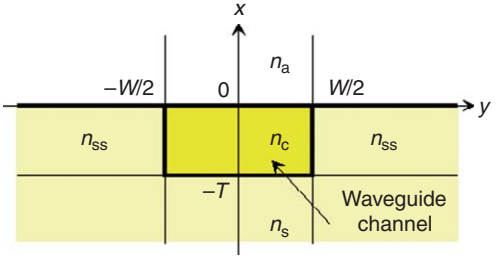

Figure 7 Cross section of a channel waveguide of step index distribution.

Tamir 1975) that applies with good accuracy for guides of $W >> T$. The channel structure is converted into two imaginary planar waveguides, and the field distribution is written approximately in the form of a product of profiles in the depth and width directions as, for example, $E_y(x,y) = E_y(x)E_y(y)$. In the first step, the depth profile $E_y(y)$ and the effective index N_I for the channel region are determined by using an imaginary planar guide model of thickness $T(W \to \infty)$. In the second step, an imaginary planar waveguide of core thickness W with an effective core index N_I and an effective cladding index $N_{II} = \left(n_{ss}^2 - n_c^2 + N_I^2\right)^{1/2}$ is considered to determine the width profile $E_y(x)$ and the mode index N. Thus the mode profile and the mode index N of guided mode in channel waveguide are obtained by repeating the analysis of planar waveguide. The normalized graphic data of **Figure 4** can be used in each step.

Another approximate method is the Marcatili's (1969) method, which gives better accuracy for cases including narrow channels. The field profile of guided modes, e.g., $E_y(x,y)$, is expressed analytically by using sinusoidal and exponential functions for five regions (core region, and upper, lower, left, and right cladding regions), and from the boundary

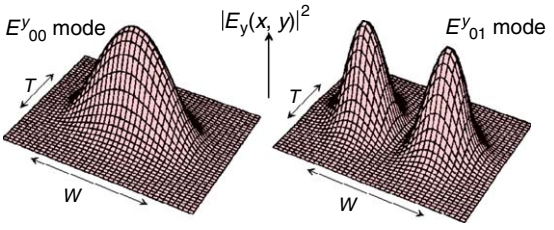

Figure 8 Optical intensity distributions of guided modes in a channel waveguide.

conditions at the upper, lower, left, and right walls of the core, characteristic equations are obtained. Integers p and q are used as mode order numbers for the depth and width directions. The propagation constant β can be obtained by solving these equations jointly. **Figure 8** illustrates the examples of the intensity distributions given by $\left|E_y(x,y)\right|^2$.

An important feature of the above channel guided modes is that, although the dominant electric field component is E_y, there are nonzero E_z and H_z. This means that these modes are not exactly TE modes but hybrid modes (Nishihara *et al.* 1989, Snyder and Love 1983). They are designated as E^y_{pq} modes. There also exist guided modes with $E_y = 0$ and dominant electric field component $E_x(x,y)$. These modes are designated as E^x_{pq} modes. The E^y_{pq} and E^x_{pq} modes are also called TE-like and TM-like modes, respectively, and are often abbreviated as TE_{pq} and TM_{pq} modes. Analysis of channel waveguides of arbitrary index profile can be performed by numerical method based on the finite element method (FEM) (Koshiba *et al.* 1992) and the finite difference method (FDM) (Stern 1988).

3.05.2.4 Waveguide Materials and Fabrication Techniques

Waveguides are fabricated by using materials selected depending on the optical wavelength and the function to be implemented. Although a large number of materials was studied, only some of them survived as materials for developing practical IO devices. They are classified into glasses, polymers, ferroelectric crystals, and semiconductors. Typical waveguide materials are listed in **Table 1** with the fabrication techniques and applications.

Typical waveguide material for passive components is optical glasses. Optical waveguides can be fabricated in multicomponent glasses by ion exchange. For example, a soda lime glass substrate is immersed in molten salt such as KNO_3, $AgNO_3$,

Table 1 Various kinds of optical waveguide materials

Category	*Material*	*Fabrication technology*	*Application*
Multicomponent glasses	Borosilicate glasses[a]	RF sputtering	PC, TO devices
	Soda lime glasses	Ion exchange	PC, TO devices
	Chalcogenide glasses[a]	Vacuum evaporation	AO devices
Silica glasses	SiO_2 (TiO_2 doped)[a]	FHD	PC, TO devices
	SiO_xN_y[a]	PCVD	PC, TO devices
	Er:SiO_2[a]	Rare-earth doping	Lasers
Ferroelectric crystals	$LiNbO_3$	Ti indiffusion, proton exchange	EO, AO, NLO devices
	$LiTaO_3$	Proton exchange	EO, AO, NLO devices
	Er:$LiNbO_3$	Rare-earth doping	Lasers
Polymers	Polymers[a]	Spin coating, dip coating, casting	PC, TO devices
	EO polymers[a]	Spin coating, dip coating, casting	EO devices
Silicon	SOI ($Si/SiO_2/Si$)	Wafer direct bonding, ion implantation	IR devices
Group III–V semiconductors	AlGaAs	MBE	Lasers
	InGaAsP	MOVPE	Optical amplifiers
	InGaAs		EA devices
	AlGaInP		Monolithic IO devices

[a]On SiO_2/Si substance prepared by thermal oxidation of Si substrate.

and $TlNO_3$ to replace Na^+ in the glass matrix by K^+, Ag^+, and Tl^+ in the salt. The refractive index is increased as a result of the exchange. Channel guides can be fabricated by using a patterned mask layer on the substrate. Fabrication techniques of glass waveguides include deposition of borosilicate glass (e.g., Corning #7059) by radio frequency (RF) sputtering and deposition of chalcogenide glasses by vacuum evaporation or RF sputtering.

An important structure for various thin-film waveguides is SiO_2/Si substrate, which is prepared by growing an SiO_2 layer on a Si wafer by thermal oxidation. The advantages are high quality and low cost, and possibilities of integration of photodiodes (PDs) and electronics. The SiO_2 layer with low refractive index serves as an optical buffer layer to isolate the guided mode field confined in the guiding layer from the high-index Si substrate. The appropriate buffer layer thickness is a few times as large as the penetration depth of the evanescent tail of the guided mode.

One of the high-quality ($<0.05\,dB\,cm^{-1}$ loss) waveguides now most widely used is buried silica (SiO_2 doped with GeO_2 or TiO_2) waveguides on Si substrate (Himeno *et al.* 1998). **Figure 9** illustrates the fabrication process of silica channel waveguides by flame hydrolysis deposition (FHD) and reactive ion etching (RIE) combined with photolithography or electron beam lithography. Silica waveguides and silicon oxynitride (SiO_xN_y) waveguides with SiO_2

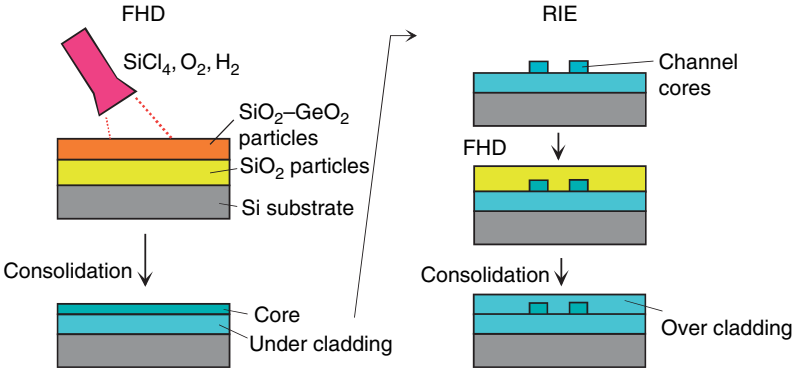

Figure 9 Fabrication process of silica channel waveguides by the flame hydrolysis deposition (FHD) and reactive ion etching (RIE).

cladding can also be fabricated by plasma-enhanced chemical vapor deposition (PCVD) and RIE.

Another important advantage of using a Si substrate is that various micromachining processes originally developed for very large-scale integration (VLSI) fabrication, including various lithography, anisotropic etching, surface micromachining, and replication process, can be employed to form 3D microstructures (Gabriel 1998). The structures can find applications as a Si optical bench. Microelectromechanical systems (MEMS) consisting of mechanical moving parts and micro actuators can also be constructed. Optical systems using MEMS structures are called optical MEMS or microoptoelectromechanical systems (MOEMS). A number of MOEMS have been developed (Giles *et al.* 1999, Lin and Goldstein 2002, Motamedi 1994).

Important waveguide materials for electrooptic (EO), acoustooptic (AO), and nonlinear optic (NLO) devices are ferroelectric crystals such as $LiNbO_3$ and $LiTaO_3$. High-quality waveguides ($<0.2\,dB\,cm^{-1}$ loss) can be fabricated by Ti indiffusion in $LiNbO_3$ and proton exchange/annealing in $LiNbO_3$ and $LiTaO_3$. The fabrication processes are illustrated in **Figure 10**. Ti:$LiNbO_3$ waveguides are fabricated by deposition and pattering of Ti film by RF sputtering and liftoff, followed by heat treatment in a quartz tube by an electric furnace at a temperature $\sim$1000°C in an appropriate atmosphere (wet N_2 to suppress LiO_2 outdiffusion). APE waveguides are fabricated by immersing the crystal with patterned mask layer in molten benzoic acid at $\sim$200°C for exchange of Li^+ in the crystal with H^+ (proton) in the acid. The exchange gives rise to increase in the extraordinary index of the crystal. Then the crystal is annealed at $\sim$350°C to obtain index profile for single-mode guiding.

Waveguides of increasing interest include Si waveguides for infrared light. Silicon-on-insulator (SOI) structures with appropriate Si thickness, prepared by wafer direct bonding, can be used as a planar waveguide (Jalali 1997). Channel guides can be fabricated by standard Si IC technologies. They exhibit low propagation losses for wavelength longer than 1.3 μm. Because of the high index of refraction, the Si layer is suitable for the fabrication of photonic crystal waveguides. They have the advantages that well-established Si IC and MEMS processes can be employed and offer the possibility of implementing devices for optical wave control by carrier or thermooptic (TO) effect and Raman optical amplifiers.

Organic polymers are a material with unique features. Waveguide layers are prepared from polymer solutions by spin coating or dip coating on various substrates, and channel guides can readily be fabricated by RIE and buried with another polymer with lower index. They are suitable for many passive devices including IO chemical and biomedical sensors. The TO coefficient is much larger than that of glass materials. EO polymers with EO coefficients comparable or even higher than that of $LiNbO_3$ have been developed.

Group III–V compound semiconductors, such as GaAs and InGaAsP, are important materials for monolithic IO devices including laser diodes (LDs) as light sources. Double-hetero (DH) and separately confinement hetero (SCH) structures for bulk and

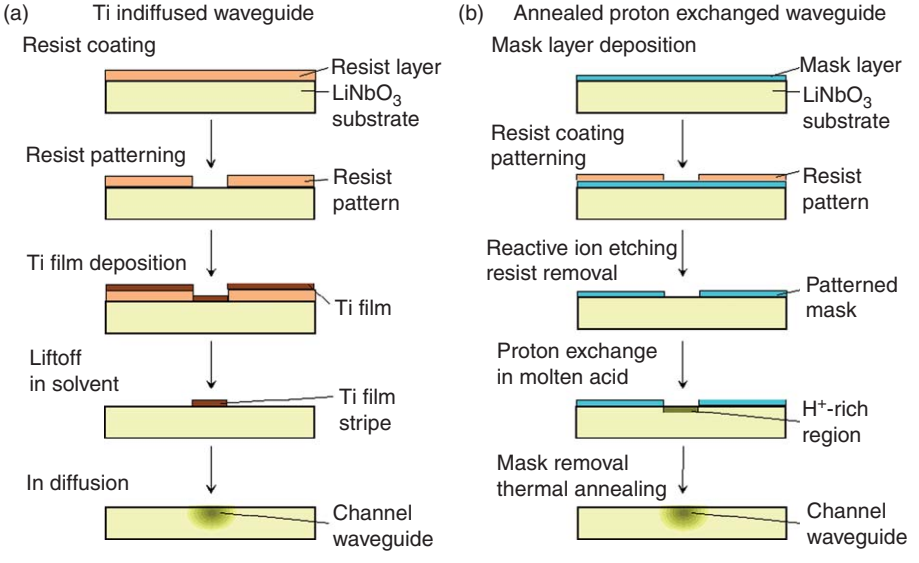

Figure 10 Fabrication process of $LiNbO_3$ channel waveguides.

quantum-well (QW) lasers can be used also as passive waveguides. They are fabricated by molecular beam epitaxy (MBE) or metal–organic vapor phase epitaxy (MOVPE). The passive waveguides without current injection, however, exhibit large absorption loss at the lasing wavelength. An important requirement for the implementation of monolithic IO devices is reduction in the passive waveguide loss. To solve the problem, area-selective MOVPE growth technique using SiO_2 mask layer (Kudo *et al.* 1997) or area-selective QW disordering (intermixing) technique (Li 2000) is employed to modify the bandgap energy distribution.

Propagation losses of guided waves has several origins. They include absorption loss due to absorption of guided wave power by the core and cladding materials (insufficient transparency). Imperfection of the interface between core and cladding and inclusion of defects in the structure give rise to scattering loss. Although the losses depend on wavelength, materials, and fabrication processes, the losses are reduced to values (typically $< 0.2\,\mathrm{dB\,cm^{-1}}$) appropriate for practical device implementation.

3.05.2.5 Excitation of Guided Mode by End Coupling

The simplest and practical method for guided mode excitation in a waveguide is end-fire coupling as shown in **Figure 11(a)**. A laser beam is focused by a lens into a small spot, and the input end of the waveguide is positioned at the focus. The input face is prepared by cutting and polishing the waveguide. For some waveguide materials, precision dicing method using a disk saw can be used. For semiconductor waveguides, a waveguide facet prepared by cleaving the waveguide with substrate can be used as the input facet. The coupling efficiency η is calculated by expanding the field distribution on the waveguide input end $E_{\mathrm{in}}(x, y, 0)$ with field profiles of the modes of the waveguide $E_m(x,y)(m = 0, 1, 2, \cdots)$ and by taking the absolute square of the coefficient for the mode to be excited and is given by

$$\eta = \frac{\left| \iint E_m^*(x,y) E_{\mathrm{in}}(x,y,0)\,\mathrm{d}x\,\mathrm{d}y \right|^2}{\iint |E_m(x,y)|^2\,\mathrm{d}x\,\mathrm{d}y \iint |E_{\mathrm{in}}(x,y,0)|^2\,\mathrm{d}x\,\mathrm{d}y} \quad [14]$$

The numerator in the RHS of eqn [14] is called overlap integral. The value of η takes the maximum of 1 when $E_{\mathrm{in}}(x,y,0)$ is proportional to $E_m(x,y)$ and is <1 otherwise. To obtain a high coupling efficiency, the beam should be focused on the input face, the focus spot should be aligned with the waveguide core, and the spot size should be matched with the mode size by optimizing the combination of input beam diameter and focal length of the lens. In many cases of appropriately designed channel waveguides, it is not difficult to achieve $\eta > 0.7$ using micromanipulator and an appropriate lens.

Laser light emitted from a semiconductor laser can be coupled directly into a waveguide by aligning the laser to the waveguide with a narrow gap between them as shown in **Figure 11(b)**. This method is called butt coupling, and the coupling efficiency is given by eqn [14] with the laser mode profile $E_{\mathrm{in}}(x,y)$ instead of $E_{\mathrm{in}}(x,y,0)$. High coupling efficiency is obtained by precise alignment and mode matching. Laser light transmitted through an optical fiber can also be coupled to a waveguide by similar butt coupling. The end of the fiber is bonded to the waveguide end using optical glue. This is called fiber pigtailing and is widely used for implementing practical devices.

3.05.3 Distributed Coupling of Guided Waves

Distributed coupling of guided waves in two or more waveguides and that in a waveguide with periodic structures or gratings provide important working principles of IO components and devices. Waveguide

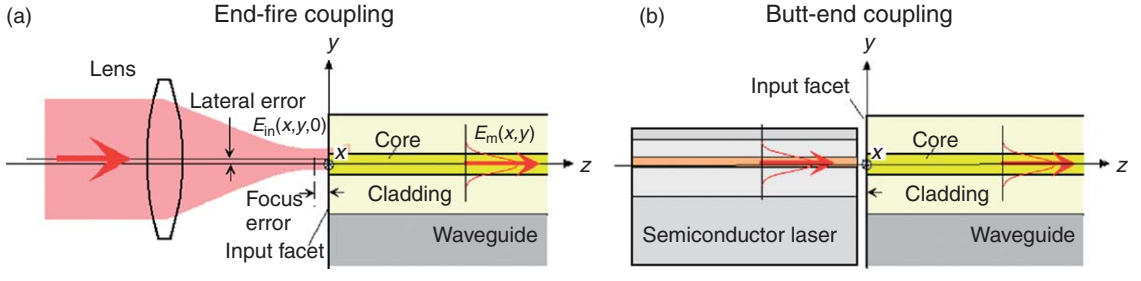

Figure 11 Excitation of guided mode by end coupling.

gratings perform various passive functions, such as deflection, reflection, input/output coupling, mode conversion, wavelength filtering, wavelength dispersion, and phase matching. Periodic modulation in refractive index produced through EO and AO effects, i.e., dynamic gratings, can provide an effective means for guided wave control. This section presents distributed coupling in waveguides and waveguide gratings based on the coupled mode theory (Nishihara *et al.* 1989, Suhara *et al.* 1986, Yariv 1973).

3.05.3.1 Description of Periodic Structures and Phase Matching

Consider a waveguide described by a cross-sectional distribution of the relative dielectric permittivity $\varepsilon(x,y)$. Expression of a waveguide grating is given by the modification in the permittivity $\Delta\varepsilon(x,y,z)$ superimposed on $\varepsilon(x,y)$. Because $\Delta\varepsilon$ is periodic, it can be written in a Fourier series as

$$\Delta\varepsilon(x,y,z)=\sum_q \Delta\varepsilon_q(x,y)\exp(-\mathrm{j}qKz),\quad K=2\pi/\Lambda \qquad [15]$$

where Λ is the grating period, and $\Delta\varepsilon_q(x,y)$ the qth Fourier amplitude. A grating of periodicity along the z-axis is assumed for simplicity. Note that a waveguide structure modified without grating can be described by $\Delta\varepsilon_0(x,y)$ and $\Delta\varepsilon_q(x,y)=0$ for $q\neq 0$.

Optical functions of the structures can be interpreted in terms of coupling between modes. When a guided mode characterized by a phase factor $\exp(-\mathrm{j}\beta_a z)$ with a propagation constant β_a is incident in the interaction region, space harmonics of phase factors β_a+qK are induced. The harmonic can propagate as a mode, provided that the β_a+qK coincides at least approximately with propagation constant β_b of a mode in the structure. This means that effective qth-order coupling between modes a and b takes place when

$$\beta_b=\beta_a+qK,\quad q=0,\pm1,\pm2,\cdots \qquad [16]$$

Eqn [16] is the phase-matching condition, and more general relation, $\boldsymbol{\beta}_b=\boldsymbol{\beta}_a+q\mathbf{K}$ with wave vectors $\boldsymbol{\beta}_a$, $\boldsymbol{\beta}_b$, and grating vector $\mathbf{K}$ is called Bragg condition and can be depicted as a wave vector diagram.

3.05.3.2 Coupled Mode Equations

The optical field in the waveguide grating structure may be written as

$$\mathbf{E}(x,y,z)=A(z)\mathbf{E}_a(x,y)\exp(-\mathrm{j}B_a z)+B(z)\mathbf{E}_b(x,y)\exp(-\mathrm{j}B_b z) \qquad [17]$$

The mode fields $\mathbf{E}_a(x,y)\exp(-\mathrm{j}\beta_a z)$ and $\mathbf{E}_b(x,y)\exp(-\mathrm{j}\beta_b z)$ satisfy Maxwell's equations with waveguide permittivity $\varepsilon(x,y)$, and the total field $\mathbf{E}(x,y,z)$ satisfies those with $\varepsilon(x,y)+\Delta\varepsilon(x,y,z)$. From these Maxwell's equations, and using the orthonormal relation of the modes, one can deduce the equations that describe the spatial evolution of the mode amplitudes $A(z)$ and $B(z)$:

$$\pm\frac{\mathrm{d}}{\mathrm{d}z}A(z)=-\mathrm{j}\kappa^* B(z)\exp(-\mathrm{j}2\Delta z) \qquad [18a]$$

$$\pm\frac{\mathrm{d}}{\mathrm{d}z}B(z)=-\mathrm{j}\kappa A(z)\exp(+\mathrm{j}2\Delta z) \qquad [18b]$$

$$2\Delta=\beta_b-(\beta_a+qK) \qquad [19]$$

As for $\pm$ in eqn [18a] (eqn [18b]), $+$ and $--$ should be taken for $\beta_a>0$ and $\beta_a<0$ ($\beta_b>0$ and $\beta_b<0$), respectively. Equations [18] are coupled mode equations, and 2Δ describes the deviation from the phase-matching condition. The parameter κ, called coupling coefficient, is given by

$$\kappa=\frac{\omega\varepsilon_0}{4}\iint \mathbf{E}_a^*(x,y)\Delta\varepsilon_q(x)\mathbf{E}_b(x,y)\mathrm{d}x\,\mathrm{d}y \qquad [20]$$

3.05.3.3 Coupling between Guided Modes

3.05.3.3.1 Collinear coupling

Coupling between guided modes propagating along the same axis (collinear coupling) is classified into codirectional coupling and contradirectional coupling. They are illustrated in **Figure 12(a)–(c)** with the wave vector diagrams.

Codirectional coupling: Consider coupling between two different modes propagating in the same direction ($\beta_a>0,\beta_b>0$). The solution of eqns [18a] and [18b] for boundary conditions $A(0)=1,B(0)=0$ indicates periodic transfer of the guided mode power from mode a to b. The efficiency of the power transfer in a coupling (grating) length L is given by

$$\eta=\left|\frac{B(L)}{A(0)}\right|^2=\frac{\sin^2\sqrt{|\kappa|^2+\Delta^2}L}{1+\Delta^2/|\kappa|^2} \qquad [21]$$

The efficiency under exact phase matching ($\Delta=0$) is given by $\eta_0=\sin^2|\kappa|L$. For coupling of guided waves of the same mode ($\beta_a=\beta_b$) in two parallel identical waveguides (a directional coupler (DC)) (**Figure 12(a)**), the phase matching is satisfied

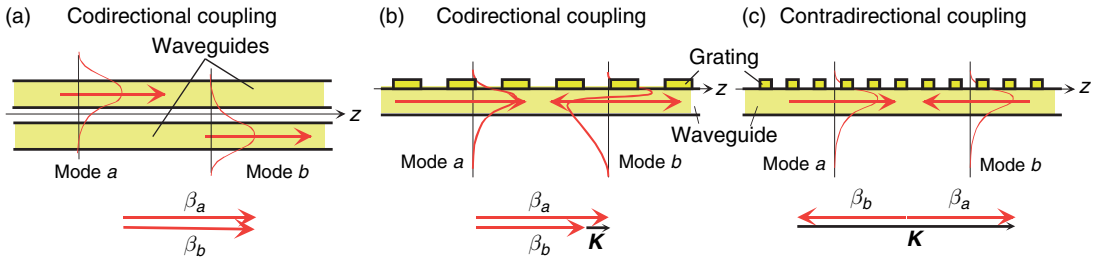

Figure 12 Collinear coupling of guides modes in waveguides or in a waveguide with grating.

automatically without grating ($q = 0$). Coupling of two different modes ($\beta_a \neq \beta_b$) in a waveguide may take place when the phase matching is accomplished by a grating of appropriate period (**Figure 12(b)**). This implies that the grating functions as a mode converter. In either case, complete power transfer takes place when L equals odd integer multiple of the complete coupling length $L_c = \pi/2|\kappa|$. The dependence of η on κL and that of η/η_0 on ΔL are plotted in **Figure 13**.

Contradirectional coupling: Consider coupling between modes propagating in the opposite directions ($\beta_a > 0$, $\beta_b < 0$) in a waveguide with grating of length L (**Figure 12(c)**). Equations [18] with $A(0) = 1, B(L) = 0$ give a solution that indicates monotonous power transfer. This implies that distributed reflection of forward mode a into backward mode b takes place. The mode b may be the same lateral mode as a ($\beta_b = -\beta_a$, reflection without mode conversion) or may be a different mode ($\beta_b \neq -\beta_a$, reflection associated with mode conversion). The grating is called distributed Bragg reflector (DBR). The conversion efficiency, or the reflectivity, is given by

$$\eta = \left|\frac{B(0)}{A(0)}\right|^2 = \left[1 + \frac{1 - \Delta^2/|\kappa|^2}{\sinh^2\sqrt{|\kappa|^2 - \Delta^2}L}\right]^{-1} \qquad [22]$$

Under exact phase matching ($\Delta = 0$), the efficiency is given by $\eta_0 = \tanh^2|\kappa|L$, and most of the power is transferred ($\eta > 0.84$) when $L > \pi/2|\kappa|$. The dependence of η on κL and that of η/η_0 on ΔL are plotted in **Figure 14**.

Equations [21] and [22] indicate that a high efficiency is obtained only when phase matching is satisfied, and the mismatch gives rise to a reduction in the efficiency. Therefore, for a given waveguide grating, a high efficiency is obtained at or near a phase-matching wavelength λ_0, and the efficiency is reduced with deviation of the wavelength from λ_0. Thus the mode conversion and the reflection exhibit wavelength selectivity, and the grating can be used as a wavelength filter. Let $\delta\lambda = \lambda - \lambda_0$ be the wavelength deviation. Assuming $N(\lambda) \approx N(\lambda_0)$, we have $2\Delta \approx (N_a - N_b)(2\pi\delta\lambda/\lambda^2)$ for codirectional coupling, and $2\Delta \approx 2N(2\pi\delta\lambda/\lambda^2)$ for contradirectional coupling of $\beta_b = -\beta_a$. Combining these relations with the bandwidths in terms of ΔL, the wavelength bandwidths are given by $2\delta\lambda/\lambda \approx 2.5\Lambda/\pi|q|L$ and $2\delta\lambda/\lambda \approx 5\Lambda/\pi|q|L$, for co- and contradirectional coupling, respectively. Because the grating period Λ for contradirectional coupling is much shorter (as can be seen from the phase-matching condition [16]), contradirectional coupling (DBR)

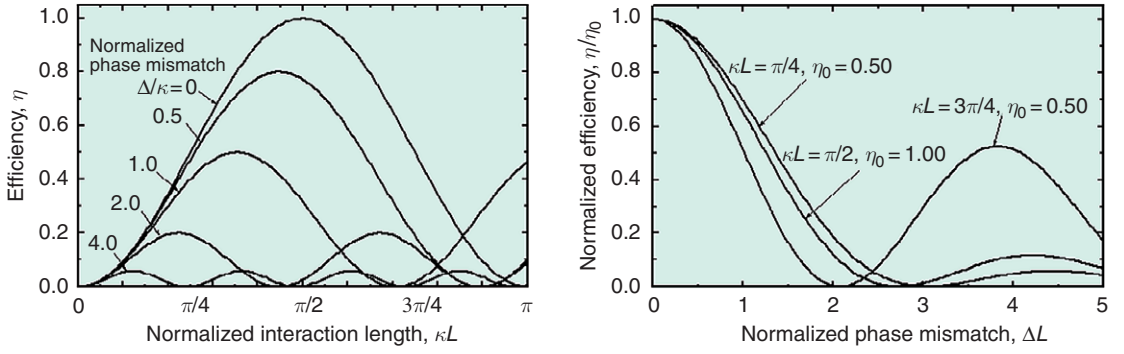

Figure 13 Dependence of the efficiency on the interaction length and the phase mismatch for codirectional coupling.

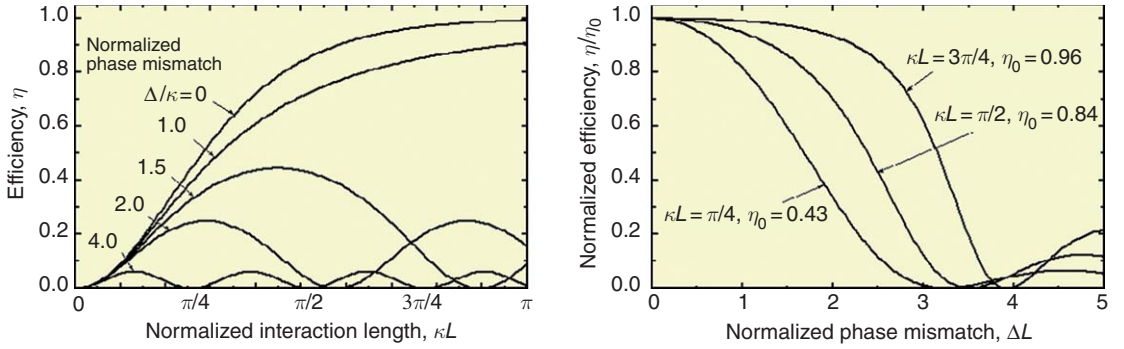

Figure 14 Dependence of the efficiency on the interaction length and the phase mismatch for contradirectional coupling.

exhibits wavelength selectivity much sharper than that of codirectional coupling.

The coupling coefficient κ is an important parameter needed to design the grating structure and predict the performances. The magnitude of κ depends on the order and polarizations of the coupling modes, and coupling order q, as well as the grating parameters. For gratings of index modulation type, for example, the κ is given by $\kappa = \pi\Delta n_q F/\lambda$, where Δn_q is the qth Fourier amplitude of the index modulation and F is an overlap integral between modes and index modulation describing the effect of mode confinement in the waveguide.

3.05.3.3.2 Coplanar coupling

In a planar waveguide (in yz-plane) with a grating (of length L in z-direction) of appropriate orientation, coplanar coupling takes place between guided waves of different propagation directions. This type of coupling is called diffraction or deflection, as it involves a change in propagation direction. Coplanar coupling is classified into two categories using a parameter defined by $Q = K^2 L/\beta$.

In a thin grating of $Q < 1$, several beams appear corresponding to different diffraction orders q, because coupling may take place even without exact phase matching in the z component. This type is called Raman–Nath diffraction. The first-order efficiency $\eta_{\pm 1}$ takes the maximum 0.34 at $2\kappa L = 1.84$. The grating does not exhibit sharp angular and wavelength selectivity. In a thick grating of $Q >> 1$, strong coupling takes place only when the Bragg condition is satisfied between the incident and the diffracted waves. Therefore, a diffracted wave of a single order appears, as illustrated in **Figure 15**. This type of diffraction is called Bragg diffraction. The diffraction efficiencies for coplanar coupling are described by the formulae similar to eqns [21] and [22]. The maximum efficiency for a transmission grating is 100%, and the diffraction efficiency of a reflection grating approaches asymptotically 100% with increasing L. In either case, the efficiency decreases with deviation from the Bragg condition, so that they exhibit the angular and wavelength selectivities.

3.05.3.4 Coupling between Guided Mode and Radiation Modes

3.05.3.4.1 Prism coupling

Prism coupling is a convenient laboratory method useful not only for guided mode excitation but also for measurement of the mode index and waveguide

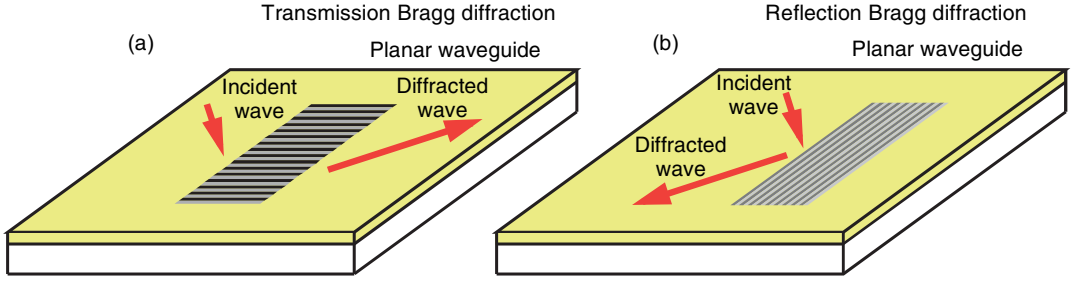

Figure 15 Bragg diffraction of guided wave in a planar waveguide.

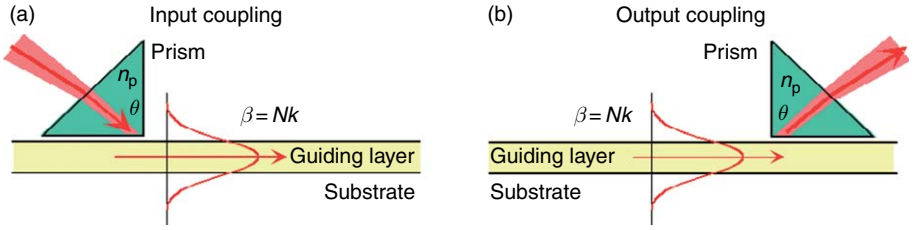

Figure 16 Prism coupling between a guided mode and radiation modes.

performances. A prism of a high refractive index n_p is pressed slightly to the waveguide surface, so that the prism base is aligned parallel to the waveguide surface with a submicron air gap between them as illustrated in Figure 16. A laser beam is weakly focused by a lens onto the edge of the prism base. The assembly is mounted on a rotary stage, and the angle of incidence θ, measured in the prism with respect to the waveguide surface normal, is adjusted so as to satisfy

$$n_p\, k \sin\theta = \beta\left(k = \frac{2\pi}{\lambda}, \beta = Nk\right) \qquad [23]$$

with the propagation constant β and the effective index N of a guided mode of the waveguide. Then the phase matching between the incident beam (radiation mode) and the guided mode is accomplished and the incident beam is coupled into the waveguide. It is necessary to use a prism of $n_p > N$. The mode index N can be determined experimentally by measuring the angle θ under the coupling. Coupling efficiency $>80\%$ is possible. Prism coupling, however, is hardly used in practical IO devices, because of the need of an expensive and rather bulky prism and critical adjustment, poor mechanical stability, and incompatibility with buried waveguides.

3.05.3.4.2 Grating coupling

Output coupling: Figure 17 illustrates coupling between a guided mode and radiation modes with a grating. Coupling takes place between waves satisfying phase matching for the z component. When a guided wave of propagation constant $\beta_0 = Nk$ is incident, the qth harmonics are radiated into air and/or substrate at angles determined by

$$n_c k \sin\theta_q^{(c)} = n_s k \sin\theta_q^{(s)} = \beta_q = Nk + qK \qquad [24]$$

The number of radiation beams equals the number of real values for $\theta_q^{(c)}$ and $\theta_q^{(s)}$. Figure 17(a) shows multibeam coupling where more than three beams are yielded, and Figure 17(b) shows two-beam coupling where only a single beam for the fundamental order ($q = -1$) is yielded in both air and substrate. Another possibility is one-beam coupling where a beam radiates only into the substrate. The amplitude of the guided and the radiation waves decays as $g(z) = \exp(-\alpha_r z)$ due to the power leakage by

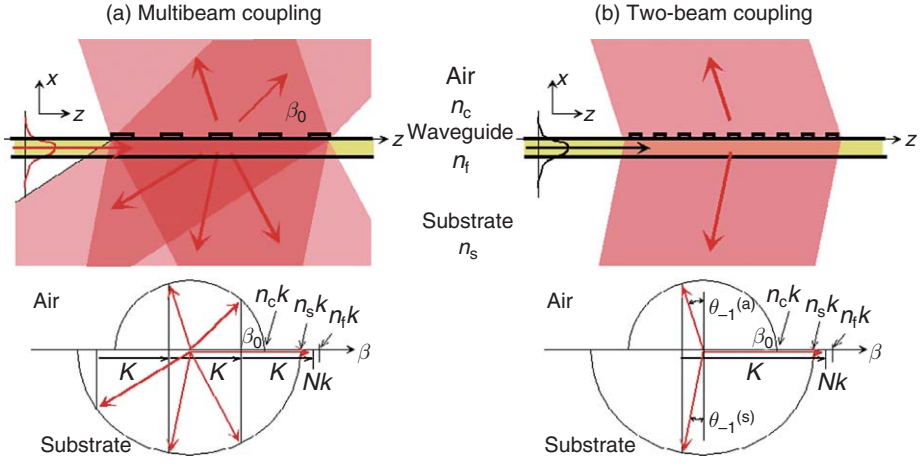

Figure 17 Coupling between a guided mode and radiation modes in a grating coupler.

radiation. Because the attenuation of the guided power corresponds to the power transferred to the radiation modes, the qth-order output coupling efficiency of a grating of length L can be written as

$$\eta_{\text{out}} = P_q^{(i)}\{1 - \exp(-2\alpha_r L)\},$$
$$\alpha_r = \sum_{q,i} \alpha_q^{(i)}, P_q^{(i)} = \frac{\alpha_q^{(i)}}{\alpha_r} \quad [25]$$

where $\alpha_q^{(i)}$ and α_r are radiation decay factors, $P_q^{(i)}$) is a ratio for power distribution to $q-(i)$ radiation beam, and $i =$ a or s. The radiation decay factors $\alpha_q^{(i)}$ are correlated with the coupling coefficient $\kappa_q^{(i)}$ by $\alpha_q^{(i)} = \pi\left|\kappa_q^{(i)}\right|^2$, and $\kappa_q^{(i)}$ can be calculated by substituting the guided and the radiation mode profiles into eqn [20]. For grating couplers of relief type with groove depth h, the decay factor α_r increases in proportion to h^2 in the region where h is small. For larger h, α_r saturates because of the limited penetration of the evanescent tail of the guided mode into the grating layer.

Input coupling: A guided mode can be excited through input coupling of an external beam incident on a grating at an angle satisfying eqn [24]. **Figure 18** compares output and input couplings. A reciprocity theorem analysis shows that the input coupling can be written as analysis shows that the input coupling can be written as

$$\eta_{\text{in}} = P_q^{(i)} I(g,h), I(g,h) = \frac{\left|\int g(z)h(z)\mathrm{d}z\right|^2}{\int |g(z)|^2\mathrm{d}z \int |h(z)|^2\mathrm{d}z} \quad [26]$$

where $h(z)$ is the input beam profile. The overlap integral $I(g, h)$ takes the maximum of unity, when the input profile $h(z)$ is proportional to the output profile $g(z)$. A high efficiency can be achieved under conditions $\alpha_r L >> 1$, $P_q^{(i)} \approx 1$ for a single $q-(i)$ beam, and $h(z) \approx g(z)$. For a Gaussian input beam, the maximum of $I(g, h)$ is 0.801 and the maximum input efficiency is 80.1%.

High-efficiency grating coupler: One-beam coupling is desirable for achieving high input and output efficiencies. Such coupling can be realized in a short-period grating, which allows only fundamental backward coupling into substrate ($\theta_{-1}^{(s)} < 0$). Two-beam couplers as shown in **Figure 17(b)** are more practical, but they have a drawback that the output power is divided into air and substrate. A high directionality into air ($P_{-1}^{(a)} \approx 1$) for eliminating this drawback can be accomplished by inserting a reflection layer on the substrate, by using the Bragg effect in a thick index-modulation grating, or by using the blazing effect in a relief grating having an asymmetric triangular cross section.

3.05.4 Passive Components

This section presents passive waveguide components that perform static functions on guided waves.

3.05.4.1 Modified Waveguide Components

Channel waveguides can be curved or bent to change the direction of guided waves and/or to give a lateral shift. They can also be tapered to change the mode size. If a waveguide is connected abruptly with another waveguide with different parameters, some of the guided wave power is transferred to radiation modes, resulting in mode conversion loss. A method to reduce this loss is to insert an adiabatic tapered region. If the waveguide is curved, the guided wave suffers from bending loss too. The bending loss increases rapidly as the radius of curvature decreases and is larger for smaller difference in index between the core and cladding. Therefore, waveguides of large index difference must be used for devices using largely curved guides. Waveguides can be branched for beam splitting (**Figure 19(a)**) (and combining for waves with

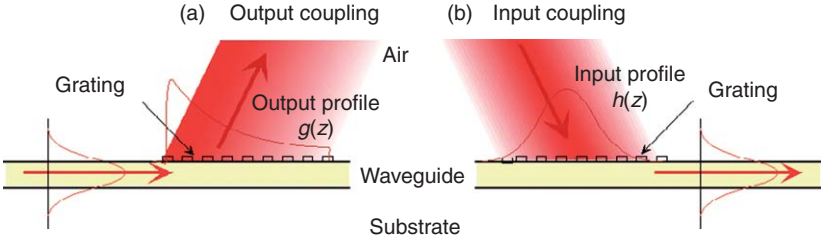

Figure 18 Comparison between grating output coupling and input coupling.

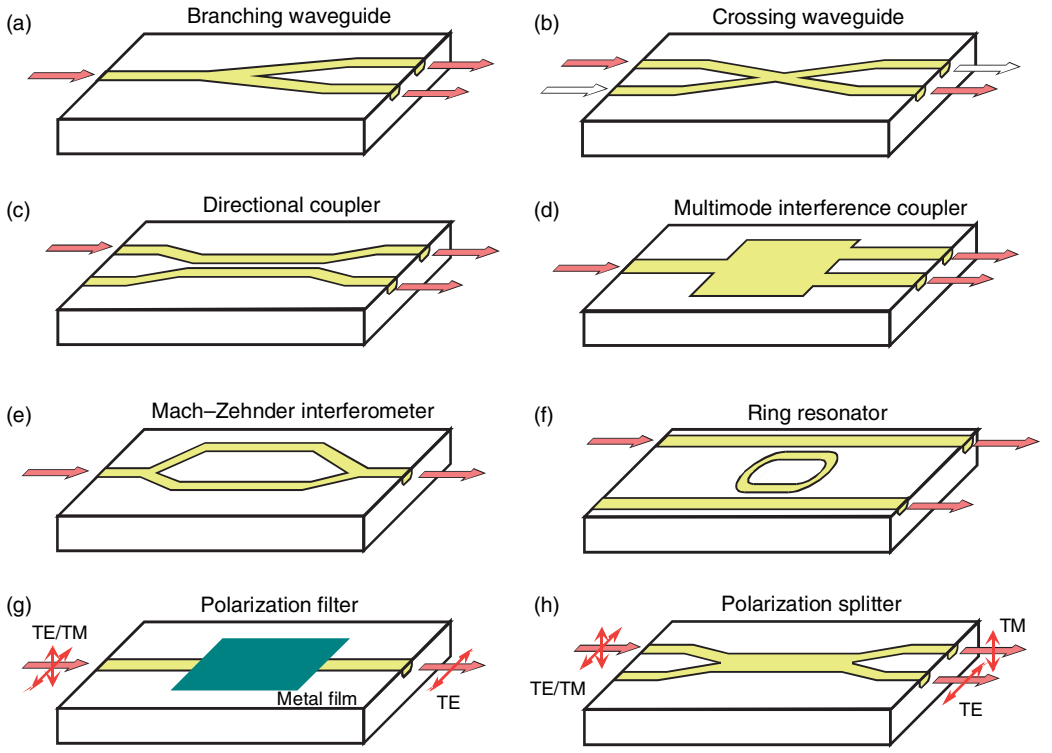

Figure 19 Various passive components using modified channel waveguides. TE, transverse electric; TM, transverse magnetic.

reverse propagation directions) and crossed for intersecting (**Figure 19(b)**). These modifications are made to interface components in IO.

One of the important components is a DC (**Figure 19(c)**), constructed with two-channel waveguides aligned parallel with a small gap for distributed coupling. The transmittances from an input port to the extended and to the crossed output ports are given by $\cos^2(\pi L/2L_c)$ and $\sin^2(\pi L/2L_c)$, respectively, where L is the length of the coupling region and $L_c = \pi/2\kappa$ is the complete coupling length, where κ is the coupling coefficient. For example, a 3-dB (50:50) coupler and a 0-dB (0:100) coupler are realized by setting $L = L_c/2$ and $L = L_c$, respectively, and they are used for beam splitting and beam transfer. Another type of coupler is a multimode interference (MMI) coupler (**Figure 19(d)**), consisting of input and output channels and a multimode section where lateral modes interfere with each other to give split outputs through output channels. Waveguide Mach–Zehnder interferometers (MZIs) (**Figure 19(e)**) are constructed by two channel guides (arms) connected by two branching guides (or two DCs). Asymmetric (different arm lengths) MZIs have applications as a course wavelength filter and sensor elements. Waveguide ring resonators (**Figure 19(f)**), constructed using input/output channel(s) and a ring channel with distributed coupling, perform wavelength filter function. The free spectrum range and the wavelength bandwidth are determined by the round-trip length of the ring and the coupling strength, respectively. Another resonator is waveguide Fabry–Perot (FP) resonator, constructed by integrating two waveguide DBR gratings or by forming multilayer reflectors on both end facets of a straight channel waveguide.

Polarization elements can also be implemented with waveguides. A waveguide polarizer can readily be realized by depositing a metal film on a dielectric waveguide (**Figure 19(g)**). The TM modes (the electric field perpendicular to the metal film) are strongly attenuated because of the coupling to the superficial plasmon modes, whereas the TE modes are transmitted. It should be mentioned that some of the waveguides in anisotropic crystals, such as proton-exchanged waveguide in $LiNbO_3$, can be used as a waveguide polarizer. Polarization beam splitters can be realized, for example, by careful design of DC or intersecting waveguide (**Figure 19(h)**) in anisotropic crystal. Another method to implement polarization elements is to form a narrow and deep groove perpendicular to the axis of a channel waveguide and insert in

the groove a thin-film-type polarizer, half-wave plate, or quarter-wave plate with appropriate orientation.

3.05.4.2 Passive Waveguide Grating Components

Examples of passive waveguide grating components are illustrated in Figure 20. They include input/output coupler, deflector/polarization splitter, focusing grating coupler (FGC), grating lens, mode converter, and reflector/wavelength filter. The grating structures are fabricated by patterning based on photolithography, electron beam lithography, or holographic interference recording, associated with dry etching to form the grating grooves. Other fabrication techniques include holographic interference recording or holographic contact printing using a phase mask in waveguides of a photopolymer or a ultraviolet (UV)-light-sensitive material such as Ge-doped silica, and direct electron beam writing, to produce periodic modulation in the refractive index. Periodic structures for IO include fiber gratings, which are fabricated by UV-light-induced refractive index change of an optical fiber.

Various wavefront conversion functions based on the principle of holography can be incorporated in mode coupling in a planar waveguide by spatially modulating the grating pattern (forming a curved and chirped grating). A useful wavefront conversion is the lens function for focusing, collimating, and imaging. Waveguide grating elements with lens function are illustrated in Figure 20(f)–(h). Suppose that $\Phi_i(y, z)$ and $\Phi_o(y, z)$ are the phase distribution functions, on the yz waveguide grating plane, of the incident wave and the desired output wave, respectively. The desired wavefront conversion is accomplished by giving the input wavefront a phase modulation corresponding to the phase difference $\Delta\Phi = \Phi_o - \Phi_i$. The waveguide grating (waveguide hologram) for such phase modulation consists of grating lines described by

$$\begin{aligned}\Delta\Phi(y, z) &= \Phi_o(y, z) - \Phi_i(y, z) \\ &= 2m\pi (m = \cdots, -2, -1, 0, +1, +2, \cdots)\end{aligned} \quad [27]$$

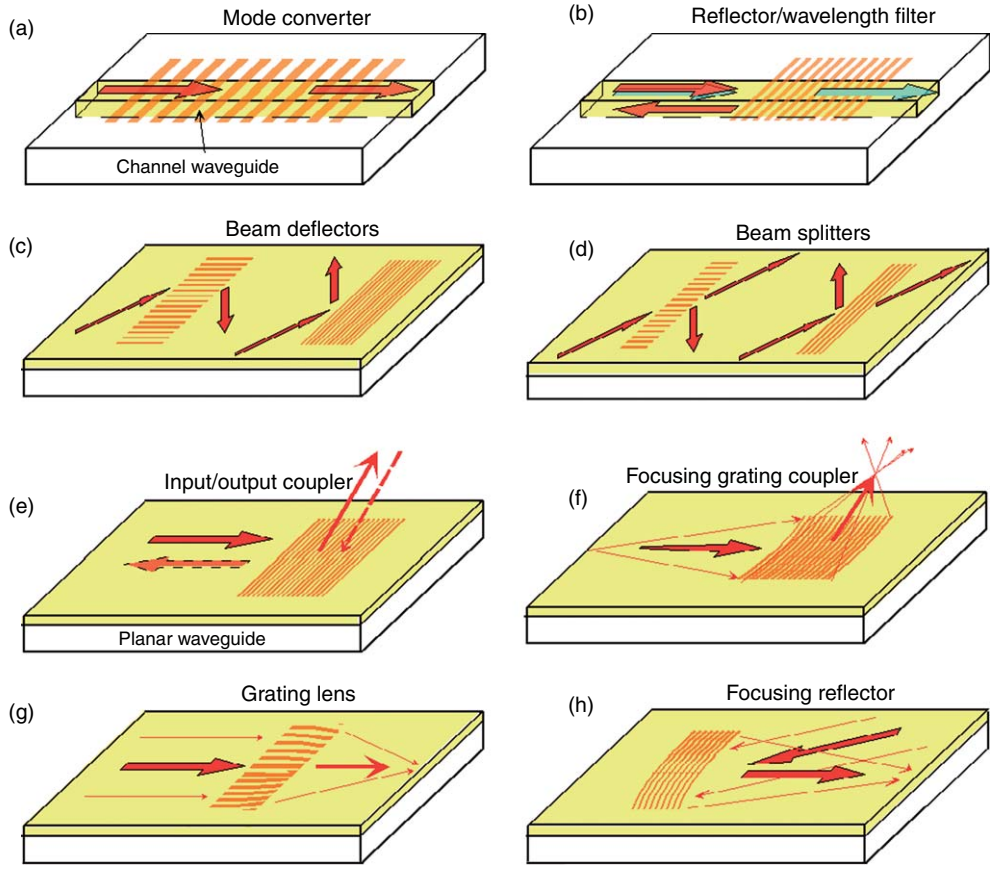

Figure 20 Various passive waveguide grating components.

The grating patterns can be generated and fabricated by computer-controlled electron beam writing technique.

3.05.4.3 Waveguide Lenses

One of the most elementary and important passive element in classic optics is a lens, which offers the functions of beam focusing, imaging, and Fourier transforming. Components that perform the lens functions in a planar waveguide are waveguide lenses. Waveguide lenses can be implemented simply by depositing thin transparent film (or ion exchange) of parabolic convex or concave pattern on a planar waveguide to change the mode index in the pattern region. This type of waveguide lens is called mode index lenses (**Figure 21(a)**), and the working principle is based on refraction. It is difficult to obtain mode index lens of short focal length, as the available index change is small.

One of the important mode index lenses is a Luneburg lens (**Figure 21(b)**), which is formed by depositing a transparent thin film with a rotation-symmetrical graded thickness on a planar waveguide. The structure realizes a graded mode index distribution designed carefully for aberration-free lens function. Another important waveguide lens is the geodesic lens (**Figure 21(c)**), which is constructed by forming a rotation-symmetrical depression on the surface of a substrate and forming a planar waveguide on the deformed surface. The ray of the guided wave changes the direction of propagation on the depression according to Fermat's principle. Although good performances can be obtained by appropriate design using Luneburg and geodesic lenses, their fabrication requires special techniques incompatible with the planar process.

Another class of waveguide lenses is diffraction lenses. It was presented in the previous subsection that waveguide holographic grating components (chirped grating lens, FGCs, etc.) can perform lens functions. A waveguide lens based partly on diffraction and partly on refraction is micro Fresnel lens (**Figure 21(d)**), which results when a convex mode index lens is segmented into zones and rectangular areas useless for lens function are deleted. The advantage of this lens is that they can be fabricated by planar lithographic process. The large wavelength dispersion of the focal length and the chromatic aberration may limit their application.

3.05.4.4 Arrayed Waveguide Gratings

A versatile device developed as wavelength multi/demultiplexers for dense wavelength division multiplexing (DWDM) photonic network systems is arrayed waveguide grating (AWG) (Smit 1988, Takahashi *et al.* 1990). The device consists of a large number of arrayed curved channel waveguides and two planar waveguides connecting them together, as shown in **Figure 22**. The optical wave transmitted through the input channel guide diverges in a sector region in the first planar part and is then divided and coupled in phase into the channel guides through the planar/channel junctions aligned on the curved (circular arc) wavefront of the diverging wave. The lengths of the channels are designed in such a manner that the optical pass difference between adjacent channel guides coincides with an integer multiple of the center wavelength λ_0. Therefore, the optical wave at λ_0 emerges in phase from the end of the channels aligned on an arc where the channels are connected to the second planar part. These wavelets form a wavefront converging into the junction to the

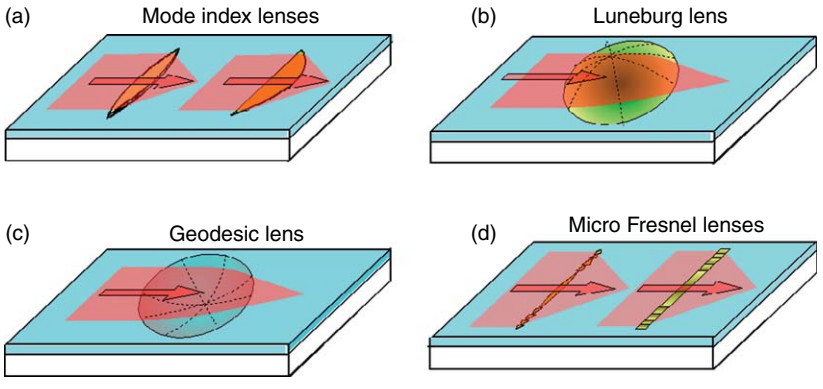

Figure 21 Various waveguide lenses.

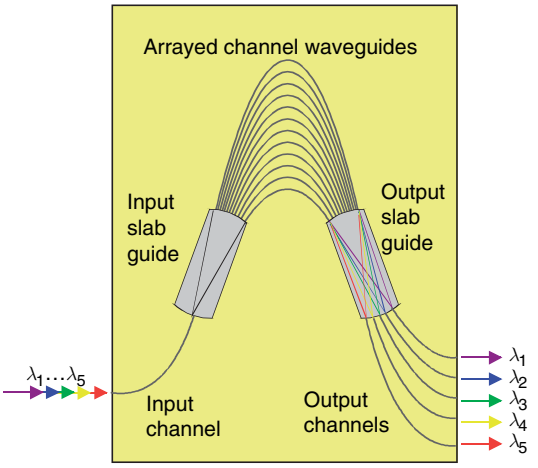

Figure 22 Schematic of an arrayed waveguide grating (AWG).

central output channel. For optical waves with wavelength deviation from λ_0, the pass difference deviates from the integer multiple of the wavelength. This gives rise to phase shifts and wavefront inclination at the planar/channel junction, and therefore, the optical wave is transmitted into another output channel depending on the wavelength deviation.

The AWGs have several advantages such as high resolution, low insertion losses, possibility of multiport input, and high degree of design flexibility. Many AWGs using silica waveguides have been developed and put into practical use. The channel number ranges from 256 channels for one-stage AWGs to 1000 channels for two-stage AWGs (Hibino 2002).

3.05.5 Active and Control Devices

3.05.5.1 Semiconductor Lasers

Many IO devices require a laser element as the coherent light source. Semiconductor LDs are well suited as a light source for IO. In the earlier hybrid IO devices, FP-type LDs were combined with dielectric waveguide components. The FP LDs, however, have problems of the poor controllability of lasing wavelength and the longitudinal mode instability such as mode hopping and multimode lasing.

The problems can be eliminated by using distributed feedback (DFB) LDs or DBR LDs (Carroll *et al.* 1998, Coldren and Corzine 1995, Suhara 2004). The fundamental structures of DFB and DBR LDs are illustrated in **Figure 23(a)** and **23(b)**, respectively. In the DFB LDs, wavelength-selective feedback is accomplished by integrating a grating structure in the active region. In the DBR LDs, grating(s) at one or both sides of the active region provides wavelength-selective feedback. The sharp wavelength selectivity of gratings assures the single longitudinal mode lasing. With appropriate design, DFB and DBR LDs maintain the single longitudinal mode lasing even under high-speed direct modulation. The lasing wavelength can be determined accurately by the grating period. QW structures with narrow gain bandwidth, lower transparency current density, and other advantages are used as an active layer to obtain high laser performances. The DFB and DBR lasers have another advantage that there is no need to form facet mirrors. This is an essential requirement for LDs for monolithic IO devices. Therefore, QW DFB and DBR LDs are now used in most IO devices.

Semiconductor optical amplifiers (SOAs) (Coldren and Corzine 1995, Suhara 2004) are implemented by depositing antireflection (AR) coating on both facets of an FP LD. SOAs can be integrated to boost the output power of an LD, amplify a weak input optical signal, or compensate for the power losses in the passive components. Another important application of SOA is the use as an optical gate switch that controls the transmission of a lightwave by binary control of the injection current.

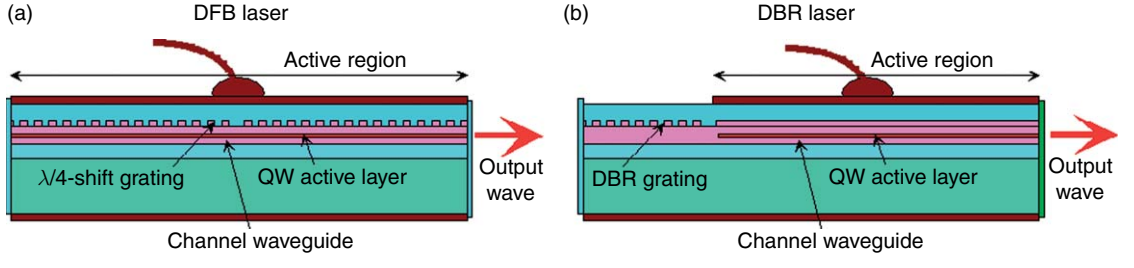

Figure 23 Schematic of fundamental cross-sectional structures of distributed feedback (DFB) and distributed Bragg reflection (DBR) lasers. QW, quantum well.

3.05.5.2 Guided Wave Photodetectors

Some IO devices require photodetectors for optical-to-electrical signal conversion. Ordinary PDs such as Si PIN (positive-intrinsic-negative) PD, Si-avalanche photo diode (Si-APD), and InGaAs PIN PD can be used by butt coupling to the waveguide. Waveguide PDs, in which the optical wave propagates along the junction interface, were also developed for monolithic integration and achieving better performances such as a large bandwidth–efficiency product (Kato 1999). PDs can be fabricated on the surface of a Si substrate for various waveguides. The guided wave coupling is accomplished by forming a taper in the SiO_2 buffer layer so that the evanescent tail overlaps with the Si PD, or using an integrated grating coupler (Suhara and Nishihara 1986). For Group III–V semiconductor waveguides, a structure similar to the active region of LDs, or actually LD itself without the feedback element, with bandgap energy control, can be used as a PD by applying appropriate back-bias voltage (Takeuchi *et al.* 1996), although an appropriate groove structure must be fabricated for electrical isolation (Hirata *et al.* 1995).

3.05.5.3 Electrooptic Devices

An effective means for high-speed dynamic control of optical wave by electric signals is to utilize the EO effects. Dielectric properties of a transparent crystal are represented by a dielectric tensor $[\boldsymbol{\varepsilon}]$, which correlates electric field and displacement vectors with dielectric constant of vacuum ε as $[\mathbf{D}] = \varepsilon[\boldsymbol{\varepsilon}][\mathbf{E}]$. The off-diagonal elements of the 3×3 tensor $[\boldsymbol{\varepsilon}]$ vanish when the coordinate axes are taken along the crystallographic optical principal axes. For optical fields, the diagonal elements are correlated with refractive indexes $\varepsilon_{11} = n_1^2, \varepsilon_{22} = n_2^2$, and $\varepsilon_{33} = n_3^2$,. For widely used uniaxial crystals, $n_1 = n_2 = n_0$ and $n_3 = n_e$, where n_0 and n_e are ordinary and extraordinary indexes, respectively. The crystals exhibit birefringence, i.e., a different refraction for ordinary and for extraordinary rays. The indexes for the ordinary and extraordinary waves propagating in the crystal in an arbitrary direction are determined by using an index ellipsoid that has radii n_o in the x- and y-directions and n_e in the z-direction. When an external electric field $\mathbf{E}^e$ is applied to the crystal through electrodes, the optical properties are slightly changed. The EO effects are described by deformation of the index ellipsoid. The deformation proportional to $\mathbf{E}^e$ is called Pockels effect and that proportional to the square of $\mathbf{E}^e$ is called Kerr effect. For Pockels effect, the deformation is given by $[\Delta(1/\mathbf{n}^2)] = [\mathbf{r}][\mathbf{E}^e]$, where $[\mathbf{r}]$ is the EO (Pockels) tensor consisting of 6×3 elements (some of them vanish because of the crystal symmetry). For example, when an external electric field of magnitude E_z^e is applied along the crystallographic $z(c)$-axis of a uniaxial crystal, the index for the ordinary wave ($\mathbf{E}$ perpendicular to the z-axis) and the index for the extraordinary wave ($\mathbf{E}$ parallel to the z-axis) change by

$$\Delta n_0 = -\frac{n_o^3 r_{13} E_z^e}{2}, \quad \Delta n_e = \frac{n_e^3 r_{33} E_z^e}{2} \qquad [28]$$

respectively.

The representative materials for EO devices are ferroelectric crystals $LiNbO_3$ and $LiTaO_3$. Various EO modulators/switches are implemented by combining channel waveguides and planar electrodes on the crystals as shown in **Figure 24**. The simplest device is phase modulators (**Figure 24(a)**). The refractive index change caused in the waveguide at the electrode gap by the driving signal gives rise to phase shift of the guided wave. The simplest waveguide intensity modulator is cutoff-type modulators (**Figure 24(b)**). An input and an output channel guide are aligned on line with short gap and electrodes are aligned at both sides of the gap. Without applied voltage, optical wave is not transferred through the gap. Voltage application gives rise to index increment that connects the channels, so that the optical wave is transmitted. Waveguide EO devices with better performances are MZI type (**Figure 24(c)**) and DC type (**Figure 24(d)**). In the MZI type, an MZI is constructed by branching waveguides (or 3 dB DCs) and parallel arm channels. Differential phase shifts are given to the guided waves propagating in each arm by the EO index change by the electric signal applied to the electrodes on the arms. The phase modulation is converted into intensity modulation by interference effect. In the DC type, a 0-dB DC is constructed by two identical channel guides aligned parallel with small gap, and electrodes are formed on the coupler. Without applied voltage, the optical wave is transmitted from one guide to another (cross state). With electric signal applied, the differential index change gives rise to the phase mismatch between channels and therefore to reduction in coupling. At a voltage, the light is

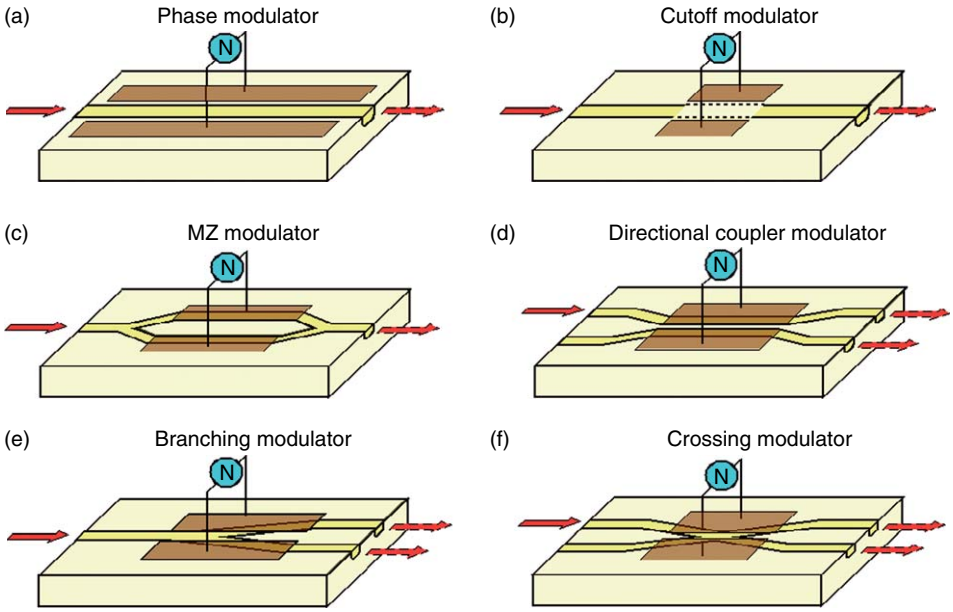

Figure 24 Various electrooptic waveguide optical modulators/switches. MZI, Mach–Zehnder interferometer.

not coupled but transmitted through the input channel (parallel state). A modification of the electrode configuration to overcome the problem that deviation of the coupling length from the complete coupling length due to fabrication errors leads to incomplete cross state is the reversed $\Delta\beta$ configuration (Alferness 1982, Kogelnik and Schmidt 1976, Thylén 1988), where one of the electrodes is split into halves and voltages of opposite polarity are applied to them. Then complete cross and parallel states can be realized by adjusting the voltage. Waveguide EO modulator/switch configurations that may allow shorter device length include those using a branching waveguide (**Figure 24(e)**) and those using a crossing waveguide (**Figure 24(f)**). In the former the branching ratio is controlled, and in the latter the TIR is controlled. Other EO devices include EO grating devices using interdigital electrodes on a planar waveguide and TE–TM mode converters using interdigital electrodes on a channel waveguide.

The EO effect is an ultrafast phenomenon originating from the change of electron states. The time response of EO devices is dominated by the driving circuit parameters and the distributed interaction of optical and RF waves. In EO devices with electrodes acting as a lumped capacitor, the modulation bandwidth and the driving voltage must be traded off, as they are inversely proportional to the electrode length L. An effective method to enhance the bandwidth without the expense of the voltage is to use the traveling wave configuration, where the modulating RF signal propagates in the same direction as the lightwave along the electrodes designed as a transmission line (Izutsu *et al.* 1977, Thylén 1988). Then the bandwidth is limited by the mismatch in the group velocities between the optical and the RF waves. It is possible to achieve a wide bandwidth and a low driving voltage simultaneously. $LiNbO_3$ waveguide phase and intensity modulators of $\sim$5 V driving voltage and up to 40 Gbits s^{-1} bandwidth are commercially available. High-speed EO polymer waveguide modulators have also been developed (Girton *et al.* 1991).

EO devices can be implemented also in Group III–V semiconductor waveguides. The Kerr effect is utilized, as the Pockels effect is small in semiconductors. In principle, EO devices with the structure and working principle similar to that of ferroelectric waveguide EO devices can be implemented, although the planar electrodes must be replaced by those of pn junction or Schottky barrier. It is also possible to implement modulator/switch using the refractive index change associated with the plasma effect caused by carrier injection, although the response is limited by the carrier lifetime (in the order of nanoseconds) and is not very fast. More effective method to implement optical intensity modulators and switches with simple device configuration is to utilize electroabsorption (EA). When an electric field is applied to a semiconductor bulk crystal, the valence and conduction band edges are inclined, and the electron wave functions are

extended slightly into the forbidden band. As a result, the effective bandgap energy is decreased, and light with a photon energy slightly smaller than the original bandgap energy is absorbed. This phenomenon is well known as the Franz–Keldish (FK) effect. In a semiconductor QW structure, the FK effect is enhanced by the electron wave confinement in the QW. In addition, absorption of light with photon energy close to the bandgap energy is significantly affected by the exciton that has a binding energy much larger than that in bulk semiconductor, and the exciton absorption spectrum is sensitively changed by the application of electric field. The total EA effect of the enhanced FK and field-dependent exciton absorption is called quantum-confined Stark effect (QCSE). By appropriate design of the QW optimized for an optical wavelength, large EA can be obtained. The absorption change is associated with the refractive index change, due to the Kramers–Kronig relation. EA modulators can be implemented simply by combining a QW waveguide with PIN-type electrodes. High-performance EA modulators of fast response (>40 GHz bandwidth), low driving voltage (<5 V), and small dimension (<1 mm) have been developed using the QCSE in multiple QW. A drawback is that the good performances are obtained only in a narrow wavelength range in the infrared region.

Nematic liquid crystals (NLCs) exhibit unique EO effect. An NLC cell is a thin layer of NLC sandwiched between two parallel substrates with narrow (several micrometers) gap. The substrate surface is treated for alignment of NLC molecule axis along a direction in the substrate surface. Because the NLC molecules are long, NLC in the cell exhibits large optical anisotropy ($|n_e - n_o|$ as large as ~ 0.1). The NLC molecular axis can be rotated within the plane of the substrate by applying an electric field through electrodes, to cause a large change (maximum is $|n_e - n_o|$)in the index for extraordinary ray with a fixed propagation direction. Waveguide optical switches are constructed, for example, by forming an NLC cell with electrodes on a crossed waveguide. The device configuration is similar to that in **Figure 24(f)**. Switch operation is accomplished by controlling the TIR at the intersection. The device has the advantage of low driving voltage, although the response is not very fast (millisecond or submillisecond range).

3.05.5.4 Thermooptic Devices

An effective method to implement lightwave control devices with waveguides of amorphous materials such as glasses and polymers is to utilize the TO effect. Because the refractive index of optical medium depends on the temperature, local heating of an optical waveguide channel gives rise to change in effective index of refraction, with which lightwave control can be accomplished. Practical TO devices can be implemented by replacing the electrodes of the EO devices shown in **Figure 24** by microheaters consisting of patterned thin metal film for Joule heating. The temperature rise and the index change are determined by the balance between heat generation and sinking, and they are proportional to the electric power fed to the heater. Many polymer materials exhibit a negative TO coefficient (temperature coefficient of index), and the magnitude is much (one order of magnitude) larger than that (positive) of silica. Therefore, polymer waveguide TO devices have the advantage of low driving power. Better stability and faster time response are obtained in TO devices using silica waveguides on an SiO_2/Si substrate. Although the response is much slower than that of EO devices, millisecond (or even submillisecond) response can be obtained by appropriate device design.

3.05.5.5 Acoustooptic Devices

When an optical medium is subjected to mechanical stresses, changes in the refractive index and birefringence are induced (photoelastic effect). The effects caused by stresses associated with an acoustic wave propagating in the medium, called AO effects, provide an effective means of controlling optical waves (Nishihara *et al.* 1989, Suhara and Nishihara 1986, Tsai 1979). Although the response of AO control is not as fast as that of EO control, unique functions such as variable angle optical deflection and optical frequency shifting can be implemented in AO devices.

Acoustic wave is a wave in the form of periodic modulation in the displacement of the medium and is expressed by the strain tensor [**S**] given by the space derivatives of the displacement vector. The stress caused by the strain is described by stress tensor [**T**], which is correlated linearly to [**S**] through Fick's law. From this relation and the equation of motion, a wave equation is derived. The equation shows that the periodic modulation propagates in the medium with a velocity v. The acoustic wavelength Λ and the frequency f are correlated by $\Lambda f = v$. In the vicinity of the surface of a medium, a surface acoustic wave (SAW) can propagate. The

amplitudes of displacement, stress, and strain of SAW are a function of the depth from the surface, and the wave is localized in a surface layer with depth comparable to the SAW wavelength Λ. The amplitudes are proportional to the square root of the SAW power density. The description of AO effects is given as the deformation of the index ellipsoid by the strain [**S**]. The deformation is correlated with [**S**] by $[\Delta(\mathbf{1}/\boldsymbol{n}^2)] = [\mathbf{p}][\mathbf{S}]$, where [**p**] is a fourth-order tensor called photoelastic tensor. The index change is proportional to the stress amplitude and is proportional to the square root of the SAW power density.

Waveguide AO devices make use of the AO effect on an optical guided wave by a SAW. They are classified into coplanar and collinear types. **Figure 25** illustrates a basic structure of coplanar AO device. It consists of a planar optical waveguide and a SAW transducer with interdigital electrodes on a substrate of ferroelectric crystal such as $LiNbO_3$. By driving the interdigital transducer (IDT) with an RF signal of frequency f, a SAW of the same frequency and a wavelength $\Lambda = v/f$ is excited through the piezoelectric effect. The SAW induces a traveling periodic modulation in the refractive index by the AO effect, and this temporal traveling grating gives rise to the coplanar diffraction of the optical guided wave. The Q parameter is defined as $Q = K^2L/\beta = 2\pi\lambda L/n_e\Lambda^2$, where λ and n_e are the wavelength and the mode index of the optical guided wave, respectively, and L is the SAW aperture. For cases where L is small or Λ is large so that $Q < 1$, the Raman–Nath diffraction takes place. The diffraction efficiency, however, cannot be very high. Devices of $Q > 10$ (large L or small Λ) are more important, as the Bragg diffraction characterized by a diffracted beam of single order with high efficiency can be obtained. Such devices are called waveguide AO Bragg cell. The propagation direction of the incident guided wave must be adjusted so as to satisfy the Bragg condition described by the closed triangle formed by the wave vectors of the incident and the diffracted optical waves and the SAW wave vector (the grating vector). The Bragg angle is given by $\theta_B = \sin^{-1}(K/2\beta) = \sin^{-1}(\lambda/2n_e\Lambda) \approx \lambda/2n_e\Lambda$. The deflection angle is given by $2\theta_B \approx \lambda/n_e\Lambda = \lambda f/n_e v$ and is approximately proportional to the frequency f of the input RF signal.

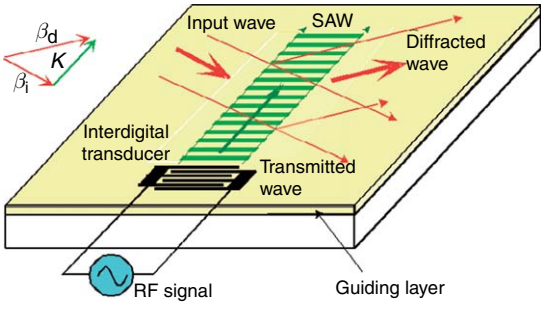

Figure 25 Waveguide acoustooptic Bragg cell. RF, radio frequency; SAW, surface acoustic wave.

The diffraction efficiency can be written as

$$\eta = \sin^2\{c\sqrt{P_s L}\} \qquad [29]$$

where P_s is the SAW power that is proportional to the RF power fed into the IDT, and c is a constant that depends on the material constants, optical wavelength, diffraction angle, and the overlap between the optical and the SAW profiles. Nearly 100% diffraction efficiency is obtained by giving appropriate RP power. In the low-efficiency region, the diffracted beam power increases approximately in proportion to the input RF power. The simplest application of the waveguide Bragg cell is its use as an AO modulator. The SAW IDT is driven by an RF signal of a constant carrier frequency with power modulated by a signal to modulate the diffracted beam intensity. Because the AO grating is traveling at a velocity v, the frequency of the diffracted wave is shifted by $\pm f$ due to the Doppler effect. This means that the AO Bragg cell can be used as an optical frequency shifter. More important application is its use as an AO deflector. The RF f is swept to scan the beam deflection angle. Because the high diffraction efficiency is obtained only at and near the Bragg condition, and the RF change gives rise to deviation from the Bragg condition, AO Bragg cells using a simple standard IDT as shown in **Figure 25** perform well only in a narrow RF region. In order to obtain a wider frequency bandwidth and deflection angle, special IDT design is required to accomplish wide SAW excitation bandwidth as well as RF impedance matching and maintain the Bragg condition. An effective method is the frequency-controlled SAW beam steering using multiple tilted array IDT, curved-finger IDT, phased array IDT, and tilted-finger chirped IDT (Tsai 1979). Bandwidth as large as 1 GHz has been obtained in $LiNbO_3$ waveguide AO Bragg cell. The temporal signal modulating the RF carrier is converted into spatial distribution by the SAW traveling effect. Therefore, a wideband Bragg cell can also be used as a spatial light modulator (SLM).

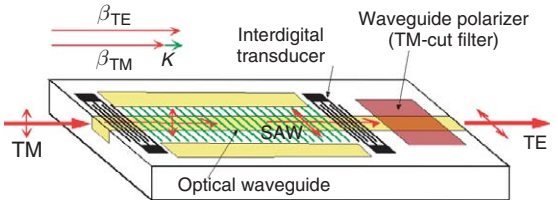

Figure 26 Waveguide acoustooptic tunable wavelength filter. SAW, surface acoustic wave; TE, transverse electric; TM, transverse magnetic.

Figure 26 illustrates a typical waveguide AO device of collinear type. It consists of a channel optical waveguide and a SAW IDT. A SAW waveguide structure for confinement in a narrow strip region may be formed to reduce the driving power. Collinear AO interaction in an anisotropic waveguide may give rise to coupling between TE and TM modes through the off-diagonal dielectric tensor element induced by AO effect. The phase-matching condition is given by

$$\begin{aligned} |\beta_{TE} - \beta_{TM}| &= \frac{2\pi}{\lambda}|N_{TE} - N_{TM}| \\ &= K = \frac{2\pi}{\Lambda} = \frac{2\pi f}{v} \end{aligned} \quad [30]$$

where β and N denote the propagation constant and the mode index, respectively. Efficient mode conversion is obtained only when the phase-matching condition is satisfied, and the conversion efficiency for interaction length L is written as

$$\eta = \sin^2\{\gamma\sqrt{P_s L}\} \quad [31]$$

An important application of AO mode converters is their use as an optical wavelength-tunable filter. Mode conversion takes place only when the phase-matching condition is satisfied at least approximately. When SAW frequency f is fixed at the value satisfying the phase-matching condition for an optical wavelength λ, a deviation in wavelength $\Delta\lambda$ results in a deviation from the phase-matching condition. The wavelength selectivity 3 dB full width is given approximately by $2\Delta\lambda/\lambda \approx 0.80\Lambda/L$. When a wavelength-selective mode converter is combined with a polarizer (or polarization beam splitter), the device works as a wavelength filter. The center wavelength can be tuned by changing the SWA frequency f. The tuning range is limited mainly by the SAW IDT bandwidth.

Although AO devices using piezoelectric (ferroelectric) crystal waveguides are described above, it is possible to construct AO devices with various material combinations, as all optical materials exhibit AO effect. They include piezoelectric waveguide on piezoelectric substrate (e.g., Ti:$LiNbO_3$), nonpiezoelectric film waveguide on piezoelectric substrate (e.g., As_2S_3 on $LiNbO_3$), piezoelectric film waveguide on nonpiezoelectric substrate (e.g., ZnO on SiO_2), and nonpiezoelectric waveguide/substrate with piezoelectric film for IDT (e.g., As_2S_3 on SiO_2/Si with ZnO IDT, and GaAs/AlGaAs/GaAs and ZnO IDT).

3.05.5.6 Nonlinear Optic Devices

NLO effects provides various unique optical functions such as optical wavelength conversion and ultrafast all-optical switching (Suhara and Fujimura 2003). The earlier R&D work on waveguide NLO devices was motivated by the need for implementation of compact short-wavelength coherent light source for optical memories. Waveguide NLO devices have also found important applications as an all-optical signal wavelength converter for WDM photonic network systems. Application of waveguide NLO devices includes ultrafast all-optical signal processing for high-speed photonic communications systems.

Figure 27(a) illustrates a fundamental waveguide quasiphase-matching (QPM)–NLO device structure. An important requirement for efficient NLO interaction for second harmonic generation (SHG), sum frequency generation (SFG), difference frequency

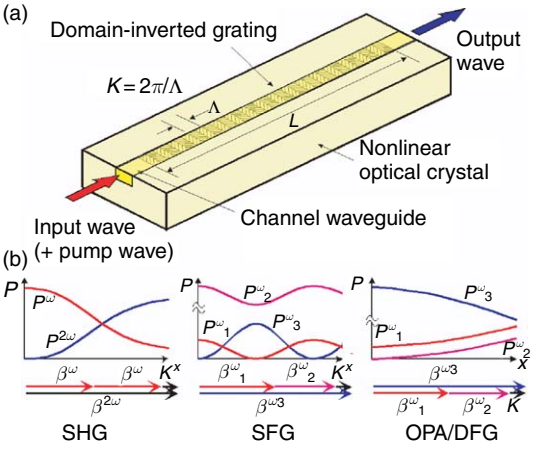

Figure 27 (a) Fundamental device configuration of waveguide quasiphase-matched (QPM) nonlinear optic (NLO) devices. (b) Optical power distributions and phase-matching diagrams for second harmonic generation (SHG), sum frequency generation (SFG), and optical parametric amplification/difference frequency generation (OPA/DFG).

generation (DFG), and optical parametric amplification (OPA) is phase matching. QPM is a technique that uses a structure with sign inversion of period Λ in the NLO coefficient along the propagation axis to compensate for the difference between the wave vectors β of the NLO polarization and the wave to be generated by the grating vector $\mathbf{K}(|\mathbf{K}| = 2\pi/\Lambda)$. The QPM condition can be described by a wave vector diagram as shown in **Figure 27(b)**, and the interaction is described by coupled mode equations. Spatial variations of the interacting wave powers are illustrated in **Figure 27(b)**.

The outstanding advantage of QPM is that the phase matching can be accomplished for any combinations of arbitrary wavelengths in the transmission region of the NLO crystal only by appropriate choice of the period, and therefore, very wide wavelength region can be covered by a single NLO crystal. Another advantage is that the maximum NLO tensor element can be exploited. By combining a QPM structure and a channel waveguide structure for confining optical waves to enhance the power densities, highly efficient and compact NLO devices of various types can be implemented. The QPM structures can be formed by periodic inversion of ferroelectric domain in NLO crystals such as $LiNbO_3$ and $LiTaO_3$. The period range is 2–20 μm for most applications. A high-voltage pulse is applied across the crystal using periodic electrodes to give electric charge corresponding to the value required to invert the spontaneous polarization.

For SHG ($\omega \rightarrow 2\omega$) under the QPM condition, the harmonic output power $P^{2\omega}$ increases with the input fundamental power P_0^{ω} approximately as $P^{2\omega} = \left(P_0^{\omega}\right)^2 \kappa_{\mathrm{SHG}}^2 L^2$, where L is the interaction length and κ_{SHG} the coupling coefficient. For SFG (ω_1, $\omega_2 \rightarrow \omega_3 = \omega_1 + \omega_2$) under the QPM condition, the output power P^{ω_3} increases approximately in proportion to $P_0^{\omega_1} P_0^{\omega_2} \kappa_{\mathrm{SHG}}^2 L^2$ in the range of small input power, while for large $P_0^{\omega_1} P_0^{\omega_2} \kappa_{\mathrm{SHG}}^2 L^2$ the interaction turns from SFG to DFG on the way of interaction region so that the output power P^{ω_3} decreases. For DFG/OPA ($\omega_1, \omega_3 \rightarrow \omega_2 = \omega_3 - \omega_1$), the difference frequency (ω_2) wave (idler wave) is generated and the input signal (ω_1) wave may be amplified. In either interaction, the wavelength bandwidth is inversely proportional to L. The SFG and OPA/DFG interactions follow the Manlay–Rowe relation, which correlates the number of photons (e.g., for SFG, the number of the generated ω_3 photons equals to the number of annihilated ω_1 photons and the number of annihilated ω_2 photons).

Many waveguide QPM SHG devices were developed for generating SH waves in wavelength region covering the visible and near-UV region. For $LiNbO_3$ waveguide QPM blue SHG generation devices, normalized conversion efficiency higher than 1500% W^{-1} has been achieved, and blue SHG laser modules have been implemented by hybrid integration with a pump semiconductor laser. Waveguide QPM DFG devices have been extensively studied as an all-optical wavelength converter for WDM photonic network, and normalized conversion efficiency higher than 1500% W^{-1} has been achieved. Several ultrafast all-optical signal processing devices using $LiNbO_3$ QPM waveguide were also reported. They include SFG device for picosecond optical sampling and picosecond SFG interferometer optical gate switches.

3.05.6 IO Devices and Applications

IO devices are implemented by integrating many components of same function, or by integrating components of different functions, to realize a higher function for a specific application. Integration schemes include hybrid integration using dielectric or ferroelectric waveguide device and butt-coupled semiconductor lasers and monolithic integration using semiconductor lasers. In the following, examples of IO devices for applications in several areas are discussed.

3.05.6.1 Signal Processing

The first application of the integrated optics concept was as an integrated optical correlator incorporating SLMs and lenses in a planar waveguide (Shubert and Harris 1968). Practical applications of RF signal processing devices were developed by using a waveguide AO Bragg cell as the SLM. The time-to-space conversion function of waveguide AO Bragg cells is utilized in combination with various types of waveguide lenses for Fourier transforming and/or imaging to develop various RF signal processing devices. Developed devices include convolvers and correlators of space-integrating type and time-integrating type (Tsai 1979).

IO RF spectrum analyzers (IOSAs), in particular, were extensively studied for their practical application to high-speed real-time radar signal analysis. Several types of IOSAs using wideband AO Bragg cells with Luneburg, geodesic (Mergerian *et al.* 1980), grating, and Fresnel waveguide lenses for Fourier

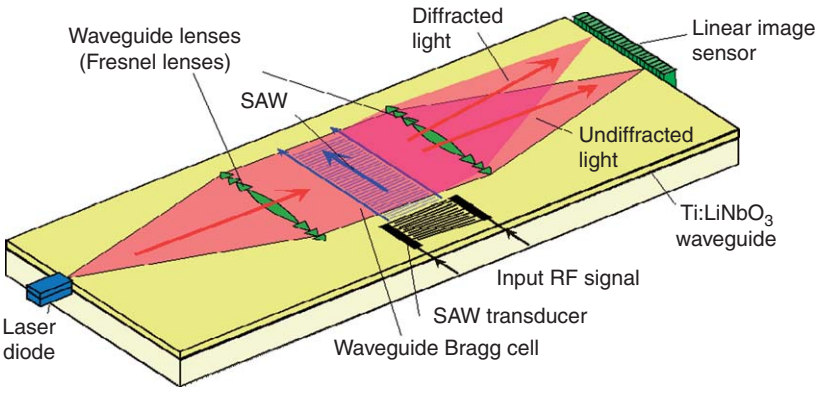

Figure 28 An integrated optic radio frequency (RF) spectrum analyzer using a waveguide acoustooptic Bragg cell and waveguide Fresnel lenses. SAW, surface acoustic wave. (Source: Suhara T, Fujiwara T, Nishihara H 1986 Proton-exchanged Fresnel waveguide lenses in Ti:$LiNbO_3$ waveguides. *Appl. Opt.* **25**, 3379–83.)

transforming were developed. **Figure 28** illustrates an IOSA using a waveguide Fresnel lens (Suhara *et al.* 1986). The RF signal to be analyzed is amplified and fed into the wideband IDT of the Bragg cell to deflect and spatially modulate the incident optical guided beam. The diffracted guided beam is then Fourier transformed by the waveguide lens and the intensity distribution on the focal line is converted to electrical signal by a linear image sensor, which gives the output spectrum signal. Typical parameters are 4 MHz resolution, 1 GHz bandwidth, and 1 μs response (analysis) time. Devices evolved from the IOSA include IO scanner for optical printer heads.

IO devices for signal processing were implemented by using EO control elements also. Many devices for high-speed electrical signal processing, such as analog-to-digital converters, analog signal multipliers, matrix–vector multipliers, and digital processors for correlation, parity generation, and error detection/correction, were implemented by integrating EO grating spatial modulators, or by integrating EO MZIs with modified electrode configurations (Taylor 1987).

3.05.6.2 Optical Communications

Optical communications have been the most important area of application of IO. Various IO devices were studied and developed. Many of them have been commercialized and put into practical use. An example of simple IO devices is $1 \times N$ couplers and $N \times N$ star couplers, which are required in multiple-access optical networks to evenly distribute optical signals to many receivers and to interconnect the transmitters and receivers. The $1 \times N$ couplers are constructed by cascading Y-branching waveguides, and the $N \times N$ star couplers are constructed by inserting a slab mixing waveguide between fan-shaped input and output channel guide arrays.

Optical switches for dynamic control of optical signal path are one of the key devices required for constructing photonic network systems, including recent advanced WDM systems using optical add/drop multiplexers (OADMs) and optical cross connects (OXCs). High-speed EO switch matrixes, such as a nonblocking 8×8 crossbar switch matrix consisting of 64 EO DCs, were implemented using $LiNbO_3$ waveguides (Thylén 1988). Several types of large-scale IO switches, such as multiple cascaded 2×2 switches, $1 \times N$ switches, and $N \times N$ switch matrixes, have been developed by using silica waveguide TO MZI switches as the fundamental building unit. The millisecond response of TO switching is appropriate for many applications in OXC and OADM systems. A high extinction ratio (>60 dB) can be achieved by cascading the MZI units. Nonblocking $N \times N$ switch matrix as large as 16×16 has been implemented (Goh *et al.* 2001) using 512 MZIs. The switch element and the waveguide layout configuration are shown in **Figure 29**. Polymer $1 \times N$ switches were also implemented by integrating Y-branching waveguide TO switches (Ooba *et al.* 2000). It should also be mentioned that many optical MEMS, free-space and fiber optic types, including optical switches, variable attenuators, tunable filters, add/drop multiplexers, gain equalizers, dispersion compensators, and polarization controllers, were developed for application to optical networks (Giles *et al.* 1999, Lin and Goldstein 2002, Motamedi 1994).

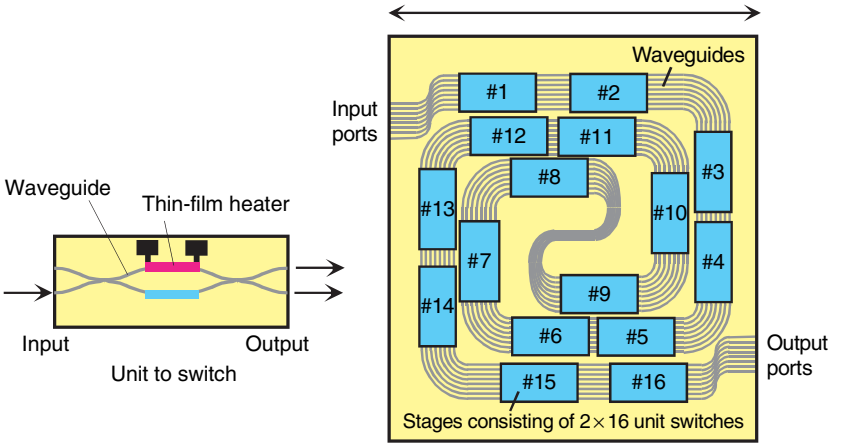

Figure 29 The unit thermooptic Mach–Zehnder interferometer switch element and the waveguide layout configuration of a nonblocking 16 × 16 switch matrix using 512 switches. (Source: Goh T, Yasu M, Hattori K, Himeno A, Okuno M, Ohmori Y 2001 Low loss and high extinction ratio strictly nonblocking 16×16 thermooptic matrix switch on 6-in wafer using silica-based planar lightwave circuit technology. *J. Lightwave Technol.* **19**, 371–9.)

WDM, proposed as an effective means of drastically enhancing the capacity of data transmission through an optical fiber, requires wavelength multiplexers and demultiplexers at the transmitter and the receiver terminals. Development of high-performance compact multi/demultiplexers has been a major subject of R&D of IO devices for optical communications. The earlier work was implementation of wavelength multi/demultiplexers using grating components as a dispersion element (Nishihara *et al.* 1989, Suhara *et al.* 1986). Waveguide demultiplexers using a curved grating, a grating and a waveguide lens, and a micrograting array were studied. **Figure 30** illustrates a demultiplexer constructed by a patterned ion-exchanged waveguide and a chirped grating butt-coupled to the waveguide (Suhara *et al.* 1982). **Figure 31** illustrates a practical IO device developed for WDM access network systems using the 1.3- and 1.5-μm bands for bidirectional signals and broadband signals (Himeno *et al.* 1998, Uchida *et al.* 1997). A silica Y-branching waveguide, a thin-film wavelength filter, an LD, and waveguide PDs are hybrid integrated on a Si platform to construct a transceiver module. The semiconductor devices were flip-chip bonded by the passive alignment technique.

Higher performances and advanced functions were accomplished by using the AWG as a key component. Development of the AWG includes modification for use as an $N \times N$ wavelength-selective star coupler, cancellation of the polarization dependence by inserting a half-wave plate, athermalization by inserting polymer section to compensate for the temperature coefficient of mode index,

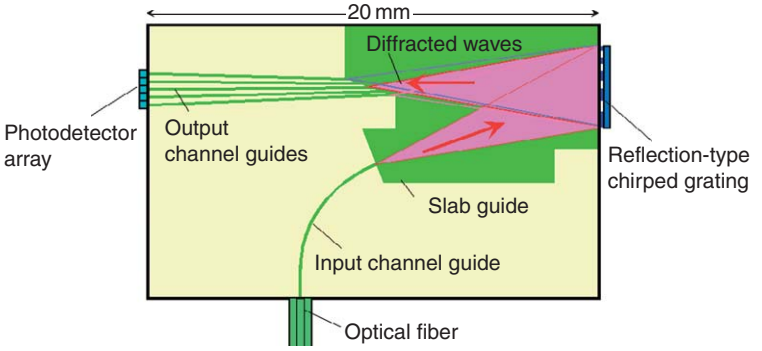

Figure 30 Wavelength demultiplexer using a reflection-type chirped grating and an ion-exchanged glass waveguide. Quantum Electron.* **4**, 913–24; Uchida N, Yamada Y, Hibino Y, Suzuki Y, Ishihara N 1997 Low-cost hybrid WDM module consisting of a spot-size converted laser diode and a waveguide photodiode on a PLC platform for access network systems. *IEICE Trans. Electron.* **E 80-C**, 88–97.)

tailoring the wavelength filter characteristics to obtain a flat passband, and reduction of the insertion loss by the use of silica waveguide and careful design (Himeno *et al.* 1998, Sugita *et al.* 2000). A two-stage AWG multi/demultiplexer of 1000 channels has been developed (Hibino 2002). AWGs are used to implement a TO wavelength-tunable filter and are also used as a building block to construct devices of more complicated functions such as reconfigurable add/drop multiplexers, channel gain equalizers, and dispersion compensators. Applications of AWG devices are not limited to optical communications but extended to optical sensing and signal processing. AWGs were also fabricated with semiconductor waveguides and were integrated with lasers and PDs to implement monolithic one-chip WDM transmitters and receivers (Yoshikuni 2002).

Various IO devices for optical communications have also been implemented by monolithic integration of semiconductor lasers with other waveguide components and devices. A typical example is a DFB laser integrated with an intensity modulator. Although optical communications signal can be produced by direct modulation of a DFB laser, the associated carrier density modulation gives rise to the lasing frequency chirping, and the resultant spectral broadening imposes limitation on the transmission capacity. An external modulator is required to solve this problem. A compact and high-speed transmitter is implemented by monolithic integration of the DFB laser and the modulator. **Figure 32** illustrates a DFB laser integrated with an EA modulator (Suzuki *et al.* 1992). DFB-EA transmitters of 40 Gbits s^{-1} data rate are commercially available.

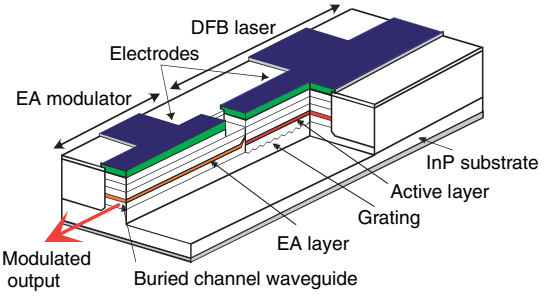

Figure 32 A distributed feedback (DFB) laser monolithically integrated with an electroabsorption (EA) external modulator.

The need of multiwavelength laser light sources with controlled wavelengths for use in WDM photonic network systems motivated the development of wavelength-tunable lasers and wavelength-selectable lasers. Various integrated tunable semiconductor lasers, such as two-section and three-section DBR lasers (Koch and Koren 1990), and advanced widely tunable lasers, such as grating-coupled sampled reflector (GCSR) laser (Oberg *et al.* 1993), superstructure grating DBR (SSDBR) lasers (Tohmori *et al.* 1993), and sampled grating DBR (SGDBR) lasers (Mason *et al.* 2000), which evolved from the multisection DBR lasers, were developed. **Figure 33** shows the cross sections of widely tunable DBR lasers. **Figure 34** illustrates an example of integrated wavelength-selectable laser consisting of eight microarray DFB lasers with slightly different lasing wavelengths, an MMI coupler, and an SOA for compensating the loss in the coupler (Hatakeyama *et al.* 2003). DFB-EA transmitter chips with assorted wavelengths for WDM systems were also developed (Kudo *et al.* 1998).

Other IO devices for optical communications include EO wavelength-tunable filters (Warzanskyj *et al.* 1988), IO heterodyne receivers for coherent transmission (Hernandez-Gil *et al.* 1989, Stallard *et al.* 1986), EO polarization controller (Heismann and Whalen 1992), and AO wavelength-selective switches (Wehrmann *et al.* 1996). **Figure 35** shows the configuration of an AO add/drop multiplexer for dynamic routing of the WDM signals (Nakazawa 2001).

3.05.6.3 Optical Interconnection

The microelectronic processing chips in present large-scale computer systems operate above gigahertz clock speed in parallel. However, severe bottlenecks of data transmission in the electrical interconnection between chips and between boards restrict the high-speed

Lett.* **12**, 762–4.)

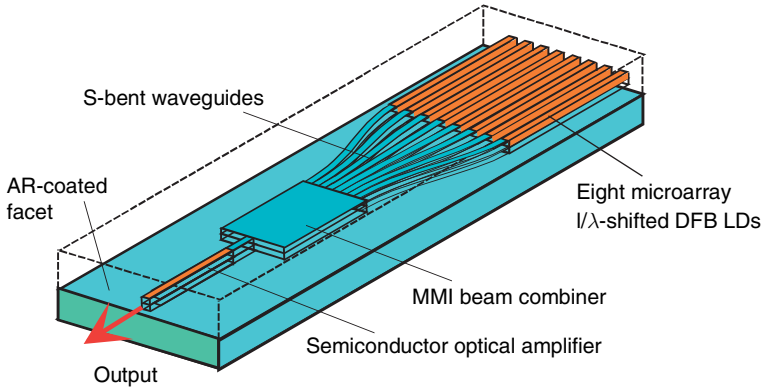

Figure 34 Integrated wavelength-selectable semiconductor laser consisting of eight microarray distributed feedback (DFB) lasers, a multimode interference coupler, and an optical amplifier. AR, antireflection; LDs, laser diodes; MMI, multimode interference. (Source: Hatakeyama H, Naniwae K, Kudo K, Suzuki N, Sudo S, Ae S, Muroya Y, Yashiki K, Satoh K, Morimoto T, Mori K, Sasaki T 2003 Wavelength-selectable microarray light sources for S-, C-, and L-band WDM systems. *IEEE Photon. Technol. Lett.* **15**, 903–5.)

processing of the systems. Optical interconnection, including high-speed parallel data transfer by laser light, as well as optical clock and data signal distribution to a large number of chips free from signal skew, is considered a promising solution to overcome this problem (Goodman *et al.* 1984). For frame-to-frame and board-to-board interconnection, optical printed circuit board (OPCB) consisting of polymer waveguides or optical fiber ribbons was developed and is widely used in combination with optical connectors and optical transmitter/receiver modules (Nordin *et al.* 1995). To achieve optical interconnection between chips in computer systems, appropriate optical components and packaging strategies for these components are required. To meet the requirements, a large number of development works are being continued (Goodman and Hutcheson 1990, Miller 2000). One of the key issues is to implement appropriate coupling elements to link the light from the laser sources (vertical cavity surface-emitting lasers) and the waveguides in the OPCB or from the waveguides to detectors (Mikawa *et al.* 2003, Ohmori *et al.* 2005). The proposed

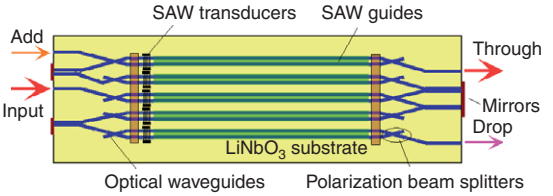

Figure 35 A multistage acoustooptic tunable filter for optical add/drop multiplexing. SAW, surface acoustic wave. (Source: Nakazawa T 2001 Integrated acousto-optic tunable filter for optical add/drop multiplexers. *Proc. Eur. Conf. Integrated Optics*, Paderborn, Germany, pp. 27–30.)

devices include the use of 45° ended waveguides and microlenses, 45° mirror and microlenses, 90° bent fiber connectors, butt-coupling devices, grating couplers, and waveguide holograms (Lin *et al.* 1990).

3.05.6.4 Optical Memories

The first work on the application of waveguide technique to optical memories was proposed and demonstrated using waveguide holograms (Suhara *et al.* 1976). The waveguide holograms stores pictorial information in a photorefractive recording layer on a planar waveguide, and the information is read out by a guided wave. They offer the possibility of hologram integration and have a very large field of view. Integrated waveguide hologram memories using EO switches and liquid-crystal switch matrixes were demonstrated (Suhara *et al.* 1981). Multilayer waveguide hologram memories are also developed (Imai *et al.* 2003).

An important device for application in optical memories is IO disk pickup (IODPU). The prototype first proposed and demonstrated is shown in **Figure 36** (Suhara *et al.* 1985, Ura *et al.* 1986). The device is constructed by an FGC, a twin grating focusing beam splitter (TGFBS), and an array of four PDs all integrated in a planar glass waveguide on an SiO_2/Si substrate. The FGC focuses the light from a butt-coupled LD into a diffraction-limited small spot on the surface of a disk. The light reflected by the disk is collected back into the waveguide by the FGC and is processed and deflected by the TGFBS to the PDs. Readout and focusing/tracking error signals are obtained by electric processing of the four photocurrents. IO differential detection system for MO disk pickup was also developed (Suhara *et al.* 1990). Readout of standard ISO CD disk by an IODPU was demonstrated by using a He–Ne laser (Kawakubo *et al.* 1994). A monolithic IO disk pickup head consisting of a DFB LD, grating components, and PDs in a semiconductor QW waveguide was also proposed and studied (Suhara *et al.* 1996).

3.05.6.5 Optical Sensors

Some of the characteristics of waveguide components are sensitive under ambient conditions and this can

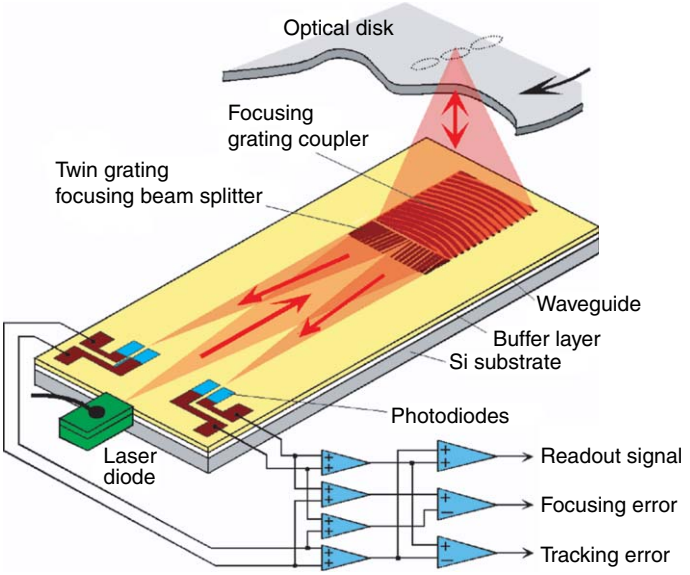

Figure 36 An integrated optic disk pickup device. (Sources: Suhara T, Ura S, Nishihara H, Koyama J 1985 An integrated optic disc pickup device. *Int. Conf. Integrated Optics Optical Fiber Communications*, Venice, Italy; Ura S, Suhara T, Nishihara H, Koyama J 1986 An integrated-optic disk pickup device. *J. Lightwave Technol.* **4**, 913–7.)

be made use of when developing sensor devices (Taylor 1987). The simplest example is the use of a waveguide interferometer as a temperature sensor head. A number of asymmetric waveguide MZIs with different arm lengths are integrated, and a laser light of constant power is fed into the input port. Because the mode index and therefore the phase difference between the waves transmitted through each arm depend on the ambient temperature, the optical power detected at the output port varies sinusoidally with temperature. The use of several sets of asymmetric interferometers with different arm length differences enables temperature measurement free from sensitivity null and ambiguity due to the periodic response of a single interferometer. The device construction can also be applied to implement sensors for other physical quantities, by incorporating some element to convert the change in the quantity to be sensed into change in the mode index. The surface of the interferometer waveguides is covered by a cladding layer with a sensing window on one of the interferometer arms. Then the device can sense the change in the refractive index of liquid in contact with the waveguide within the window area and thus can be used as chemical sensors and biomedical sensors. Waveguide sensor heads based on the similar concept include humidity sensors with polymer and metal film cladding and pressure sensors with interferometer arm formed in a diaphragm structure. Similar sensor devices can be implemented also with other interferometer configurations, such as Michelson interferometer, and also with ring resonators. Waveguide grating components such as input coupler can also be used as a sensor element, as the coupling efficiency for a fixed optical wavelength and the incident angle depend on the mode. A compact IO immunosensor using chirped grating couplers was developed (Dübendorfer and Kunz 1998).

Waveguide EO modulators have application as a sensor head for RF signal. An RF antenna is directly connected to the electrodes of an EO modulator, and the modulated optical wave is transmitted through an optical fiber to a remote receiver.

One of the IO sensing devices is the IODPU presented in Section 3.05.6.4. Another sensor that evolved from the IODPU is an IO head of confocal scanning laser microscope that was proposed and demonstrated (Sheard *et al.* 1993). IO interferometer position/displacement sensor (IOPS) was constructed based on the grating elements (Suhara *et al.* 1989). **Figure 37** illustrates the IOPS demonstrated as the first fully integrated monolithic one-chip optical sensor device (Suhara *et al.* 1995). A monolithic double Michelson interferometer

(Source: Suhara T, Taniguchi T, Uemukai U, Nishihara H, Hirata T, Iio S, Suehiro M 1995 Monolithic integrated-optic position/displacement sensor using waveguide ratings and QW-DFB laser. *IEEE Photon. Technol. Lett.* **7**, 1195–7.)

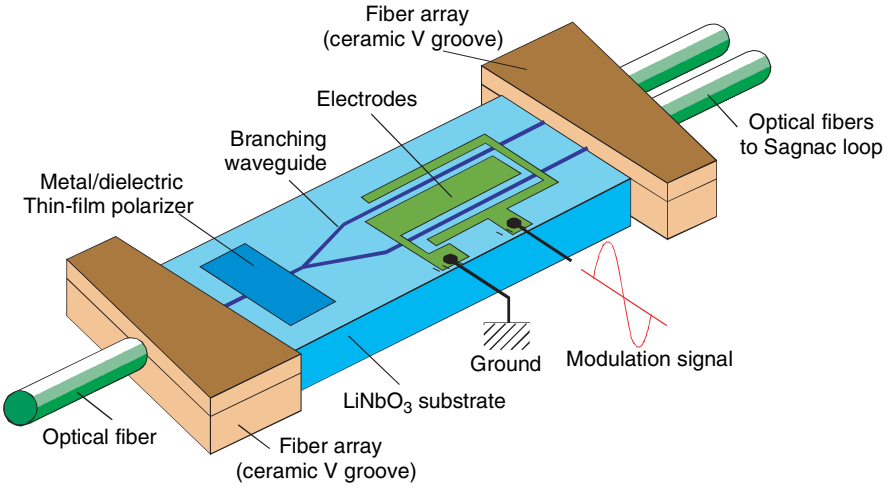

Figure 38 An integrated optic electrooptic push–pull phase modulator, a polarizer and a Y-branching waveguide for optical fiber gyroscope. (Source: Kozuka Y, Toyoda S, Ichigi T, Kondo A, Asano M, Osugi Y, Kondo J, Hamajima A, Ejiri T, Enomoto A 1999 High-reliable $LiNbO_3$ integrated optical device for consumer fiber optic gyroscopes. *Proc. Eur. Conf. Integrated Optics*, pp. 269–74.)

displacement sensor was also demonstrated (Hofstetter *et al.* 1996).

An IO device for fiber laser Doppler velocimeter (LDV) was constructed by integrating an EO frequency shifter, a TE–TM mode converter, and a mode splitter (Toda *et al.* 1987). The device produces a frequency-shifted reference wave and combines it with a Doppler-shifted signal wave transmitted through an optical fiber sensing probe for heterodyne detection.

Advanced fiber sensors include the fiber optic laser gyroscope using the Sagnac interferometer configuration for rotation sensing. To achieve high sensitivity and high stability, several components such as couplers and a phase modulator or a frequency shifter are required. IO devices for constructing such a gyroscope in combination with a fiber coil were developed. As the frequency shifter, an EO phase modulator driven by a sawtooth wave, called serrodyne frequency shifter, and AO Bragg cell integrated with waveguide lenses were developed (Taylor 1987). One of the commercialized device is constructed with an EO push–pull phase modulator, a polarizer, and a Y-branching waveguide in $LiNbO_3$ substrate as shown in **Figure 38** (Kozuka *et al.* 1999). Considerable effort was devoted also to the implementation of IO version of Sagnac interferometer rotation sensor. The first device using a silica waveguide coil fully integrated on a Si substrate demonstrated a typical sensitivity of $1°s^{-1}$ and a full linearity in $\pm 900° s^{-1}$ (Mottier and Pouteau 1997). IO gyro device using silica waveguide and TO phase shifter was also demonstrated (Suzuki *et al.* 2000).

3.05.7 Conclusions

An outline of the IO technology was presented – the concept, theories, materials, design and fabrication techniques, and applications. The IO technology has now reached a high degree of maturity and is one of the most important elements supporting information technology. Many IO devices for optical communications and optical memories including those with advanced functions are or will be practically and widely used. It is clearly expected that further development will be made to improve the performances and production efficiency and to extend the applications. Future research and development works are also required to extend the applications in the areas such as optical interconnection for computer systems, integrated waveguide nonlinear optics, biomedical sensing, and quantum information processing.

Biography

Toshiaki Suhara was born in Wakayama, Japan, in 1950. He received the BS, MS, and Ph.D. degrees from Osaka University in 1973, 1975, and 1978, respectively. He joined the Department of Electronics, Faculty of Engineering, Osaka University, in 1978, and has been a professor since 2002. He was at the Technical Research Centre of Finland as a guest research scientist in 1980, and in Glasgow University, UK, as a guest research fellow in 1986–1987, and in Chalmers University of Technology, Sweden, as a guest professor in 1997. He is the author of *Optical Integrated Circuits* (Japanese, English, and Chinese versions), *Semiconductor Laser Fundamentals* (Japanese, Chinese, and English versions), *Waveguide Nonlinear-optic Devices*, *Quantum Electronics*, and *Optical-wave Engineering*. His research interests include integrated optics, integrated semiconductor lasers, nonlinear optics, quantum optics, and optical memories. Professor Suhara is a senior member of IEEE, and a member of OSA, SPIE, IEICE of Japan, and the Japan Society of Applied Physics. He received the Paper Awards in 1977, 1986, 1994, and 2001, and the Young Engineer Award in 1980 from IEICE, and the Paper Award in 1990 from the Laser Society of Japan. In 1995, he was awarded the IBM Japan Science Prize.

3.06.1 Introduction

The most frequent cause of blindness is the degeneration of retinal cells. In developed countries macula degeneration is the main cause of blindness and strong visual impairment. About 25–30 million people are suffering from this disease. During the course of this disease the tissue of the macula is first destroyed. This leads to a complete loss of vision in the center. Reading is no longer possible for these patients. Another group of people suffer from retinitis pigmentosa (RP), a genetic disorder. The worldwide number amounts to 1–3 million affected persons. This disease often starts with night blindness.

Contrast and color vision as well as visual acuity diminish. Peripheral vision diminishes first. The field of vision becomes narrower and is completely lost in later stages. These symptoms are because of the degeneration of the light-sensitive rods and cones of the retina. This process can continue for decades depending on the individual concerned. **Figure 1** shows a photograph of a normal and a degenerated retina.

Bypassing the nonworking retina or the optic nerve by a technical implant might restore some vision to these patients. Brindley and Lewin (1968) were the first who tried to develop a visual prosthesis that stimulates the visual cortex directly for blind people.

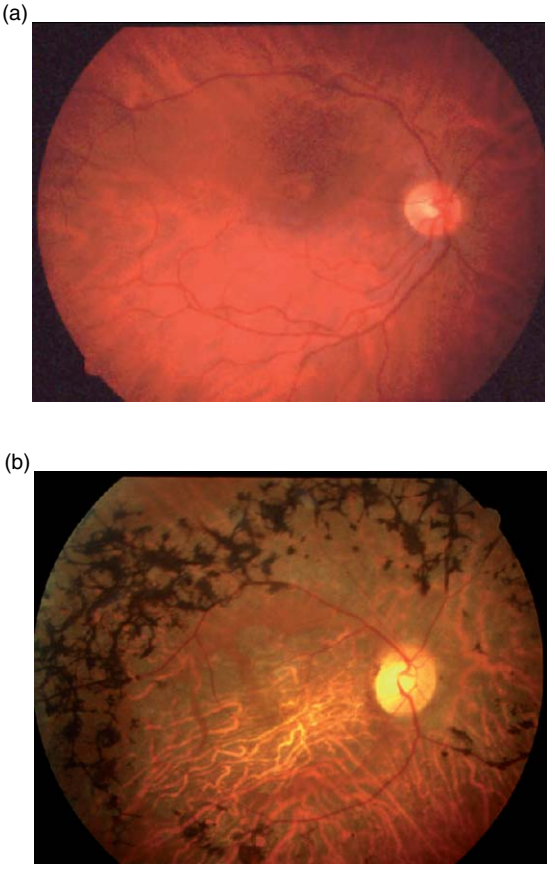

Figure 1 (a) Photograph of a normal human retina. The yellow spot in the right part is the optic disk where the optic nerve leaves the eye. It has a diameter of about 3 mm. (b) Photograph of a degenerated retina of a retinitis pigmentosa (RP) patient. The degenerated regions at the outer border look black. The field of vision is drastically reduced to the central part of the retina. (Courtesy P Walter, Department of Ophthalmology, University Hospital, RWTH Aachen University, Aachen, Germany.)

3.06.2 Physiology of the Human Eye

A cross section of the human eye is shown in **Figure 2** . The outer tissue consists of three different layers: the sclerotic coat, the choroidic coat, and the retina. The retina is the inner layer of the eye and contains the light receptors: the rods and the cones (**Figure 3**). The number of rods is about 60–125 million. Rods are extremely sensitive to light but do not provide a sharp image. They allow us to see in the dark and are responsible for peripheral vision. The number of cones is about 3–6.5 million. They need bright light to be functional. Cones are responsible for seeing colors and provide us with sharp images. An area with a diameter of about 5 mm around the central axis of the retina is called the macula, the region for sharp vision. In the center of the macula, there is a small pit with a diameter of about 1.5 mm, the fovea, the center responsible for sharpest vision. Here the cones are present at a very high density (10%). It is important to emphasize that the rods and cones are beneath a layer of neural cells. Light enters the eye through the cornea, the pupil, and the lens; passes the vitreous body and the neural cells; and is absorbed by the cones and rods. Here the light is converted into nerve pulses that are transferred via different neural cells (bipolar and ganglion cells) to the brain through the optic nerve. Within the visual cortex, a region of the brain that is responsible for visual perception, the incoming pulses are interpreted and converted to a picture. In the eyes of vertebrates, signal processing starts in the retina. There is a complex array of interneurons (amacrine and horizontal cells) that form synapses with the bipolar and ganglion cells by forming a neural network that modifies the activity (**Figure 3**). By this a preprocessing of the signals is achieved, leading, for example, to an increase in contrast. More detailed information on the physiology of the eye can be found in Kaufman and Alm (2003).

3.06.3 Possible Approaches to Restore Vision by Electrical Stimulation of Nerve Cells

3.06.3.1 Retinal Implants

3.06.3.1.1 System concept

Studies have found that about 30% of retinal ganglion cells of RP patients are still functional even after several years of blindness. It has been shown that electrical stimulation of ganglion cells inside the eye at the inner surface of the retina results in visual sensations (Benjamin *et al.* 1994, Santos *et al.* 1997, Stone *et al.* 1992). Therefore, bypassing the degenerated photoreceptors by electrically stimulating the retinal ganglion cells seems possible (Humayun *et al.* 1996, 1999, Walter Heimann 2000, Wyatt *et al.* 1994). By this, action potentials are evoked in retinal ganglion cells, causing a visual sensation.

Most approaches presented up to now for a retinal implant use, besides the implant, an extraocular part that records visual images. The images are transformed by a digital signal processor (DSP) into corresponding signals for stimulation of the nerve cells. These signals are transmitted to the receiver unit of an implant. Integrated circuitry of this unit decodes the signals and transfers the data to a stimulation circuitry that selects stimulation electrodes of the implant and generates current pulses to the electrodes (Schwarz *et al.* 2000). By this, action potentials in the nerve cells of the retina, in the optic nerve, or in the nerve cells of the visual cortex are evoked, causing a visual sensation.

3.06.3.1.2 Subretinal stimulation

Several groups are working on the concept of subretinal stimulation (e.g., Chow 1993, Peachey and Chow 1999, Sachs and Gabel 2004, Schwahn *et al.* 2001, Zrenner 2002, Zrenner *et al.* 1999).

In the subretinal approach the degenerated photoreceptors are replaced by a chip that has a microphotodiode array together with a stimulation electrode array implanted in it (**Figures 3** and **4**). By using the natural optics of the eye an image is mapped onto the photodiode array. The photodiodes respond to the incoming light. Depending on the output of the photodiodes, on-chip electronics generate the necessary stimulation currents that activate healthy bipolar and ganglion cell layers of the retina. Positioning and fixation of the implant are relatively easy. No external camera or image processing is needed. Eye movement can be used to localize objects. A basic requirement for this approach to work is that the optics of the eye should still be functional. Because of the necessary on-chip electronics, energy is required for operation and it has to be supplied externally by means of electromagnetic or optic coupling.

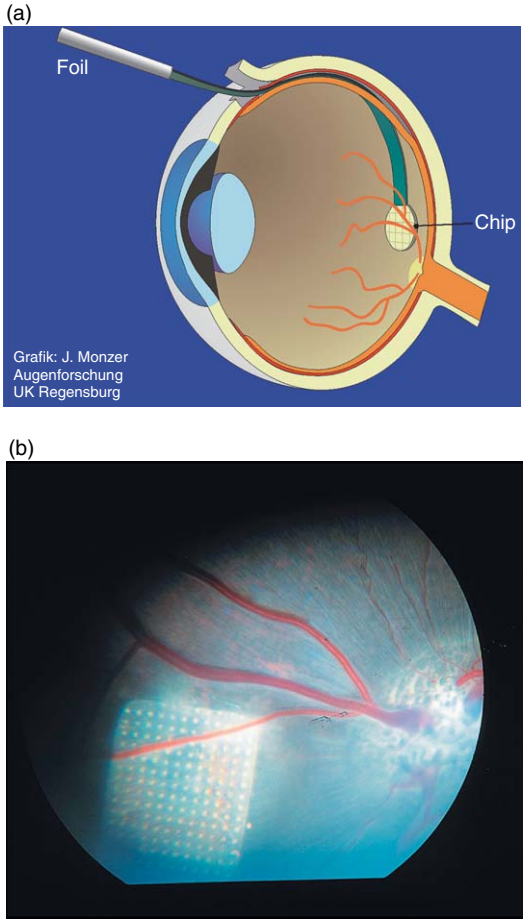

Figure 4 (a) Schematic view of the subretinal approach. (b) View of a subretinal implant through the ganglion cell layer. The implant has an area of 3 mm × 3 mm and a thickness of 50 μm. One thousand five hundred pixels are on this implant with a pixel size of 70 μm × 70 μm. It can be clearly seen from the blood vessel over the implant that the implant is located subretinally. (Courtesy Retinal Implant AG, Reutlingen, Germany.)

3.06.3.1.3 Epiretinal stimulation

In contrast to subretinal stimulation, in epiretinal implants the stimulation electrodes are placed on the inner side of the retina (compare **Figure 3**). Therefore, retinal ganglion cells are stimulated where some preprocessing of the signals has already taken place. This preprocessing has to be considered when transforming the visual information recorded by a camera into data stimulation patterns. Eckmiller (1995, 1996, 1997) was the first to introduce the concept of a retina encoder simulating the neural network of the retina.

The concept of an epiretinal system can be illustrated through **Figure 5** (Schwarz *et al.* 2000). The system consists of an extraocular and an intraocular part. The components of the extraocular part are a complementary metal oxide semiconductor (CMOS) image sensor for capturing visual images, an artificial neural net that imitates the functions of different ganglion layers of the retina (retina encoder), and a transmitter. The visual images are transformed by the neural net into control signals for the stimulation electrodes (Mokwa 2004). These signals are finally transmitted into the interior of the eye together with the energy needed to supply the intraocular part. For the energy transfer a radio frequency (RF) link is used (Mokwa 2004) and for data transfer an RF link (Mokwa 2004) or an optic link is used (Laube *et al.* 2004a). The intraocular part of the system consists of a receiver circuitry where energy and data signals are separated, the clock signal is extracted, and the data signals are decoded. These data are transferred via a microcable to the stimulation unit. An integrated circuitry decodes the information from the serial data stream. From this information the requested electrode is selected and current pulses are generated. **Figure 6** shows an encapsulated implant that was developed by the German EPIRET team and was successfully tested in animals (Laube *et al.* 2004a, b, Mokwa 2004, Walter *et al.* 2005).

Second Sight and partners introduced a similar system based on a cochlea implant (Humayun *et al.* 2003). The whole electronics are mounted on the outer side of the sclera. From there a cable is laid through the sclera into the eye. The cable connects a 4 × 4 stimulation electrode array that is fit into the retina (**Figure 7**).

3.06.3.2 Stimulation of the Optic Nerve

In the optic nerve about 1 million nerve fibers connect the retina with the visual cortex. It is possible to reach the optic nerve through surgery. The idea of realizing a visual prosthesis by stimulating the optic nerve was conceived by Thomas Mortimer and Claude Veraart in the early 1990s (Veraart *et al.* 1998). **Figure 8** shows a schematic view of the system.

For stimulation of the fibers a cuff electrode is wound around the optic nerve. This cuff is connected to implanted stimulation electronics. Information is exchanged with the implanted system via telemetry. The team of Claude Veraart developed a spiral cuff that was made from rubber and flexible silicone (**Figure 9**). The first version was equipped with four platinum contacts and a later version with eight. The electrode diameter is about 3 mm;

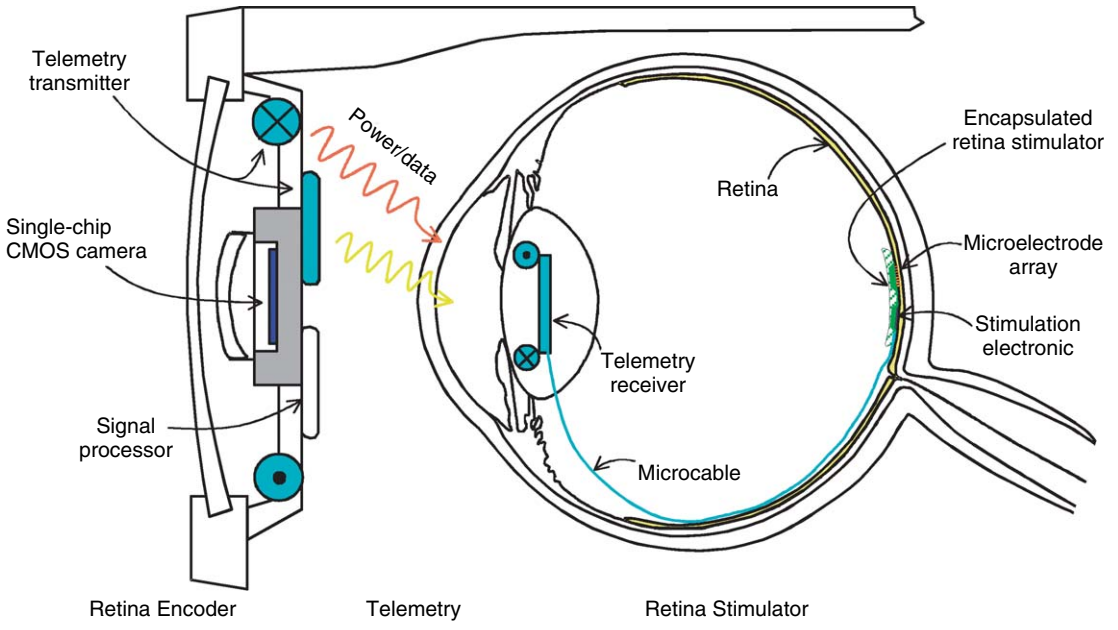

Figure 5 System concept of a visual prosthesis for epiretinal stimulation.

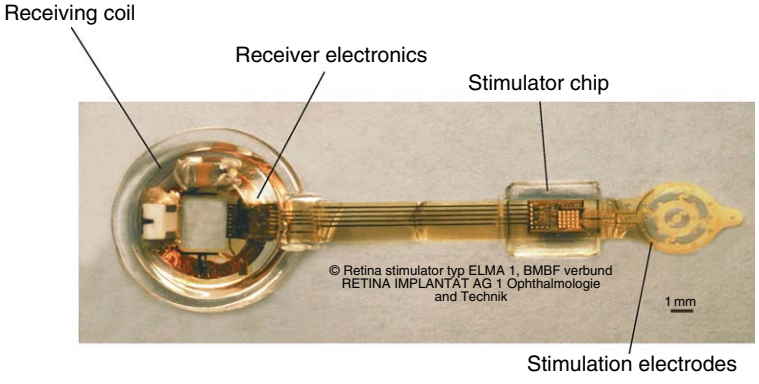

Figure 6 Photograph of an encapsulated retinal implant. The left part is formed like an artificial lens. This lens contains the receiver coil and the chip. A microcable connects the receiver electronics with the stimulator chip. At the right, the stimulating electrodes are visible. The whole implant is encapsulated with silicone.

stimulator dimensions are 25 mm× 30 mm with a 6-mm thickness. To avoid any lesion of the optic nerve the geometry of the cuff allows to adapt continuously to the diameter of the optic nerve while at the same time guaranteeing close contact between the electrode and the nerve. The first implantation of the system was performed in February 1998 by Prof. C. Raftopoulos of the Neurosurgery Unit, St-Luc's University Hospital, UCL, Brussels, on a long-term RP patient (Veraart *et al.* 1998). A spiral cuff was implanted intracranially around the right optic nerve. The cable of the cuff was connected to the implanted connector and was brought through the skin at the clavicle level where it ended in an external connector. By this, optic nerve stimulation could be achieved by using external stimulators. After a brief period of convalescence, the optic nerve fibers were electrically stimulated. The patient reported on sensations (phosphenes) generated by the stimulation of the optic nerve that were exclusively visual. These phosphenes can be obtained at low thresholds. The characteristics of the phosphenes depend on the conditions of electrical stimulation like pulse shape and frequency (Delbecke *et al.* 2003).

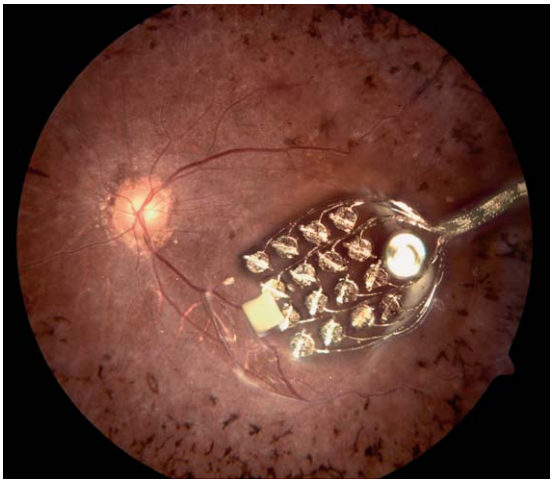

Figure 7 Photograph of a passive epiretinal stimulation array placed on the retina. The array size is about 6 mm × 6 mm and contains 16 stimulation electrodes on a flexible foil. The array is fixed on the retina by a retinal tag placed just to the right of the stimulation electrodes. The stimulation electrodes are connected to electronics outside the eye by a cable that penetrates the sclera (Humayun *et al.* 2003). (Photograph by Jessica Dougall, Copyright 2005, Doheny Eye Institute and Second Sight Medical Products, Inc. All rights reserved, USA.)

Later in 2000, a neurostimulator and an antenna were implanted below the skin and connected to the previously implanted spiral cuff electrode. The X-ray photograph in **Figure 10** shows the different parts of the implanted system (Veraart *et al.* 2003).

3.06.3.3 Stimulation of the Visual Cortex

Some patients have lost their vision because the fibers of the optic nerve lost their function. In these cases only a cortical implant can help. Like in epiretinal implants, the hardware components of such a system are a camera that converts light into electrical signals and an implantable interface to the nervous system. In addition, software that converts the image to an appropriate stimulation pattern, thus transforming an image to a retinotropic map, is needed. This information is transmitted to the cortical implant that has stimulation electrodes implanted in the visual cortex (**Figure 11**). By proper stimulation a phosphene pattern is produced. But there is a difference to retinal implants. A square electrode array will elicit a square grid of phosphenes (Dagnellie 2006). Stimulation of the visual cortex will lead to a

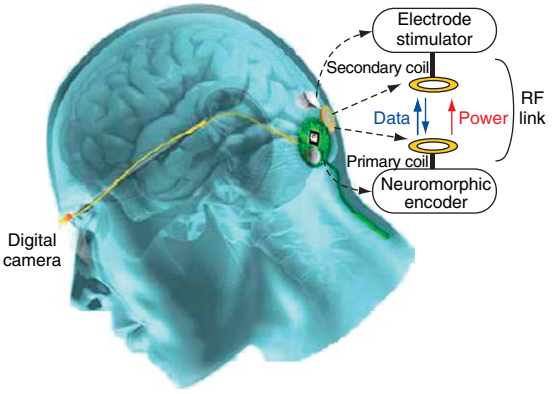

Figure 11 Schema of a cortical neuroprosthesis system. (Source: Reprinted from Piedade *et al.* 2005. © 2005 IEEE.)

phosphene pattern that is likely to be quite irregular. It is necessary to establish crude cortical maps by proper techniques before prosthesis implantation in order to know where to place the electrodes (Dagnellie 2006).

Dobelle *et al.* (1976) performed the implantation of a 64-channel platinum disk electrode array on the surface of the occipital cortex of blind patients. These electrodes were interfaced with a camera consisting of a 100×100 charge-coupled phototransistor array. Random letters were recorded by the camera. According to this information 6 out of the 64 electrodes were stimulated. The patients reported that they were able to recognize characters. However, stimulation on the brain's surface has some drawbacks: to stimulate the target cell in the brain a relatively high voltage is needed and it is not possible to stimulate small groups of cells.

These disadvantages of planar surface electrodes can be overcome by using penetrating electrodes. They can be in direct contact with the target cell. Thus, the voltage needed is drastically reduced (Maynard 2001, Troyk *et al.* 2003). **Figure 12(a)** and **12(b)** shows the configuration Troyk *et al.* (2003) used in their experiments. **Figure 13(a)** and **13(b)** shows two examples of penetrating electrodes developed at the University of Utah (Maynard 2001).

The needle electrodes are about 80 µm in diameter at the base and have a length of 1.5 mm (typically 100 in a 10×10 square grid). They are made from doped silicon. Besides the sharpened tip, the needles are electrically isolated. Each electrode is connected via a bonded, isolated 25-µm wire to a percutaneous connector. Electrode impedances of 100–500 kΩ were measured with a current of

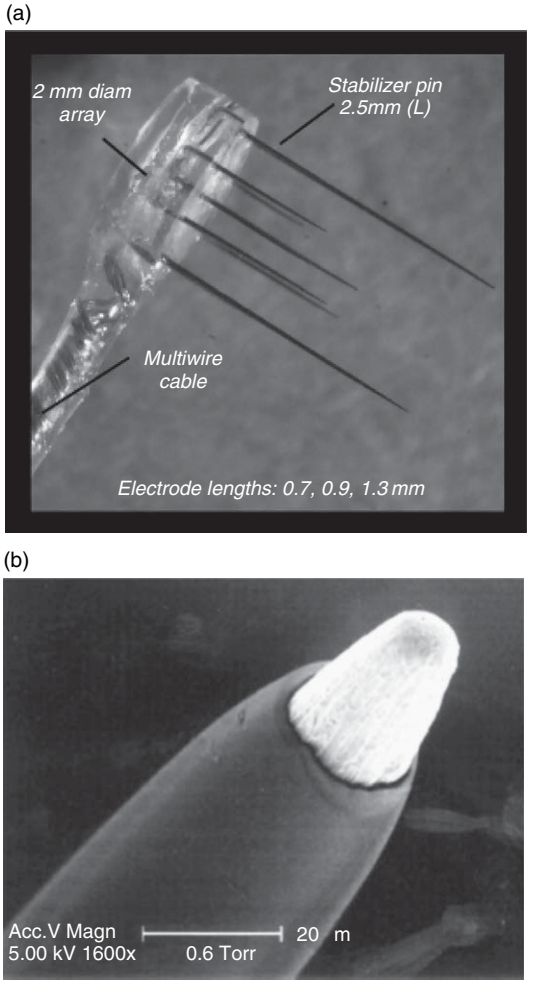

Figure 12 (a) Configuration of HMRI (Hunter Medical Research Institute) arrays used for implantation. The long stabilizer pins help to maintain the position of the array in the cortex (Troyk *et al.* 2003). (Courtesy P R Troyk, Illinois Institute of Technology, USA, with permission of Blackwell Publishing.)

100 nA at 1 kHz. These electrodes were implanted successfully in trained animals for 100 days.

While the cortical implant has the potential to help a greater number of people than does the retinal implant, it may require a longer investigation period because it involves implanting a device into the brain and because it has not been studied as much as the retinal implant.

3.06.3.4 Biohybrid Retinal Implants

A biohybrid retinal implant combines regenerative medicine with retinal implants. Microelectromechanical

systems (MEMS) is combined with nerve cells that are grown on top of stimulation electrodes. In an epiretinal approach Yagi from Nagoya University cultured nerve cells on top of electrodes (Yagi *et al.* 1999). If nerve cells and Schwann cells are brought together, the lengthening of nerve cells is promoted by factors that are produced in the Schwann cells. An artificial optic nerve can be prepared from Schwann cells and the extracellular matrix. The axons of the nerve cells are guided to the higher visual cortex. They are used as a cable to connect the MEMS electrodes with the visual cortex (**Figure 14**). It is assumed that after a connection of the nerve fibers with nerve cells of the visual cortex is formed, the nerve fibers transmit signals to the visual cortex in response to electrical stimulation of the fibers by a stimulation electrode array (Yagi *et al.* 1999). The hybrid retinal implant requires neither the retinal ganglion cells nor the optic nerve.

For successful electrical stimulation it is necessary that the stimulation electrodes be in close proximity to the nerve cell. This is being studied at Stanford University by using a subretinal approach. The nerve cells are brought in the proximity of the stimulation sites by so-called retinal migration. Retinal cells migrate rapidly (within 48–72 h) into a perforated subretinal implant while preserving their axonal connections to the retina above the implant (Palanker *et al.* 2004a, b, 2005). Within the pores in the implant, stimulating electrodes can be positioned and in this way an intimate proximity between electrodes and target cells is automatically achieved along the whole surface of the implant (**Figure 15**) (Palanker *et al.* 2005).

3.06.4 Technical Challenges

3.06.4.1 Fabrication of Flexible Retinal Implants

During surgery the implant is pushed into the eye through a tiny cut in the cornea. Flexibility and foldability of the implant allow for a smaller cut and

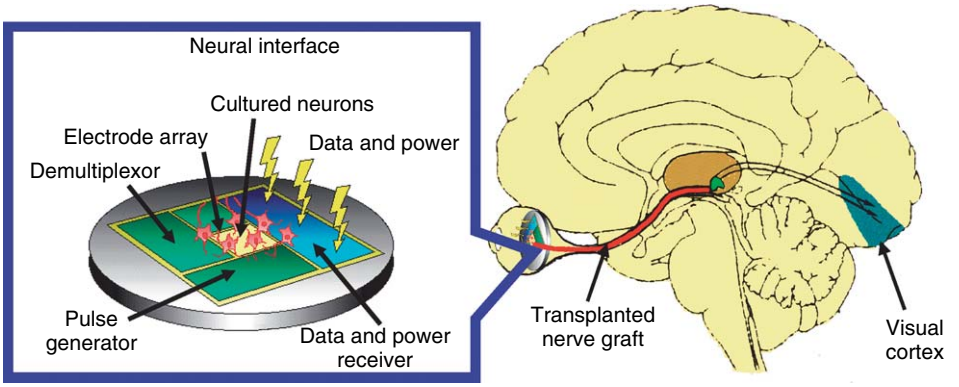

Figure 14 Schematic view of the system proposed by Yagi (Yagi *et al.* 1999). The neural interface consists of a silicon chip with circuitry that communicates with an external system. Neurons are cultured on an electrode array and will grow through a transplanted nerve graft toward the visual cortex. Figure 15 Concept of protruding electrodes on the subretinal array penetrating deep into the retina after migration of the retinal cells into the empty spaces between the pillars. Penetration depth is set according to the length of the pillars, which are insulated at the sides and exposed at the top. (Source: Palanker D *et al*. Design of a high resolution optoelectronic retinal hypothesis. *J. Neural Eng.* **2**, S105–20; reproduced with permission from IOP Publishing Ltd.)

hence less invasive surgery. Because of these requirements, the production of the implant by using a thin polyimide foil and a flexible electroplated coil seems to be the most promising choice (Mokwa 2004).

A typical fabrication process is described in Hungar *et al.* (2005). The polyimide foils are produced using standard and nonstandard wafer-level processes. Silicon wafers (4″) coated with a sacrificial layer are used as substrates for the production process. Polyimide is spin-coated onto the sacrificial layer and structured along the outlines of the implants and around the electrode array in the form of cloverleaves. This structuring is necessary not only to define the separation lines between implants but also to speed up the etching of the sacrificial layer at the end of the production process. In an electroplating step, gold wiring is grown before a second polyimide film is spin-coated and patterned. At this point, the trenches forming the outlines of the implant and the cloverleaves of the electrode array are structured and the openings of the pads and electrodes are etched. A second gold electroplating step is performed to add 26 µm to the height of the electrodes. At this point, the implants could in principle be assembled to fully functional telemetric eye prostheses. However, the electrode material gold has some disadvantages with regard to electrical stimulation of nerve cells. Therefore, a suitable coating material like iridium oxide is added to the electrodes. The coating is done by reactive DC magnetron sputtering from an iridium target in an argon/oxygen plasma (Slavcheva *et al.* 2004). Parylene C is then added from a gas phase to form a biocompatible protective coating. Parylene C has a long history of use in permanent medical implants, and it is an FDA-approved USP class VI polymer and is hence suitable for chronic implantation (Schmidt *et al.* 1988, Yuen *et al.* 1987). On the electrodes, holes are etched into the Parylene C film so that the electrodes can electrically contact the ganglion cells of the retina. A schematic view of the cross section of an electrode and an implant is shown in **Figure 16**.

Finally, the implants are removed from the wafer by etching away the sacrificial layer (Hungar *et al.* 2005). Then the implant is coated with silicone as an additional biocompatible protective layer. As the electrodes have to remain free from silicone, a special mould must be used for this process step. The complete encapsulated implant is shown in **Figure 6**. Biocompatibility and long-term stability of this implant were studied in a simple model (Stieglitz *et al.* 2003). No degradation was found within a period of 1 year.

Figure 17 shows a photograph of a second-generation prototype of the implant shown in **Figure 5** before encapsulation with silicone, with the main components mounted onto a flexible polyimide tape (from left to right): receiver coil, capacitor, diode,

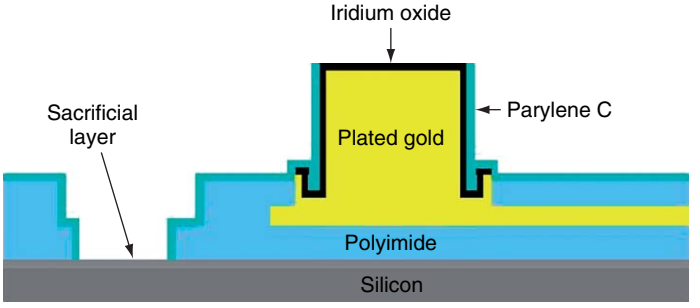

Figure 16 Schematic view of wafer-level cross section of an electrode and an implant.

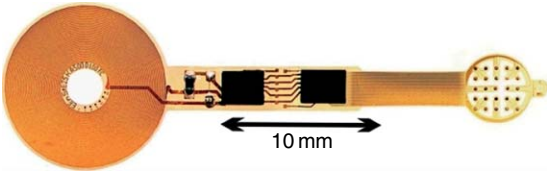

Figure 17 Second-generation prototype of a telemetric eye prosthesis. (Source: Mokwa 2004 MEMS technologies for epiretinal stimulation of the retina. *J. Micromech. Microeng.* **14**, 12–16.)

receiver chip, stimulation chip, microcable, and a 5×5 array of 3D iridium oxide-covered gold electrodes (Mokwa 2004, Wessling *et al.* 2005).

Around the electrodes the polyimide tape is patterned in the shape of cloverleaves, with each carrying four electrodes. This gives the implant additional flexibility, allowing it to be better adapted to the round shape of the retina and hence improving electrical contact between the electrodes and the retina.

3.06.4.2 Stimulation Electrodes

3.06.4.2.1 Requirements for stimulation electrodes

In view of their specific application the implantable electrodes must fulfill several very stringent requirements such as a miniaturized geometry (to match the limited space in the biological units and to ensure a good stimulation selectivity), softness and flexibility (to prevent damage to the surrounding tissue due to mechanical stress), and long-term stability and corrosion resistance (to withstand the corrosive attack of the physiological environment). Biocompatibility is another very important feature of the stimulating electrodes because stimulation must be accomplished without leakage of toxic products that cause damage to the neural cells. However, the most essential precondition for the success of functional electrostimulation (FES) is the availability of highly electroactive electrode materials capable of delivering enough charges across the phase boundary stimulating electrode/stimulated tissue as well as the low impedance of this boundary, especially in the frequency range of 10 Hz to 1 kHz, which is relevant for neural stimulation (Blau *et al.* 1997, Fröhling *et al.* 1996). It is difficult to find a material conforming to all these requirements. Thus, the practical decisions taken are often a compromise.

3.06.4.2.2 Research on stimulation electrodes

In the search for the ideal candidate, microelectrodes of different shapes and sizes have been fabricated, including planar disk electrodes (Agnew *et al.* 1983, Hesse *et al.* 2000, McCreery *et al.* 1990), tethered microwires and intrafascicular electrodes (Googall *et al.* 1993, Naughton and Horch 1996, Silva *et al.* 1998, Yoshida and Horch 1993a, b), cuff electrodes (Duysens and Stein 1978, Meier *et al.* 1986, Schuettler *et al.* 2002, Veraart *et al.* 1998), and various microfabricated 2D and 3D microelectrode arrays (Anderson *et al.* 1989, Rutten 2002, Tanghe *et al.* 1990, Weiland and Anderson 2000). The electroactive metallic materials that have been tested as stimulating electrodes are numerous, the ones most frequently used being Ti, TiN, and different Ti alloys (Blau *et al.* 1997, Haemmerle *et al.* 2002, Walter and Heimann 2000), Au (Haemmerle *et al.* 2002, Hung *et al.* 2002), Pt and some of its alloys such as Pt/W and Pt/Ir (Hesse *et al.* 2000, Lee *et al.* 2002, Yoshida and Horch 1993b), and most recently Ir and IrO_x (Anderson *et al.* 1989, Blau *et al.* 1997, Bolz *et al.* 1995, Fröhling *et al.* 1996, Fröhling *et al.* 1998, Lee *et al.* 2002, Walter and Heimann 2000, Weiland and Anderson 2000).

The performance of a metallic electrode in a physiological fluid environment is mainly determined by the properties of the phase boundary electrode/tissue. This boundary is a complex system exhibiting nonohmic behavior. From a physical point of view it acts as an electrochemical transducer exchanging electrons with ions, the current carriers in the electrode and the electrolyte (body fluid), respectively. As the stimulation of the neuronal action potential depends on the amount of charge transferred across the phase boundary, it is important to select an electrode material that is capable of delivering high charge densities reversibly, i.e., a material that possesses a high charge delivery capacity, Q_{CDC}– a parameter that describes the highest possible charge accumulation at the electrode in a defined environment. The charge delivery must be accomplished safely, which means without occurrence of irreversible processes such as gas evolution due to water electrolysis, major pH changes, metal dissolution, or oxidation of organics that cause damage to the neural cells. A reversible charge injection is possible by two basic mechanisms: capacitive charging and discharging of the electrical double layer formed on the phase boundary and Faradaic redox reactions involving species that remain bound

to the electrode surface. It is ideal from a safety point of view to stimulate only capacitively, and the initial focus has been on the search for capacitive electrodes. An example of such an electrode material is TiN. It has been extensively tested and has shown typical capacitive electrochemical behavior and a very good corrosion resistance in different electrolytes (Haemmerle *et al.* 2002, Janders *et al.* 1997, Walter and Heimann 2000). The capacitive stimulation, although safe, has one essential disadvantage. It seriously limits the transferable charge: generally only 20–30 $\mu C\,cm^{-2}$ are passed during the charging of the electrical double layer of a smooth electrode material (Cambell and Jones 1992). This layer behaves as a parallel plate capacitor and its capacitance is proportional to the electrochemically active surface.

3.06.4.2.3 Enhancement of charge delivery capacity

The miniaturization of the stimulating electrodes enhances the spatial resolution and the selectivity of the stimulation. On the other hand, the smaller the electrode the lower the charge transfer and the higher the impedance of the phase boundary. In order to overcome this contradiction an active area that is as large as possible must be integrated on an electrode of limited size. This can be achieved to some extent by preparing macroporous structures through sintering, etching, electrochemical plating, and plasma-enhanced chemical or physical vapor deposition (Bolz *et al.* 1995, Fröhling *et al.* 1996, Hung *et al.* 2002, Janders *et al.* 1997, Naughton and Horch 1996).

The Faradaic mechanism is an alternative stimulation mechanism that requires the usage of electroactive electrode materials capable of transferring high charges through reversible redox reactions in the safe water window potential range, i.e., between the potentials of H_2 and O_2 evolution. In this case the current flow across the phase boundary is due to changes in the oxidation state of the participating materials. The ability of various noble metals to act through this stimulation mechanism has been studied extensively. For instance, the silver–silver chloride electrode (Ag/AgCl) has been widely used for measuring the action potential. However, it has been found that when in contact with biological tissue, the silver chloride on the surface dissolves and causes inflammations due to its toxicity. That limits its application for stimulation purposes (Moussy and Harrison 1994, Yuen *et al.* 1987). Application of gold, another noble metal known for its biocompatibility, is also restricted (Haemmerle *et al.* 2002, Janders *et al.* 1997) due to the low current densities of its redox reactions in physiological solutions and the narrow potential range in which it shows reversible electrochemical behavior (Slavcheva *et al.* 2002). The elements of the platinum group have received special attention because they have at least two different oxidation numbers and hence higher electrochemical activity. Some of these metals like osmium are toxic, while the charge-delivering capacity of others, for example, palladium, is not high enough (Fröhling 1996). One of the metals that has been used often in FES is platinum (Anderson *et al.* 1989, Hesse *et al.* 2000, Hung *et al.* 1999, Humayun *et al.* 1996, Lee *et al.* 2002, Naughton and Horch 1996, Walter and Heimann 2000, Yoshida and Horch 1993b). It has a stable reversible electrochemical behavior in a comparatively broad potential range (from –0.6 to 1.0 V). Its charge delivery capacity is between 100 and 400 $\mu C\,cm^{-2}$ (Brummer and Turner 1977a, b, Brummer *et al.* 1983, Cambell and Jones 1992) and can be increased by electroplating platinum black on the top of a platinum electrode (Brummer *et al.* 1983, Cambell and Jones 1992, Naughton and Horch 1996). However, these electroplated platinum black films have a flimsy dendritic structure and are mechanically not stable. Hence some amount of charge is always lost due to metal dissolution, especially when used in the long term (Brummer and Turner 1977a, b, Fröhling *et al.* 1996, Hung *et al.* 2002, Janders *et al.* 1997). Some platinum alloys (platinum/tungsten, platinum/iridium) have also been tested as stimulating electrodes. For instance, 70% platinum/30% iridium has been used because of its greater mechanical strength when compared to pure platinum (Robblee *et al.* 1983). Another alloy, 90% platinum/10% iridium, has recently been used in heart pacemakers. A drawback of platinum and its alloys, according to some authors (Gielen and Bergveld 1982), is their unstable impedance in the low-frequency range. Other metals from the platinum group, namely rhodium, ruthenium, and iridium, can take up to four different oxidation states and thus they possess an increased electroactivity. However, it has been demonstrated that in the case of rhodium and ruthenium, the low initial impedance of the phase boundary electrode/electrolyte increases essentially during electrochemical loading and that their long-term stability is not adequate for FES (Fröhling *et al.* 1996). Thus, among all the tested materials, iridium seems to be the most promising

candidate for implantable stimulating electrodes. It is an attractive alternative to platinum mainly because it has four oxidation states (platinum has two) and has shown a superior corrosion resistance. Another characteristic feature of iridium that is beneficial for FES is its ability to form a contact with an aqueous environment, hydrated oxide surface layers, resulting in an increased electrochemically active surface and a higher charge delivery capacity (Robblee *et al.* 1983, Weiland and Anderson 2000). The formation of these oxide layers requires continuous potential cycling between defined lower and upper potential limits specific for the electrolyte medium. The films obtained are known as anodic/activated iridium oxide films (AIROFs). It has been unambiguously proved that AIROFs have a 100-fold higher charge delivery capacity compared to nonactivated pure iridium electrode and a very broad safe potential range (free of gas generation). The problem with these films from the FES point of view arises in connection with their long-term stability (Blau *et al.* 1997).

Another method for producing iridium oxide is by reactive sputtering of iridium in an oxygen atmosphere (Bestaoui *et al.* 1993, Wessling *et al.* 2005). The obtained films, known as sputtered iridium oxide films (SIROFs), have a highly developed fractal surface with a microporous structure and a density of about $10\,g\,cm^{-3}$ (**Figure 18**). SIROFs have unusual electrocatalytic properties and are highly efficient anodes for water electrolysis. They possess a very low overvoltage for oxygen evolution and are stable at high potentials where other catalysts corrode at a significant rate. They also exhibit an outstanding charge delivery capacity (**Table 1**).

Table 1 Charge delivery capacity of different metals

Material	Q_{CDC} ($\mu C\ cm^{-2}$)
Au	490
TiN	687
Pt	4134
Ir	17 078
IrO_x	28 450
IrO_x (after activation)	95 100

3.06.4.3 Appearance of Phosphenes

Phosphenes caused by electrical stimulation may be fuzzy, irregular in shape, varying in size and color, and limited in brightness range and gray-scale resolution; their positions may be scattered relative to an idealized grid (Dagnellie 2006). In retinal prostheses the positional irregularities can be expected to be small, but they can be widely scattered in cortical implants. Therefore, it is very important to determine these properties for each phosphene and to perform inverse image transformation to achieve the closest approximation between the original and the perceived pictures (Dagnellie 2006). For an epiretinal system, Eckmiller and others (Eckmiller 1995, 1997, Eckmiller *et al.* 2005) proposed an adaptive learning retina encoder to perform image preprocessing to optimize stimulus perception by the implant wearer (**Figure 19**). This has to be an interactive and iterative process.

The retina encoder was designed as a neural net with flexible antagonistic receptive field properties (receptive field–adaptive biology–inspired pulse

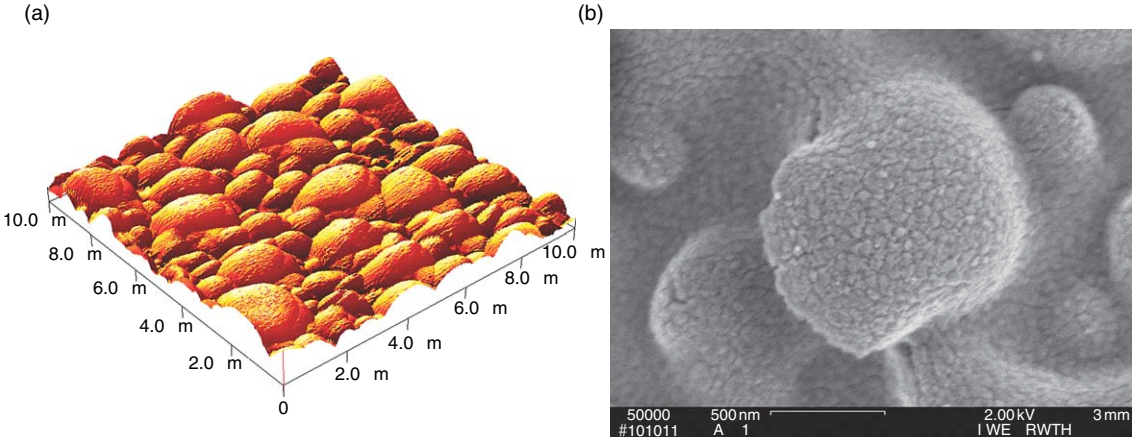

Figure 18 (a) Sputtered iridium oxide film (SIROF) surface after activation (atomic force microscopy). (b) SIROF surface after activation (scanning electron microscopy).

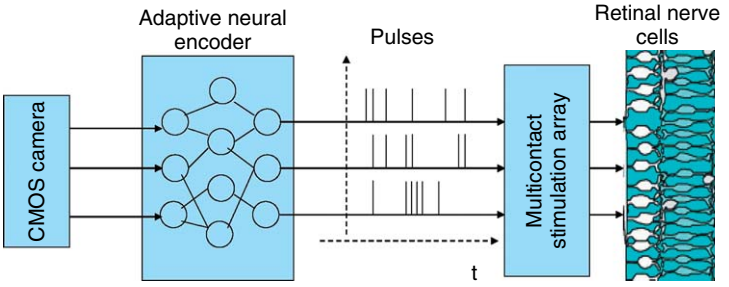

Figure 19 Working scheme of an adaptive encoder.

processing neural network, RF-BPN). The RF-BPN module allows for modification of spatial and/or temporal parameters in order to adjust the RF-BPN to the desired receptive field properties of a given ganglion cell. Specifically, in a learning process each RF-BPN module can be tuned to the receptive field properties of different cell types in the retina with regard to parameters such as RF center and time constants (Eckmiller 1995).

3.06.5 Clinical Studies

3.06.5.1 Verification of Visual Cortex Activation by Epiretinal Stimulation of Animals

In different experimental approaches it could be proven that electrical stimulation of the retina of animals leads to relevant activation of the corresponding areas of the visual cortex. Walter and Heimann (2000) proved the activation by noninvasive recording of evoked potentials after epiretinal electrical stimulation. By recording neuron activity with intracortical electrodes, it could be shown by Schanze, Eckhorn, and coworkers that the stimulation of a distinct area of the retina leads to cortical activation of the corresponding area. The cortex activations after electrical stimulation take place at the same area where the retinal ganglion cells are represented in natural sight (Eger *et al.* 2005, Schanze *et al.* 2002, 2003).

Complete epiretinal systems (compare **Figure 6**) were implanted into mini pigs and cats. Full telemetric functioning could be shown with several systems. **Figure 20** shows a cortical recording from a mini pig after telemetric stimulation of retinal ganglion cells. As expected, the response can be seen in about 25 ms after stimulation (Laube *et al.* 2004a, b).

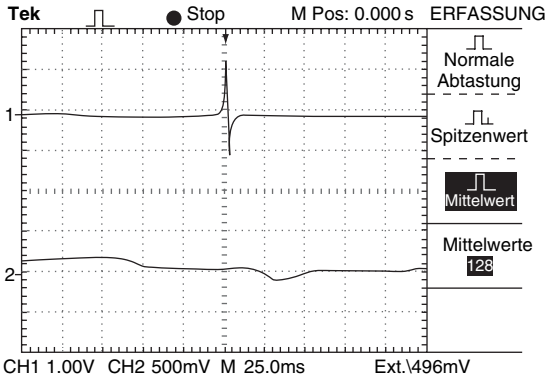

Figure 20 Cortical recording after electrical stimulation of the retinal ganglion cells of a mini pig by a retinal implant (system shown in **Figure 6**); the upper curve shows a stimulation artifact; the lower curve shows the cortical response after electrical stimulation. (Courtesy Laube, Department of Ophthalmology University Essen, Germany.)

In **Figure 21** the area of cortical activity of a cat during electrical stimulation is given. This picture was obtained by the method of optical imaging. The method distinguishes between oxygenized and deoxygenized hemoglobin. Thus, the areas of active and less active metabolism can be distinguished. The areas of increased activation in **Figure 20** correspond to the areas on the retina that had been electrically stimulated (Walter *et al.* 2005).

3.06.5.2 Experiences with Epiretinal Stimulation in Humans

Currently a lot of research activities are going on for developing implantable retina stimulators. The development of epiretinal implants seems to be relatively close to a product. Several working groups have been conducting acute trials on the question whether blind RP patients recognize visual sensations after electrical stimulation. In these trials, electrodes were

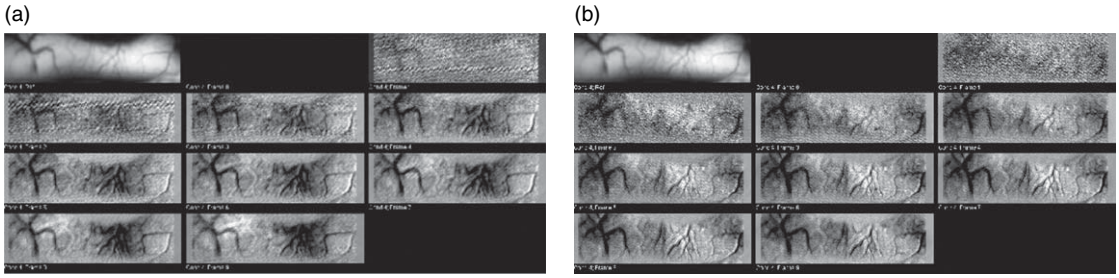

Figure 21 (a) Optical imaging from the visual cortex of a cat during electrical stimulation of the corresponding regions on the retina. The black regions in the right part of the pictures show increased oxygen consumption in areas of the visual cortex that correspond to the stimulated areas of the retina (Walter *et al.* 2005). (b) Control experiment without stimulation pulses (Walter *et al.* 2005). (Courtesy P Walter, Department of Ophthalmology, University Hospital, RWTH Aachen University, Aachen, Germany.)

placed on the retina under the conditions of vitrectomy and the patients were asked whether they had visual sensations. By this the current threshold for stimulation was obtained. The results differ very much partly because of the different experimental conditions for the electrode configuration. Values between several microamperes and milliamperes were reported (Humayun *et al.* 1996, 2003, Rizzo *et al.* 2003a, b).

The US company Second Sight has already implanted a system with 16 stimulation electrodes for chronic application in six patients. The German company IIP Technologies used their system for semichronic studies in two patients (Wickelgren 2006).

3.06.6 Conclusions

Various successful approaches for developing an artificial retina have been presented in this chapter. It is estimated that in a couple of years complete systems will be available for chronic implantation in humans. With respect to the total retina implant system there are still many unanswered and maybe unknown questions with regard to the high complexity of the system. Questions concerning a long-term stable fixation, a long-term stable stimulation, and the minimization of power consumption of the implant have to be answered before chronic implantation in humans.

These examples have shown that MEMS technology is a powerful tool for realizing small and complex electronic implants. This technology will help to increase the functionality of existing systems in a significant way. New applications that nobody thought that they were possible some years ago will be possible. These intelligent implants and prostheses will support the field of home care to a great extent. They will also have a strong impact on clinical research. Implants of the future will have an increased biological part like the biohybrids mentioned earlier.

Biography

Wilfried Mokwa received the Dipl.-Phys. degree in Physics from the RWTH Aachen University, Germany, in 1977 and the Dr. rer. nat. degree in 1981 from the same university. From 1981 on he worked at the Department of Experimental Condensed Matter Physics at the RWTH Aachen University on studies of catalytic reactions on gas sensor surfaces. Then he joined the Fraunhofer Institute of Microelectronic Circuits and Systems (IMS) in Duisburg, Germany, in 1985. At the IMS he managed a group working on the monolithic integration of silicon sensors. In 1996 he became a full professor in the Faculty of Electrical Engineering at the RWTH Aachen University where he is director of chair 1 of the Institute of Materials in Electrical Engineering (IWE-1) with special interests in the field of MEMS technologies for medical applications.

3.07.1 Introduction

Ubiquitous broadband communication has revolutionized all aspects of our lives in the early 21st century, affecting business and personal commerce, workplace mobility and globalization, military operations and security awareness, information distribution, learning, shopping, and entertainment, leading to unheralded empowerment of the individual. The infrastructure supporting and reliably delivering all this information within and between cities, countries, and continents is based on fiber-optic transport. The significant advantage of fiber-optic transport over alternative methods is its unique ability to carry high bit-rate information streams for substantial distances. This ability is the culmination of decades of research in the field of photonics, providing us with the elements of today's optical communication systems: diverse laser sources, high-speed optoelectronic devices for modulation and detection, low-loss optical fibers, optical amplifiers, dispersion management solutions, and means for multiplexing and demultiplexing many wavelength channels. But as optical communication systems flourished, and branched out further, and with improvements in transport distances and data rates, it became necessary and more economically viable to operate the transport infrastructure as optical networks, as opposed to static optical communication links. Optical networks are remotely managed, able to respond to changes in traffic demand and system conditions, and combine electronic and optical switches at the network nodes. The migration toward optical communication networks requires new components and subsystem elements that provide the functionality to enable the operation of these networks. These elements need to provide the adaptability, reconfigurability, and control to the network at relatively slow rates ranging from approximately a millisecond scale when service protection from failure is concerned to seconds and minutes for monitoring purposes. These requirements fit well with the capabilities of optical microsystems that rely on mechanical motion of micron-scale structures.

Optical microsystems and microelectromechanical system (MEMS) actuation are highly compatible, as the MEMS feature sizes are comparable in size to the optical wavelength. This compatibility enables interference-based devices to be constructed, and whose response will change significantly for wavelength-scale motion. MEMS brings many of the advantages of macroscopic elements, such as mirrors, shutters, translation stages, and lenses, but on a submillimeter scale. They maintain the performance of their macroscopic counterparts on account of the well-established microfabrication processes that have been developed by the electronics industry. MEMS is a batch fabrication method, driving down cost in mass production. MEMS devices can be highly complex, implementing the functional element that interacts with the optical field, its support structure, actuation mechanism, and alignment features, all with micron-scale resolution and registration. Because the integration complexity is assigned to the device fabrication process, completing the optical subsystem assembly is greatly simplified. The silicon material from which most MEMS devices are constructed can serve to guide the light, as it is transparent in the optical communication wavelength range, or reflect the light after metallization of mirror surfaces. Deployed communication equipment should be compact, lightweight, and robust, which are all attributes of well-designed optical microsystems.

This chapter provides an overview of the major applications where microsystems can impact optical communication networks. It starts with a review of optical networking that highlights the functional requirements of different network elements where microsystems may contribute. The optics of microsystems, which is based on free-space propagation of single-mode radiation, is examined afterwards.

Microsystem implementations that have been developed for five exemplary applications are subsequently reviewed. The future outlook for optical microsystems is addressed in the conclusion.

3.07.2 Emergence of Optical Networking

What is the difference between optical communications and optical networking? Optical communications has been researched and developed for many decades, and has brought the transport technology to a very mature level. Its fundamental goals are to increase the transmission capacity, the transmission range, and/or the transmission capacity-range product. This has been primarily achieved by utilizing many wavelength channels concurrently on the fiber (a technique known as DWDM or dense wavelength division multiplexing), optical amplification, dispersion compensation, and efficient modulation formats. Optical networking is what happens beyond optical communications, the effective utilization of the transport layer to deliver the connectivity, accessibility, reliability, and survivability at the network level. It is about protocols for access, routing, protection, and restoration, as well as the electronic, optical, and optoelectronic (or photonic) hardware required for implementing it. This new field even has a dedicated research journal inaugurated in 2002 (*Journal of Optical Networking*). Optical networks are customized and optimized for a specific operating environment; a continental-scale backbone network for connecting cities is very different from a neighborhood access network for individual households or from an optical data network within a supercomputing center. Backbone networks, which support the data and voice traffic infrastructure, are required to establish long-term light paths with high availability and fast restoration. Due to their geographical extent, they are the most expensive to deploy and maintain (Fishman *et al.* 2006). Access network are the most price conscientious, due to the economy of scales required for deployment. To reduce deployment and operational costs, access networks utilize passive optical networking strategies (Feldman *et al.* 1998). Computer data networks are designed for communication throughput between supercomputers as well as to mass storage, to maintain the processing cycles active. Such networks operate in accordance to changing resource allocations and demand variations, and can tolerate periodic changes to the topology (Taesombut *et al.* 2006).

Of the broad optical networking categories described above, backbone networks as well as the smaller scale metropolitan networks are most receptive to deployment of components offering adaptability and reconfigurability. There are several reasons for this acceptance. First, these networks are required to operate their communication services with defined restoration speeds stipulated under quality of service contractual obligations. An example for a stringent requirement for maintaining synchronization between two end points communication with SONET (Synchronous Optical NETworking) protocol is a 50 ms restoration of service in the case of interrupts (component failures, fiber cuts, etc.). This level of restoration requires that link and path protection schemes be employed, requiring basic switching elements with millisecond-scale response times. However, such protection schemes increase the network redundancy and cost while reducing the network capacity utilization. By using more advanced network protocols and more capable switching elements, shared path protection plans can be offered with high availability assurances, as the likelihood of multiple network interrupts occurring simultaneously is extremely low. Shared protection also increases the network's capacity utilization, achieving a better return on investment for the service provider (Ye *et al.* 2000). The second reason is related to path provisioning and reconfigurability. As bandwidth demand increases with the introduction of new electronic services, new light paths that traverse the network have to be established to support the increased load. This act of provisioning light paths may sometime include rerouting of existing light paths, to more evenly spread the load across the network links. Provisioning used to be a manual process, and required a technician's visit to every network node. The manual process was also prone to human error, and requires additional visits for verification, all leading to notoriously long provisioning times (measured in months from request to completion) and high operating expenses. By introducing advanced switching elements at the network nodes, remote provisioning from a centralized control center can be performed, reducing the provisioning time to potentially seconds. The third reason is related to the efficient utilization of the fiber transport capabilities. The advances made in transport technology have enabled deployed systems to achieve transmission distances beyond 2000 km. However, most light paths supported by the network have shorter path lengths. (Rent's rule for interconnection lengths applies; the distribution of network light path lengths is inversely proportional to the length. In other words, there

are more short light paths than there are long ones.) Hence, for efficiently using an optical network, light paths carried on specific wavelengths are required to be managed, i.e., extracted and reintroduced at different nodes of the network at the command of the centralized control center. This functionality is known as reconfigurable optical add-drop multiplexing (ROADM). More recently, the ROADM equipment has acquired the additional task of light path link switching at network nodes (Bonenfant and Jones 2003). Finally, a fourth reason for the greater acceptance of adaptable components in backbone networks is that they enable the optical network to operate more efficiently, from transport as well as maintenance points of view. The optical network topography is nonunifirm, having links of different lengths due to the locations of cities and possible mix of optical fiber types. Customized equipment can be placed on the different links to achieve a more uniform response, but inventorying many variants of a certain component is an inefficient solution. Adaptive components can be used instead of carrying many variants, with tunable dispersion compensators as an example. Stockpiling different laser transmitters for compatibility with any DWDM wavelength is another example where inventorying becomes prohibitively expensive. Tunable lasers spanning the entire communication window can be used instead. Balancing the signal levels within the network after changes such as the introduction or extraction of channels maintains the optical network performing at the correct power levels, and is important for maintaining the optical signal-to-noise ratio (OSNR). The price premium for the tunable and adaptable components over fixed components more than pays for itself in performance and operational savings.

To illustrate the form and functionality provided by optical networks, an exemplary backbone optical network as well as its interface to a metropolitan network is depicted in **Figure 1**. The backbone network is typically of national or continental scale, and serves to interconnect major sites where data needs to be introduced or extracted from the network, typically at major cities. Backbone networks are usually deployed with a mesh architecture, where each network node is attached to its nearby neighboring nodes (typically two to four links fan out per node). The links in a backbone network vary in length with the distribution of the network nodes or cities, and can vary from tens to hundreds of kilometers. In the latter case, optical amplification has to be periodically provided along the link, to maintain the signal strength. An optical in-line amplifier (ILA) is typically inserted for every 60–100 km of optical fiber; the actual distance between amplifiers is a network optimization parameter balancing performance versus cost (closely distributed amplifiers offer better optical signal-to-noise characteristic at the expense of higher amplifier count). The optical amplifier may include additional equipment to balance the optical signals as well as accompanying power taps and a monitor, for maintaining the proper signal strength and network performance. At an optical add-drop multiplexer (OADM) node, most of the DWDM channels typically continue unimpeded in the optical domain while a fraction is selected to be dropped and then added back after data are extracted and new data are introduced. The added and dropped signals are converted between the electrical and optical domains at optical translator units (OTU), which consist of optoelectronic components such as lasers, modulators, detectors, and electronic circuitry. The data in the electrical domain are handled by electronic equipment operating the protocols employed by the networks. This multiservice provisioning platform (MSPP) interoperates with the transport networks, performs grooming and tributary hand-off tasks (splitting, distributing, and combining the fractional data rate signals that make up the aggregate line signal), and enable services such as Ethernet, SAN (storage area networking), ATM (asynchronous transfer mode), GMPLS (generalized multiprotocol label switching), and private line circuits. The MSPP serves as a data gateway between different optical networks, in this case between the backbone mesh network and the metropolitan ring. The metropolitan DWDM ring distributes and collects data to and from its ring nodes, which separate the data streams to finer granularity and serve as gateways to local access networks (not shown in **Figure 1**). The basic OADM architecture is based on a power splitter, which generates two replicas of the signals, one for the drop and one for the channels that will continue through the nodes. A channel blocker prevents those channels that have been selected to be dropped from continuing to the OADM output. This architecture requires a fixed demultiplexer to separate the dropped channels, with deployed OTUs to receive the dropped channels. Such architecture is restrictive because a network reconfiguration is limited on the add and drop sides to specific channels that have OTUs on them, as there is a fixed assignment between the OTU and optical channel due to the fixed optical demultiplexer. An alternative OADM architecture is based on wavelength-selective switches (WSSs) for switching the dropped channels to individual ports.

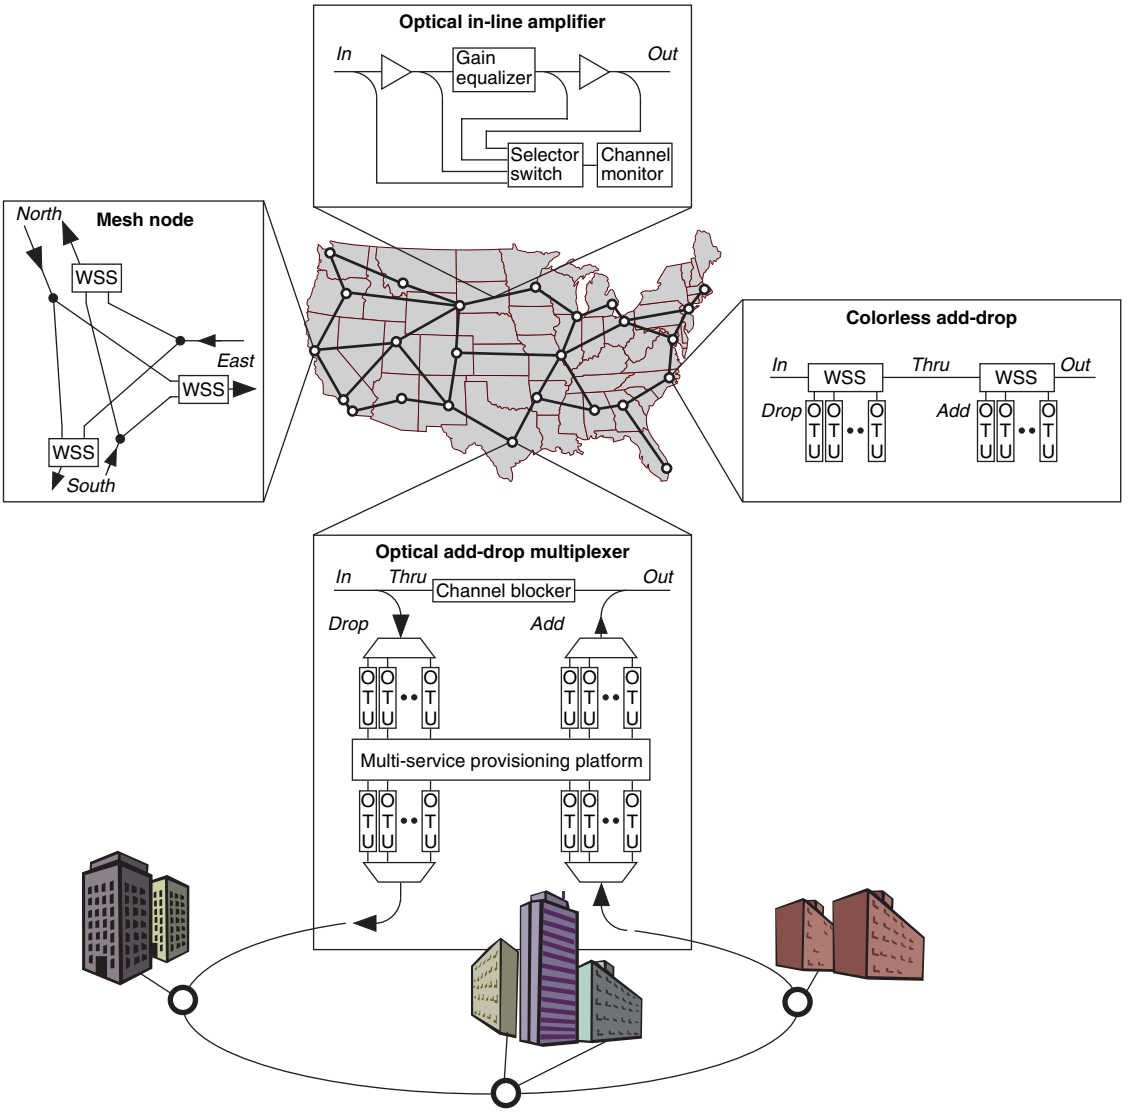

Figure 1 A typical continental-scale backbone optical network layout, demonstrating the major functions at mesh switching nodes, add-drop nodes, and its interface to a local metropolitan-scale ring.

This colorless add-drop solution is completely reconfigurable; any wavelength channel can be selected to be dropped to any fiber port. Thus, the fixed association between OTU and DWDM channel is broken, enabling greater flexibility in the network operation and necessitating that OTU support all the DWDM channel on command (the major implication being for the laser transmitter to tune to any channel; detectors have negligible wavelength dependence). The WSS port count has to match the channel drop count, with eight ports typically sufficient for most add-drop sites. The DWDM channels in the backbone mesh network traverse intermediate nodes between their ingress and egress nodes. At these intermediate nodes, the channels are path switched to the proper link that will route the channel to its intended destination. This path switching task at mesh nodes is best accomplished with WSSs, which independently route each DWDM channel to an output port that is assigned to the desired output link. Each input link at the mesh node has a WSS for splitting and combining the channels according to the routing assignment. The WSS port count has to match the node fan-out, with four ports typically sufficient for most mesh nodes.

Many telecommunication components are based on optical microsystem principles. Some of these are

adaptive, by changing certain optical parameters using MEMS or liquid-crystal (LC) devices. Others are fixed, but still benefit from microsystem construction over other implementations. Some examples of fixed optical microsystems include optical isolators (used to prevent back reflections) and circulators (for separating light propagating in the forward and backward direction), free-space optical multiplexers and demultiplexers (achieve very good thermal stability for outdoor deployment), and spectral filters using thin-film interference (for implementing fixed OADM). Examples of active optical microsystems are fiber switches (small, medium, and large varieties for implementation of various network functions, according to size), variable optical attenuators (required to maintain acceptable power levels impinging on photodetectors), tunable filters (for channel selection in broadcast networks and for optical monitoring), WSSs (for realization of ROADMs), tunable dispersion compensators, and even beam steering mirrors for free-space optical links). The active optical microsystems listed above (and some described in depth in the bulk of the chapter) all exhibit operating speeds in the millisecond timescale. Even though this characteristic speed is much slower than the data bit rate of SONET or packet rate of IP (Internet protocol), it is more than suitable for tracking network changes due to ambient conditions (variations of the network infrastructure due mostly to temperature) and for supporting light path provisioning as well as protection and restoration functions. The component marketplace is flush with competing products and technologies from many companies (~1000 companies present at the largest technical conference and trade show, *Optical Fiber Communications*), all vying for a fraction of the global component sales.

3.07.3 The Optics of Telecommunication Microsystems

The optical communications field matured considerably since the days of the first deployment in 1978, in a sequence of several generations. First-generation systems were based on 780 nm GaAs laser transmitters using multimode fibers. The systems were limited to low bit rates due to modal dispersion. Second-generation systems addressed the bit-rate limitations by using single-mode fibers and shifting the operating wavelength to 1300 nm. Modal dispersion is nonexistent when using single-mode fibers, and at 1300 nm chromatic dispersion is minimized in glass (silica) waveguide. However, lacking optical amplifier technology at the time, the communication range became signal-level limited, due to propagation losses at 1300 nm (losses attributed to Rayleigh scattering, which decrease for longer wavelengths). Third-generation systems shifted the operating wavelength to 1550 nm, where the optical fiber exhibits its minimal losses of 0.2 dB km^{-1} (attenuation increases for longer wavelengths due to silica molecular vibration absorption). Many additional advancements have been introduced to create the fourth-generation systems, some of which must be mentioned for completeness: optical amplification allowing for compensation of the fiber's attenuation, DWDM enabling multiple channels to copropagate in the same fiber, dispersion management for reducing chromatic dispersion impairments, advanced optical modulation formats for achieving higher spectral efficiencies, and nonlinear propagation. However, fiber transport largely remains around 1500-nm wavelength over single-mode fiber, which will be the focus of this section (with the exception being in short-haul links and local area networks, where range is less of an issue).

Realizing optical networks requires integrating many additional components to the transport layer. These components must exhibit low losses, as losses must be compensated for with amplification, which reduces the OSNR. Hence, the design of optical components has to be extremely well engineered to minimize these losses. For components based on interaction with unguided light, or light propagating in free space, which is the case for most optical microsystems described in this chapter, this is especially challenging as the light must radiate out of the input fiber, be manipulated by the microsystem, and then be coupled back into the output fiber. Depending on functionality, the optical microsystem enables the interaction of the MEMS element with the delivered light, in the form of refraction, reflection, diffraction, or absorption. Loss sources can creep up quickly and they are usually cumulative; hence, the microsystem's optical design has to be optimized for high coupling efficiency as well as tolerant of natural component variations, misalignments, and deployment conditions.

3.07.3.1 Gaussian Beam Optics in Free Space

The light propagating within a step-index single-mode fiber is confined by the higher core refractive index. The light has a transverse profile given by

radial Bessel functions in the core and cladding regions. However, for optical microsystem design purposes, the precise transverse profile is approximated by a Gaussian one, with an excellent fit at a beam diameter of 10.4 μm at an operating wavelength of 1.55 μm. The advantage of using the Gaussian profile approximation is that it is a solution to the paraxial Helmholtz equation, which describes light propagation in a homogeneous region (Saleh and Teich 1991). Hence, a Gaussian profile shall remain Gaussian as long as it does not encounter nonhomogeneous regions, such as an aperture.

The Gaussian beam field, $U(x, y, z)$, is described in a Cartesian coordinate system with the propagation direction along the z-axis by

$$U(x,y,z) = U_0 \frac{w_0}{w(z)} \exp\left(-\frac{x^2+y^2}{w^2(z)} - \mathrm{j}\frac{2\pi n}{\lambda} \times \left(z + \frac{x^2+y^2}{2R(z)} \right) + \mathrm{j}\phi(z) \right)$$

where $R(z)$ is the field radius of curvature varying as

$$R(z) = z\left(1 + \left(\frac{z_0}{z}\right)^2\right)$$

$w(z)$ is the beam radius defined by

$$w(z) = w_0\sqrt{1 + \left(\frac{z}{z_0}\right)^2}$$

and $\phi(z) = \tan^{-1}(z/z_0)$ is a phase delay along the propagation direction giving rise to a Guoy phase shift associated with a π phase jump when propagating past the beam waist (**Figure 2**). The beam waist is defined at $z = 0$, and is the location where the beam is at its narrowest spot, a location associated with a minimal beam radius w_0 and an infinite radius of curvature (flat phase front as would appear on a plane wave; however, the field is apodized by a Gaussian envelope). The distance z_0 is known as the Rayleigh length, defined by

$$z_0 = \pi \frac{w_0^2 n}{\lambda}$$

where n is the refractive index of the medium. The Rayleigh length measures the distance from the waist to the location where the beam grows by a factor of $\sqrt{2}$. The Gaussian beam size is symmetric about the beam waist, with the radius of curvature defining whether the beam is converging toward the waist (negative radius of curvature) or diverging from the waist (positive curvature). The fiber mode is approximated by the Gaussian beam with the waist located at the fiber tip. Hence, light radiating out of the fiber diverges, with a Rayleigh length of 55 μm (for air with $n = 1$), and the same parameters have to be satisfied for efficient coupling into a fiber.

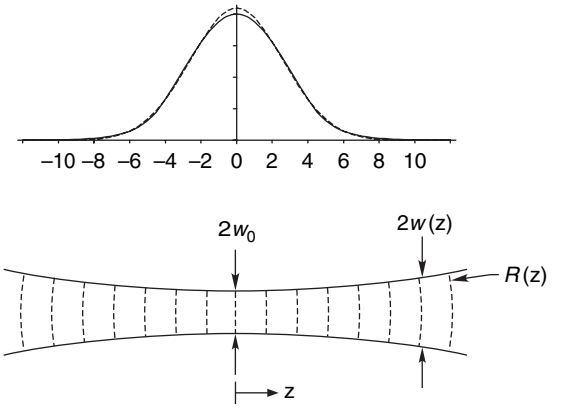

Figure 2 *Top*: The mode shape of the standard single-mode optical fiber (solid line), and its Gaussian approximation of width $2w_0 = 10.4$ μm at an operating wavelength of 1.55 μm (dashed line). *Bottom*: A Gaussian beam propagating in free-space, dashed lines show phase fronts. The beam has a minimal waist at location $z = 0$. A Gaussian beam converges toward the waist and diverges afterward. The light radiating out of a cleaved optical fiber is well approximated by a Gaussian beam.

The Gaussian beam can be manipulated in free space by mirrors, lenses, and prisms. Flat mirrors do not affect the Gaussian beam profile evolution, but do change the propagation direction. Curved mirrors have a lensing effect, with the effective focal length equal to half the mirror radius. Lenses, when treated as thin lenses, change the Gaussian beam radius of curvature by a factor of $F/(F–R)$, where F is the lens focal length and R is the Gaussian beam radius of curvature impinging on the lens. Simple beam relationships can be established with the aid of Gaussian beam propagation formulas and the lens radius transformations for cases of interest such as the maximum throw distance of a lens (i.e., for a given input Gaussian beam and lens focal length, how far and large can a Gaussian beam waist be projected from the lens). Prisms refract light in accordance to Snell's law, and can be used to expand or contract the beam in one direction, converting the circular Gaussian beam to an elliptical profile. Note that the beam propagation calculations can be in the forward or backward directions, and are valid as long as the beam does not encounter an aperture.

3.07.3.2 Misalignment Losses

A Gaussian beam can be propagated within an apertureless optical microsystem in a lossless fashion, as the

beam propagation does not take into account Fresnel reflections at dielectric interfaces (which can be minimized to ~0.1 dB per interface with antireflection coating), and finite metallic reflectivity (~0.25 dB per reflection). The forward propagation eventually leads to the output fiber end face, where the beam has to couple back into a single-mode fiber. The coupling can be evaluated with the complex ovelap integral between the incident beam wavefront $\varphi(x,y)$ and the fiber mode profile $\phi(x,y)$, which is approximated by the Gaussian distribution, and given by

$$\eta = \frac{\int_{-\infty}^{\infty} \varphi(x,y)\phi^*(x,y)\mathrm{d}x\mathrm{d}y}{\sqrt{\int_{\infty}^{-\infty} \varphi(x,y)\varphi^*(x,y)\mathrm{d}x\mathrm{d}y}\sqrt{\int_{\infty}^{-\infty} \phi(x,y)\phi^*(x,y)\mathrm{d}x\mathrm{d}y}}$$

The calculated coupling η can yield complex results, leading to spectral phase variations or chromatic distortions. The power coupling, $|\eta|^2$, is typically the quantity of interest and is often expressed in decibel scale $\left(10\cdot\log_{10}\left[|\eta|^2\right]\right)$. When using normalized field distributions, the denominator of the coupling integral is unity. An incident wavefront that exactly matches the fiber mode profile will achieve a power coupling efficiency of one. The coupling integral can be evaluated numerically for any field distribution, and analytically for the Gaussian beam case. It is instructive to inspect the effects of lateral misalignment, angular misalignment, mode mismatch, defocus, and combinations thereof (**Figure 3**). The power coupling in the presence of lateral and angular misalignments is

$$|\eta|^2 = \exp\left(-\frac{x_0^2+y_0^2}{w_0^2} - \frac{w_0^2\pi^2\left(\theta_x^2+\theta_y^2\right)}{\lambda^2}\right)$$

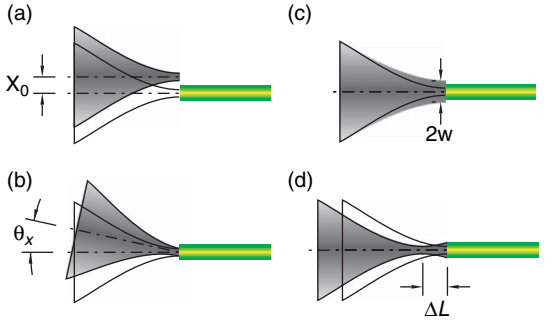

Figure 3 Mechanisms for coupling losses into single-mode fiber. (a) Lateral misalignment between incident Gaussian beam and fiber endface. (b) Angular misalignment. (c) Mode-size mismatch. (d) Waist location shift or defocus.

and has Guassian distributions in the lateral misalignment, x_0 and y_0, and angular misalignments, θ_x and θ_y. For single-mode fiber, a total lateral misalignment of 4.4 μm or a total angular misalignment of 4.5° will give rise to a 3-dB penalty (half the power is lost). Because the lateral and angular misalignment dependencies are Gaussian, or quadratic in decibel scale, a factor of $1/x$ improvement in power coupling requires a factor of $1/\sqrt{x}$ tightening in the misalignment. For example, reducing fiber misalignment losses from 3-dB to 1-dB penalty (factor 1/3 improvement) shall require a 2.5 μm lateral misalignment (factor of $1/\sqrt{3}$ tightening). Mode mismatch (different waist size incident on fiber) and defocus (longitudinal displacement of waist location) do not follow a Guassian relationship. The mode mismatch coupling loss, given by

$$|\eta|^2 = \frac{4w_0^2w_1^2}{\left(w_0^2+w_1^2\right)^2}$$

is small for waist variations as large as 20%. The defocus coupling loss is given by

$$|\eta|^2 = \frac{1}{1+\left(\frac{\Delta L}{2z_0}\right)^2}$$

where ΔL is the defocus distance and will provide 80% efficiency (or a loss of about 1 dB) at the Rayleigh distance (55 μm for single-mode fiber).

The coupling integral was evaluated above at the output fiber end face. However, as the Gaussian beam can be propagated forward as well as backward, the overlap integral can be evaluated anywhere within the optical microsystem. This propagation to a different location within the microsystem is instructive for cases involving a single aperture in the beam path.

3.07.3.3 Beam Clipping Losses

After a Gaussian beam is clipped by an aperture, the field distribution is no longer Gaussian and the beam propagation formulas provided above are no longer valid. Because all real elements in the beam path have finite extent, we shall define a criterion for a tolerable aperture size for a given Gaussian beam size later in this section. For the instructive case of a single clipping element in the beam path, we can use the forward and backward Gaussian beam propagation technique to meet at the aperture. Consider the configuration shown in **Figure 4**, where the input fiber waist is projected by a collimator lens of infinite

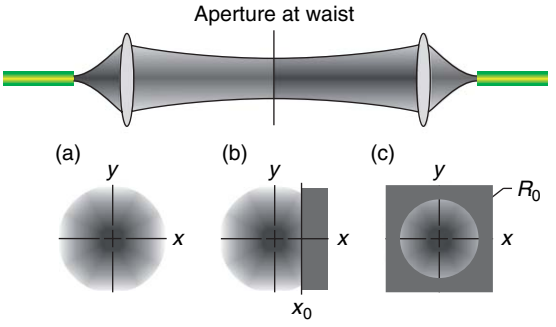

Figure 4 *Top*: Imaging arrangement between two fiber endfaces, having a wide collimated beam region in between where optical devices may be inserted. Effect of single aperture in the beam path can be analyzed: (a) circular Gaussian beam profile at aperture location; (b) shutter aperture blocking parts of beam; and (c) circular aperture.

extent to create a secondary waist of size w_1, and a similar collection lens couples the light into the output fiber. The configuration can be properly designed with ideal lenses to deliver a perfect mode to the output fiber with no coupling losses. If an edge shutter is inserted into the beam path at the Gaussian beam waist location, the beam will be clipped by the edge of shutter. The coupling integral can easily be evaluated at the location of the shutter using the ideal Gaussian waist of w_1; the impact of the shutter is introduced by adjusting the integration area. If the edge of the shutter is at position x_0, then beam regions for $x > x_0$ are clipped and the power coupling is given by

$$|\eta|^2 = \frac{1}{4}\left(1 + \mathrm{erf}\left(\frac{\sqrt{2}x_0}{w_1}\right)\right)^2$$

The power coupling approaches 1 for $x_0 \gg w_1$ (shutter far from interacting with the beam), and approaches zero for $x_0 \ll -w_1$ (shutter blocks most of the beam). It is interesting to note that when the shutter is blocking half the beam (edge is at $x_0 = 0$) the power coupling is 1/4 (or −6 dB). This somewhat surprising results occur because half the beam is clipped (1/2 power lost) and the modal overlap contributes another factor of 1/2. Clipping effects from sharp edges often occur in variable optical attenuators, blockers, and WSSs (see Sections 3.07.4.3 and 3.07.4.5).

Lenses and other optical elements are oftentimes circular, and will clip the extent of the circularly Gaussian mode. The analysis of a single beam clipped by a circular aperture can be performed in the same fashion as for the shutter edge. Adopting the configuration of **Figure 4**, a circular aperture of radius R_0 is placed at the location of the Gaussian waist of radius w_1. The aperture and beam centers are aligned, and beam regions for $r > R_0$ are clipped, defining a power coupling efficiency of

$$|\eta|^2 = \left(1 - \exp\left(\frac{2R_0^2}{w_1^2}\right)\right)^2$$

The power coupling approaches 1 for $R_0 \gg w_1$ (aperture far from interacting with the beam), and approaches zero $R_0 \to 0$ (aperture blocks most of the beam). When $R_0 = 1.5w_0$, the fiber coupling loss is nearly lossless at −0.1 dB.

When multiple apertures are present in the beam path, the analysis becomes much more complex. The Gaussian beam from the input fiber can be propagated until the first aperture. Likewise, the Gaussian mode from the output fiber can be back propagated to the last apertures. Gaussian beam propagation cannot be used for the region between the first and large apertures, and Fresnel propagation must be used instead. Because Fresnel propagation in the presence of apertures is difficult to compute, a design rule has been established stating that if the aperture is 50% larger than the Gausian beam, then clipping effects can be ignored and Gaussian beam propagation can be still be used. When the condition is satisfied $(R_0 > 1.5w)$ the light throughput of the aperture is 99%. Note that the stated condition does not consider any beam to aperture misalignment tolerance, so a slightly more stringent condition might be adopted in practice to avoid clipping effects.

The characterization of optical components intended for integration into optical communication systems is not complete without procedural tests to ascertain the compliance to generic requirements (GR) put forth by Telcordia, the advising body to the regional service providers in the United States (www.telcordia.com). The two most often cited documents are GR-1209, GR for passive optical elements, which specifies the operating conditions that components must achieve, and GR-1221 that specifies the reliability testing procedures. The listed tests include temperature cycling and temperature and humidity cycling, high-temperature storage, high-temperature and humidity storage, cold temperature storage, vibrational tests, and shock tests. Some of the tests are performed while the device is in operation, others mimic extreme conditions the component may experience in storage conditions. The components have to pass the tests to gain Telcordia compliance certification.

3.07.4 Exemplary Optical Networking Microsystems

Of the many possible networking applications for which optical microsystems have been demonstrated, at both the research or development levels, five concerted efforts are reviewed here. For each highlighted application, several microsystem implementations are reviewed, demonstrating the diversity of creativity in the face of a challenging task.

3.07.4.1 MEMS Tunable Lasers

Optical communications have been utilizing semiconductor lasers almost exclusively, from early systems lasing at 850 nm and based on GaAs, to modern systems based on InGaAsP and operating at either the 1300- or 1550-nm communication bands. The main advantages of semiconductors lasers for communications are their compactness, high power conversion efficiency, wafer-scale processing, and the capability of direct modulation of the electrical pump current, even though the latter has been abandoned as the communication bit rate has reached $10\,\mathrm{Gb\,s^{-1}}$ due to chirp effects (leading to bandwidth broadening). The basic structure of a laser consists of an optical cavity with a gain section introduced into it. The semiconductor section provides a relatively broad and continuous gain spectrum, whereas the cavity provides finite, equally spaced modes defined by the phase continuity of the cavity round trip travel for specific wavelengths. The basic Fabry–Perot cavity laser, formed from a cleaved section of a semiconductor chip with a waveguiding structure defining the transverse confinement, lases at the multiple longitudinal cavity modes under the gain spectrum. However, lasers for high bit-rate optical communications are required to lase on a single cavity mode only, to minimize chromatic dispersion-induced distortions upon propagation. To limit the laser cavity modes, a filtering component is introduced into the cavity that selects a particular cavity mode while attenuating all others. The cavity filter can be incorporated into the fabrication of the semiconductor chip, by slightly etching or longitudinally modulating the waveguide structure at the cavity ends. This periodic modulation forms a reflective filter for a wavelength component satisfying the Bragg criterion, limiting the lasing to a single frequency in each distributed feedback (DFB) laser.

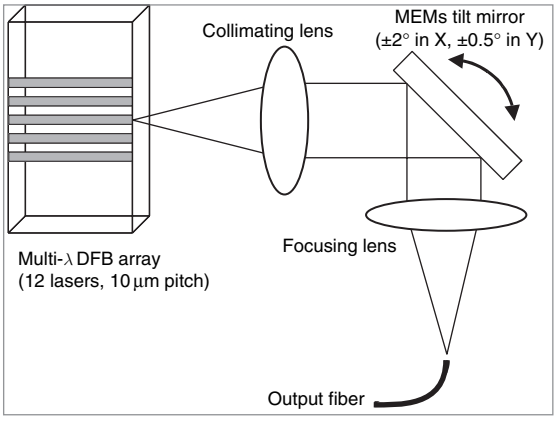
DWDM transmission necessitates discrete individual lasers to match the channel numbers in operation by the optical communication system. With DWDM channel counts of few tens to one hundred or more, having unique single-frequency lasers poses a manufacturing, inventory, and management cost to the component manufacturers, system vendors, and network operators. Tunable semiconductor lasers can eliminate the inventory cost and manufacturing variations by having a single laser serve any wavelength used in the communications band on command. The overall cost savings that can be afforded by using tunable lasers should more than offset the price premium for such lasers over their single-frequency counterparts. Optical networking introduces additional functional motivations for deploying full band tunable lasers. New light paths in the network can be established by provisioning an available wavelength channel through intermediary network nodes. Networks can respond to changes in demand patterns due to daily, weekly, or seasonal variations, releasing resources (wavelengths) from one end and reassigning them to others. These scenarios require that the laser transmitter be capable of tuning to any prescribed DWDM channel (Coldren *et al.* 2004).

The earliest tunable lasers utilized thermal tuning of the DFB laser. The DFB laser already incorporates a thermal feedback loop for stabilizing its center wavelength, so providing tunablility by tuning the temperature setting came practically free. However, the possible thermal tuning range of DFB lasers is a few nanometers only, far short of the full communication bandwidth. Full band tunable lasers require greater complexity, and the research community has demonstrated several innovative solutions. The principle behind all the tuning techniques is based on an intracavity filter that can effectively span the entire communication band and select a single cavity mode for lasing. A differentiator among the tuning technique is the tuning speed; physical property variations such as thermal or mechanical requires a few milliseconds or longer, whereas electronic techniques can switch faster than microsecond speed. For the foreseeable future, the relatively slow tuning speed should suffice for applications in optical networking. The faster switching speeds are reserved for optical packet switching applications, which are currently under the exploratory research realm. Slow tunable lasers pose fertile ground for MEMS ingenuity, as exemplified in the following.

3.07.4.1.1 DFB array selector

One of the main advantages of single-frequency DFB lasers is that the entire laser is completely integrated on a semiconductor chip, guaranteeing that the laser

cavity is very stable and robust. The laser package is completed after fiber attachment, typically via collimation optics that converts the elliptical laser output mode to the circular fiber mode for efficient coupling and also incorporates an optical isolator to prevent back reflections into the laser. One possible tuning approach is to capitalize on this mature laser technology, and to provide wide-band tuning by fabricating an array of DFB lasers in close proximity, each with an offset center wavelength that can be thermally tuned over a few nanometers. A MEMS switching mirror is placed within the free-space collimation optics and serves to select which waveguide of the waveguide array is coupled to the output fiber (**Figure 5**). Any wavelength can be set by electrically activating the single laser waveguide that can tune to the desired waveguide and thermally tuning the entire chip to the predetermined temperature (Pezeshki *et al.* 2002, Ton *et al.* 2004, Zou *et al.* 2004). The lasing characteristics are similar to those of conventional DFB lasers.



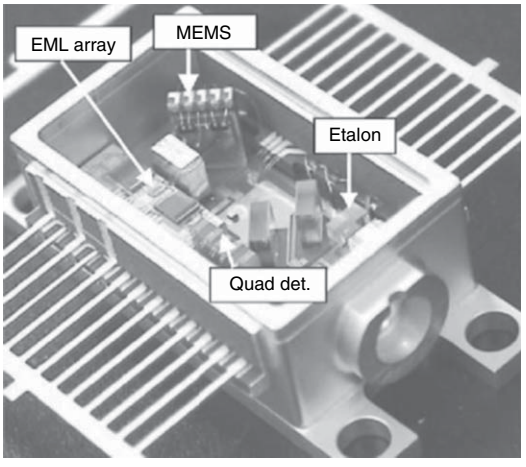


Figure 5 Tunable laser using an array of thermally tunable distributed feedback (DFB) lasers and a microelectromechanical systems (MEMS) selector switch. *Top*: Schematic of laser structure. *Bottom*: Packaged laser in standard butterfly package. (Source: Pezeshki B *et al.* 2002 20-mW Widely tunable laser module using DFB array and MEMS selection. *IEEE Photon. Technol. Lett.* **14**, 1457–9, © [2002] IEEE.)

The MEMS micromirror angle is tilted to the angle that couples the selected output laser from the DFB array to the fiber output and associated optics and isolator. The laser array consists of 12 lasers on a 10-μm pitch, each with a center wavelength shift of 2.8 nm by varying the longitudinal grating pitch. The chip size is similar to that of a fixed wavelength DFB laser, and contains no additional processing steps. To prevent erroneous wavelengths from being emitted from the laser to the optical communication system during the tuning process and thermal settling time, the MEMS mirror is intentionally misaligned from the output fiber during the tuning operation. When tuning is complete, the mirror is adjusted to optimally couple the laser output to the fiber. A 1.5 mm diameter mirror consisting of a gimbaled structure with torsional springs, is fabricated using bulk silicon micromachining, and reaches its maximum deflection angle at 120 V. The MEMS steering mirror can tilt ±2° in the waveguide selection direction, and ±5° in the orthogonal axis. The large mirror tilt range in two axes allows for loose placement of the optical components within the laser package, and using the MEMS mirror for correcting for the placement errors. A feedback loop based on 1% power dither at 50 Hz applied to the mirror maintains the optical alignment and compensates for any possible mechanical drift or creep. Shock and vibration do not influence the wavelength stability of the laser, as the cavity is self-contained within the chip, and only results in coupled output power variations.

The laser chip, MEMS mirror, and all other collimation optics and control electronics are packaged in a standard butterfly package, as well as a wavelength locker to provide a feedback signal for the chip heater. The laser module provides 20 mW fiber coupled power, tunable over the entire C-band (greater than 30 nm tuning). A typical ~1 s laser tuning speed is limited by the thermoelectric cooler (TEC) cooling capacity.

3.07.4.1.2 External cavity with grating filter

The DFB laser's small refractive index change limits their useful thermal tuning range to a few

nanometers. Different filtering techniques must be introduced into the laser cavity to extend the tuning range to cover the entire communication band. When the wide-tuning filtering mechanism cannot be implemented directly on the semiconductor gain chip due to an imcompatibility with the lithographically predefined and rigid cavity structure, external cavity laser architecture can be utilized. In an external cavity laser, the cavity consists of a semiconductor gain waveguide, typically with a cleaved facet mirror on one end and an antireflection coating on the second end, followed by a free-space propagation section with collimation optics to an end mirror defining the cavity. Within the free-space section of the external cavity laser, other tunable filtering elements can be introduced. A tunable external cavity laser can be based on a Littman–Metcalf geometry (Littman and Metcalf 1978, Liu and Littman 1981), consisting of a diffraction grating illuminated at near-grazing incidence for angularly dispersing light and a mirror on a rotation block for retroreflecting finite spectral components (**Figure 6**). Continuous tunability is achieved by rotating the mirror and selecting the wavelength that satisfies retroreflection. However, as the cavity supports equally spaced discrete modes, the cavity length typically needs to be minutely perturbed to shift the cavity mode to coincide with the desired lasing wavelength. Moreover, the filter passband has to provide sufficient loss to the adjacent cavity modes to suppress their lasing. Because the cavity mode spacing is inversely proportional to the cavity length and the external cavity

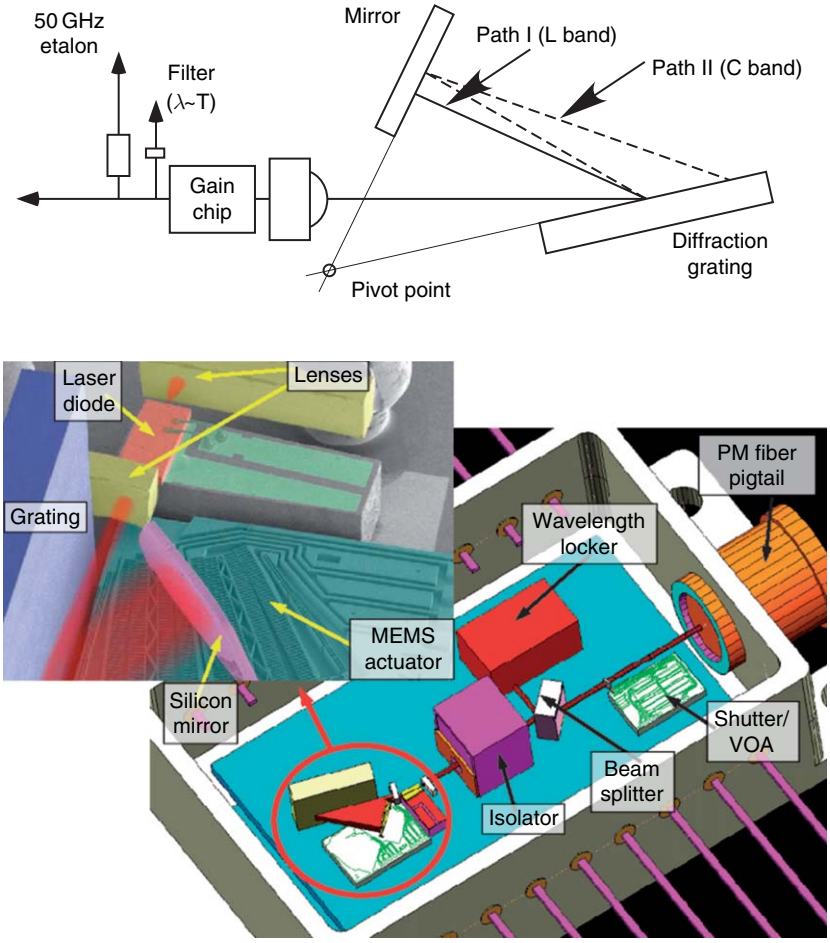

Figure 6 Tunable laser with an intracavity grating spectral filter. *Top*: Schematic of laser cavity with rotating end mirror for wavelength selection. *Bottom*: Schematic of packaged laser. *Inset*: Cavity and mirror mounted on microelectromechanical systems (MEMS) actuator. laser has significant length due to the space necessary for collimation optics and the tunable components, the filter must have narrowband characteristics.

The retroreflection mirror can be placed on a MEMS rotation block fabricated from 85-μm-thick single-crystalline silicon using deep reactive ion etching (DRIE) (Anthon *et al.* 2004a, b, Berger *et al.* 2001). Multiple comb drives electrostatically rotate the actuator about a virtual pivot point that is at the intersection of the grating and mirror planes. The pivot point placement is critical for mode-hop free tuning per the Littman–Metcalf design, where the mirror rotation is accompanied by displacement for maintaining the overlap of the cavity mode and the filter center wavelength. In practice, and especially for full communication band tuning range, additional controls need to be added for controlling the cavity mode locations. Cavity length control is provided by a piezoelectric actuator that translates the diffraction grating. To reduce the mirror's angular rotation range requirement, which is directly related to the filter's tuning range, a double reflection–diffraction arrangement is used (the light diffracts from the grating toward the mirror, reflects back to the grating, diffracts a second time from the grating and then in incident on the mirror at retroreflection for the center wavelength). The double reflection–diffraction arrangement also increases the cavity length, which decreases the cavity mode spacing, but the double diffraction generates a narrower filter passband that more than compensates for the tighter mode spacing. The MEMS actuator rotates the mirror $\pm 2.8^\circ$ for 140 V driving voltages, providing at ± 2.5 THz laser tuning range, easily covering the communication band. Because both the cavity and the tuning element are defined by the large rotating end mirror, vibrational sensitivity of the cavity is a major concern with this design.

The laser can be tuned continuously and mode-hop free with simultaneous control of the mirror rotation angle and grating position. However, in an optical networking environment, the laser cannot emit light during tuning to prevent interference with other signals. This can be addressed by adding a MEMS optical shutter between the laser cavity and the optical fiber to blank the signal during tuning. Additionally, a wavelength locker is used to provide a feedback signal necessary for wavelength tuning the laser with the MEMS and piezoelectric actuators. Laser tuning is complete in less than 15 ms, and the laser's wavelength locker ensures stable long-term operation.

3.07.4.1.3 Vernier thermal etalons

A different approach to tuning an external cavity laser is demonstrated by utilizing dual silicon etalons within the cavity (Finot *et al.* 2004, McDonald *et al.* 2006). The standard external cavity layout is formed with a semiconductor gain chip (one facet used for the cavity end mirror and the other antireflection coated) and a second mirror in the free-space region. The cavity mode selection is accomplished by the cascaded filtering response of the two etalons that are inserted within the free-space region (**Figure 7**). Each etalon, fabricated from a polished silicon wafer of unique thickness, has a transmission function consisting of a frequency comb. The comb spacing is determined by the etalon thickness, and as the silicon etalon is much shorter than the laser cavity length, its modes are spaced much wider apart. The etalon comb mode widths and position are determined by the etalon reflectivity, or finesse (see Section 3.07.4.2 for definition), and etalon phase – the desired reflectivity achieved by proper coating of the silicon and the etalon phase controlled by thermally tuning the silicon's refractive index. Because the two etalons are slightly different in width, their cavity mode spacing is also slightly different. The etalons are engineered such that their spacing difference and finesse ensure that only a single etalon mode overlaps over the laser gain spectrum. This Vernier effect tuning determines the desired lasing wavelength, and allows the dual etalons to cover a wide bandwidth with only a small cavity mode shift. Finally, for the laser to operate at this overlap peak, it must also coincide with one of the laser cavity's modes. The laser cavity's modes are tuned by varying the cavity phase with a lithium niobate crystal.

The silicon etalons are fabricated using wafer-level MEMS processing, even though the etalons have no moving parts. A polished silicon-on-insulator (SOI) wafer is used to define the silicon disks that form the etalons. The silicon handle on the backside is removed and the disk is suspended with a SiN membrane in tension. The etalon is thus thermally isolated from the handle, reducing the heating load required to stabilize its temperature. The fundamental resonance frequency of the silicon and membrane is above 10 kHz. The etalons have integrated heaters and temperature sensors formed by two Ti/Pt conductors tracing the etalon's optical aperture circumference. Heating is achieved by the power dissipation from the heating conductor, and the temperature is sensed by circuitry that registers the resistance of the second conductor, which depends on the etalon temperature. A 30°C temperature rise is achieved with 15 mW power

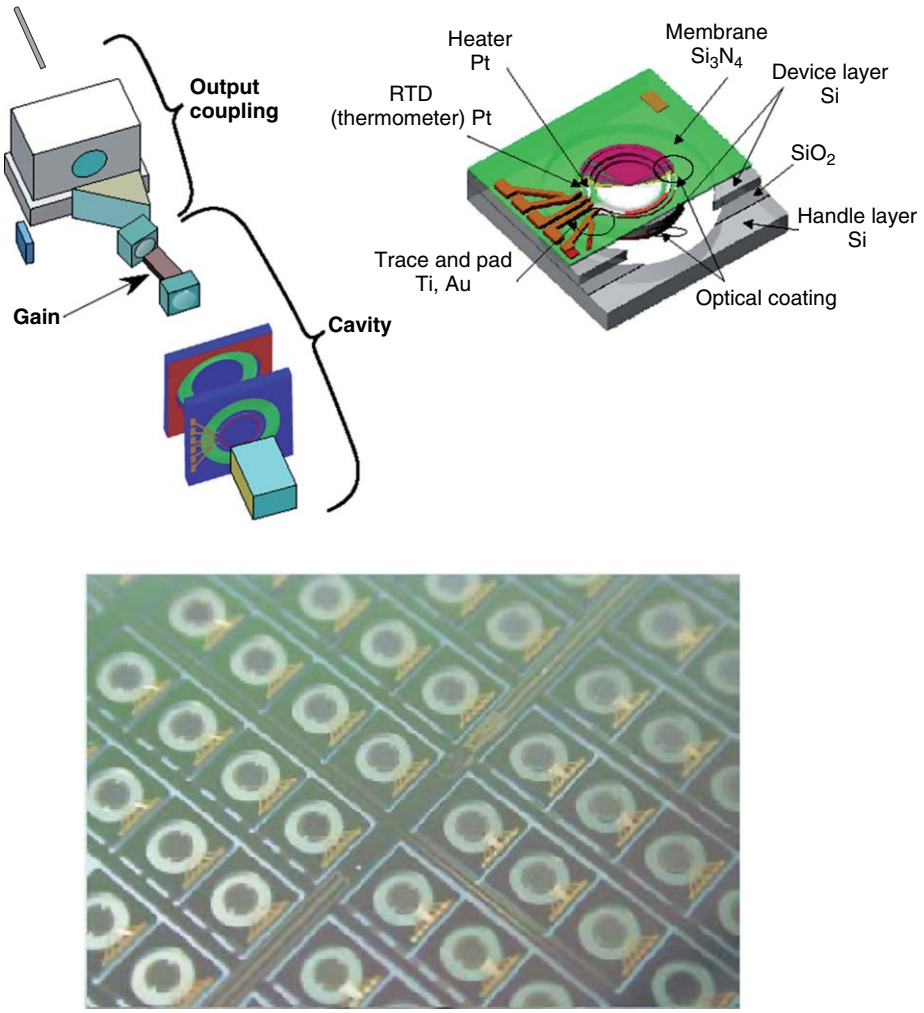

Figure 7 Tunable laser with intracavity thermally tuned etalon filters. *Top-left*: Schematic of laser cavity with two filters. *Top-right*: Details of thermally tuned silicon microfabricated etalon filter. *Bottom*: Wafer-level batch fabrication of filters. J.* **8**; McDonald M *et al.* 2006 Wavelength filter with integrated thermal control used as an intracavity DWDM laser tuning element. *IEEE Optical MEMS Conference*, Piscataway, NJ, USA, © [2006] IEEE.)

dissipation. The thermal time constant, determined by the resistance and thermal mass of the etalon, is under 1 s. The etalon's finesse is achieved with a four-layer reflection coating.

The stability and repeatability of the etalon's response allows the etalon to serve as the wavelength reference for the laser. Laser tuning is performed by heating the two etalons to the prestored values and then adjusting the cavity phase to maximize the lasing power. The cavity phase is determined by a peak-locating algorithm with electro-optical dithering of the lithium niobate modulator. Because the inter cavity etalons serve as the wavelength reference, no wavelength locker is necessary after the laser. Moreover, the etalon wavelength tuning can be performed without lasing, so the laser cavity can be tuned in the dark state and turned on with the pump current when the temperature has settled, eliminating the need for an additional shutter.

3.07.4.1.4 Tunable cavity VCSEL

If placing a filter in an external cavity is challenging, why not do away with it entirely? VCSEL (vertical cavity surface emitting laser), in contrast to the aforementioned edge emitting lasers, have a vertical optical cavity that enables different laser designs,

fabrication sequences, and beam characteristics. VCSELs are fabricated in a single epitaxial growth sequence, starting from a bottom distributed Bragg reflector (DBR), a semiconductor gain section, followed by a top DBR mirror, resulting in a short pillar laser geometry. The DBR consists of many alternating layers of lattice-matched materials; the large number of layers is required to achieve high reflectivity from materials with similar refractive indices. The high reflectivity is crucial for reducing the cavity losses, as the small gain available from the short gain section must be larger than the losses to support lasing. The short cavity length implies that the cavity modes are spaced widely apart, and typically only a single cavity mode exists within the gain bandwidth. Hence, no mode-selection filter is required in a VCSEL. Other advantages VCSEL offer are wafer-level inspection, as the laser emits out of plane, circular beam modes compatible with optical fiber mode, and 2D array geometries important for some applications. Conversely, their output powers are much lower than those of the DFB laser, and heat removal is challenging due to their pillar structure leading to high thermal resistance.

Tunable VCSEL can be realized by thermally changing the refractive index or by changing the cavity length. Thermal tuning is compounded by the laser's inherent thermal resistance, and cavity length changes are incompatible with the monolithic pillar structure. By introducing an air gap into the cavity and integrating a MEMS actuator with the top mirror, the cavity length and lasing wavelength can be directly tuned (**Figure 8**). Many variations on this theme have been reported in the scientific literature: using a flat mirror

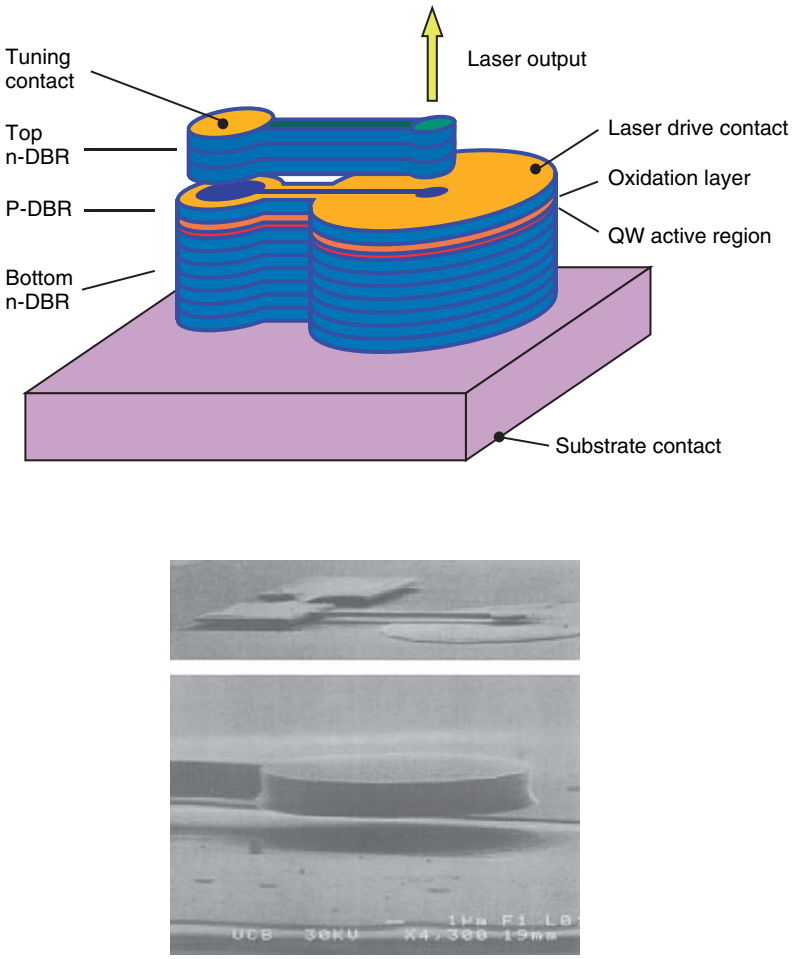

Figure 8 Tunable vertical cavity surface-emitting laser (VCSEL) with cavity length modulation. *Top*: Schematic of piston-motion VCSEL. *Bottom*: Top mirror mounted on piston motion actuator. (Source: Chang-Hasnain C J 2000 Tunable VCSEL. *IEEE J. Select. Top. Quant. Electron.* **6**, 978–87, © [2000] IEEE.)

versus a curved mirror, suspending the movable mirror with a continuous membrane versus a symmetric beam support structure or a cantilevered beam, electrostatic versus thermal actuation, one- and two-chip laser assemblies, and electrical or optical pumping of the laser. Each variation has its unique traits, but all share the principle that the cavity tunes by adjusting the air gap regions (Chang-Hasnain 2000, Kner *et al.* 2003, Li *et al.* 1998, Sugihwo *et al.* 1998, Tarraf *et al.* 2004, Tayebati *et al.* 1998).

As an exemplary VCSEL design, an electrically pumped, single-chip laser depicted in **Figure 8** is described. The entire laser is grown in one epitaxy run. The DBR mirrors are fabricated from a GaAs–AlGaAs heterostructure, and an InGaAs active region. An oxidation layer serves as a current guide, for effective electrical pumping of the gain region. The top mirror is suspended with a cantilever beam from a large, parallel plate electrostatic actuator. Because the actuator is physically decoupled from the laser section, its design can be optimized for operation at low voltages (<30 V), with a reported switching time of 1–10 ms. The mirror can displace up to a 1/3 of the initial gap size, with the lasing wavelength shifted toward shorter wavelengths as the gap size decreases upon actuation. The laser utilizes a wavelength locker for stabilizing the mirror position and emission onto the DWDM grid. The VCSEL can be directly modulated via the injection current at 2.5 Gb s^{-1} and the signal carried with a small impairment for 100 km on single-mode fiber, making it suitable for metropolitan-scale networks. However, the laser had a reported limited tuning range of ~10 nm in the 1.55 μm communication window and DC power levels approaching 1 mW. It should be noted that optically pumped VCSEL can exhibit a tuning range spanning the entire communication window and higher output powers, as less heat is generated at the active region (heat removal associated with electrical pumping remains an issue with VCSELs).

3.07.4.2 MEMS Tunable Filters

Fourth-generation DWDM optical communication systems achieve increased capacity through efficient utilization of the optical fiber bandwidth by multiplexing many wavelength channels. Optical networking uses the foundation of DWDM optical transport to interconnect geographically dispersed end users. The role of the optical network is to provide communication conduits at high or guaranteed availability between any two end points wanting to exchange information. An early optical network prototype based on DWDM used a broadcast-and-select topology (Dono *et al.* 1990). Each network user is distinguished by a unique laser wavelength, and all users transmit their signals simultaneously into a common fiber distribution network. An end user can select a communication partner by tuning his receiver to the wavelength corresponding to the desired transmitter. The receiver tuning is accomplished by placing a tunable filter in front of the optical detector. The filter permits the desired wavelength channel to go through, while blocking all the other DWDM channels. This early broadcast-and-select network topology could not support many users or reuse wavelength, and did not offer any security measures. More advanced network prototypes ensued (Kaminow *et al.* 1996), providing routing and wavelength management features present in modern networks, while continuing to advocate for tunable receivers. In today's deployed optical networks, both at the core and metro levels, tunable channel selection filters are not used for establishing connections (that task is performed by reconfigurable add-drop filters with WSSs). However, as fiber network venture deeper into access network and eventually to individual homes, tunable filters may once again be considered as they are the least expensive wavelength-tunable element. Other uses for tunable filters in today's networks are primarily for system monitoring. It is imperative to maintain the operational parameters of optical networks, and track any deviations from them. This is typically accomplished by tapping a fraction of the optical signal, and scanning the optical bandwidth with the filter to monitor the presence and power level of all channels in the fiber.

MEMS technology is very attractive for implementing tunable filters, as most tuning mechanisms are based on motion. Other competitive technologies do exist; however, the wide tuning requirement for spanning the entire communication window is typically more challenging for these alternative technologies. The tunable filter structures most commonly implemented using MEMS can be categorized by function: tunable resonant devices, deformable gratings, and spatial filters of spectrally dispersed light.

3.07.4.2.1 Tunable resonant devices

One of the simplest and well-known spectral filters is the Fabry–Perot interferometer or etalon, comprised of two partially reflective and mutually parallel surfaces separated by a finite gap. The transfer function of

the Fabry–Perot etalon consists of narrow spectral peaks with unity transmission; the complementary reflectance consists of the entire spectrum except for narrow spectral notches. The transmission/reflection is periodic in frequency, with the frequency period denoted by the free spectral range, $\mathrm{FSR} = c/(2d)$, where d is the etalon gap and c is the speed of light in vacuum, under the assumption that the gap region refractive index is unity (air) and under normal incidence. A transmission peak occurs whenever the round trip path length is equal to an integer multiple of an optical wavelength; hence, it is said to be resonant when the condition is satisfied. The half-width, Δf, of the Fabry–Perot etalon spectral peak is determined by the mirror reflectivity, R, and is defined by

$$\Delta f = \frac{c(1-R)}{2\pi d\sqrt{R}}$$

Narrow peak widths, which are necessary for channels isolation in DWDM, are achieved when the reflectivity approaches unity. The dimensionless ratio of the FSR to the half-width Δf is denoted by the finesse, $\mathcal{F}$, of the etalon and is given by

$$\mathcal{F} \equiv \frac{\mathrm{FSR}}{\Delta f} = \frac{\pi\sqrt{R}}{1-R}$$

The finesse measures the resolving power of the etalon, and is strictly determined by the mirror reflectivity. Locations of the transfer peaks are shifted by adjusting the gap separation. The FSR periodicity is inherent to resonant structures and is an undesirable feature when one wants to select a signal channel from the communication bandwidth. To overcome this effect, a telecom Fabry–Perot filter is constructed with a very narrow gap, which has a correspondingly large FSR. The requirements that need to be satisfied are that the FSR be larger than the communication bandwidth – to eliminate the periodicity within the bandwidth – and that the resolving power is sufficient to perform channel selection, implying that the gap region be on the order of a few wavelengths and that the mirrors have high reflectivity. The gap size as well as the mirror displacement requirement suggests that MEMS devices are well suited for construction of the etalons. MEMS Fabry–Perot etalons have been demonstrated in both in-plane and surface-normal arrangements (**Figure 9**). The latter is more common, as it is easier to fabricate using surface micromachining processes, and high mirror reflectivity is achieved by metallization and/or multilayer coatings. The actuation of one of the etalon's end mirrors is typically achieved with electrostatic forces or thermal bimorph displacement. The high finesse values that can be achieved with high-quality mirrors in the surface micromachining processes results in narrow transmission peaks. The MEMS surface micromachining diversity of material systems is demonstrated in the reported Fabry–Perot implementations in silicon (Niemi *et al.* 2001), GaAs (Amano *et al.* 2000, Kim *et al.* 2003a), InP (Daleiden *et al.* 2002), and elastomers (Blake 2003). In-plane Fabry–Perot implementations are based on DRIE in a thick SOI wafer (Yun *et al.* 2003). The two etalon mirrors are formed by etching vertical sidewalls in the silicon, one of which electrostatically actuates toward the other for tuning, and achieving relatively low finesse due to the low Fresnel reflectivity between silicon and air. Because it is difficult to metalize the vertical mirrors, the reflectivity can be enhanced by etching multiple vertical mirrors satisfying the Bragg criterion (Lipson and Yeatman 2005, Saadany *et al.* 2006). To achieve a significant reflection enhancement from the multiple reflectors, the surface quality of the vertical mirrors has to be improved after the deep etch process. The tuning speeds for electrostatic mirror actuation are typically submilliseconds, with a few volts required for submicron motion necessary for tuning across the communication band. Thermal bimorph actuation requires longer settling times, and consumes power in maintaining a filtering wavelength. Narrowband thermal tuning can also be used for modulating the refractive index of the gap region of a solid Fabry–Perot filter, as demonstrated with a silicon ridge waveguide with etched Bragg end mirrors (Angulo Barrios *et al.* 2004, Yun 2003). However, with extreme temperature tuning (up to 450°C), 41.7 nm was achieved for a silicon Fabry–Perot membrane with dielectric Bragg mirrors (Hohfeld and Zappe 2005).

A second category of resonant filters is implemented with microrings or microdisks disposed between two optical waveguides. Both the microdisks and microrings support propagation modes; in the microring case these modes are those of the curved waveguide structure, whereas in the microdisk case the propagation modes are azimuthal and are commonly termed whispering gallery modes (**Figure 10**). Each of the waveguides can couple energy into the microdisk/ring evanescently. The microdisk/ring form a recirculating cavity for the propagating light, and a resonance condition occurs when propagation around the disk/ring is an integer multiple for a certain wavelength of light. If the light coupled into the microdisk/ring from the input waveguide does not

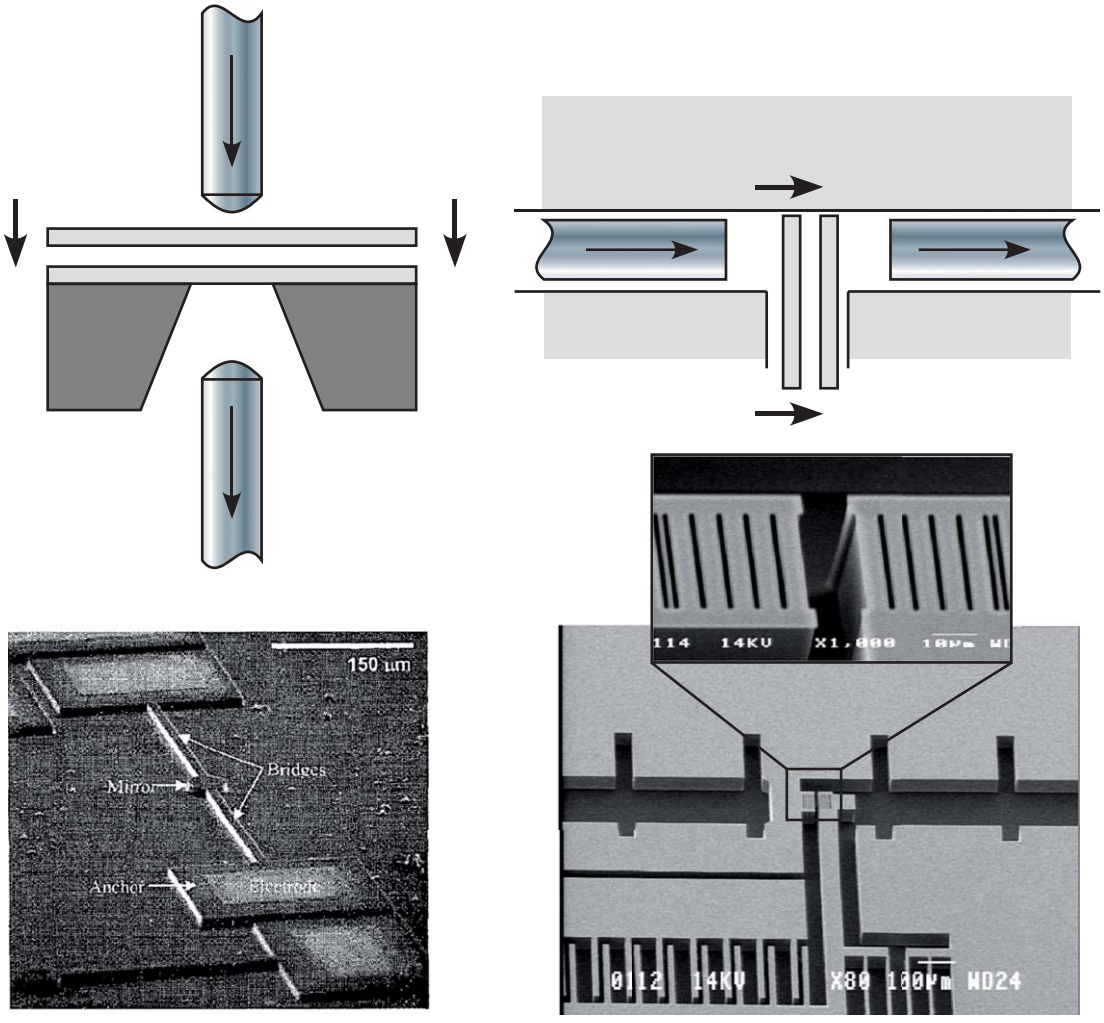

Figure 9 Fabry–Perot tunable filters. *Left*: Surface-normal arrangement and implementation. (Source: Kim C-K *et al.* 2003a 47 nm Tuning of thermally actuated Fabry–Perot tunable filter with very low power consumption. *IEEE Optical MEMS Conference*, Hawaii, HI, USA, © [2003] IEEE.) *Right*: In-plane arrangement and implementation. (Source: Saadany B *et al.* 2006 Electrostatically-tuned optical filter based on silicon Bragg reflectors. *IEEE Optical MEMS Conference*, Piscataway, NJ, USA, © [2006] IEEE.)

satisfy the resonance condition, the light will also couple out to the same waveguide and continue to propagate on the same input waveguide unimpeded. However, if the light does satisfy the resonance condition, the light will couple into the microdisk/ring from the input waveguide, and likewise will couple out of the disk/ring onto the second, drop waveguide. As in the Fabry–Perot case, the microdisk/ring bandwidth will be determined by the coupling coefficient into the cavity (similar to the partial reflectivity of the etalon), and the path length around the disk/ring. Moreover, the resonance condition is satisfied periodically in frequency, giving rise once again to a free spectral range. Their ratio is the characteristic quality factor, or Q, of the resonator. Because it is desirable to have only one resonance peak within the communication bandwidth, the microdisk/ring diameter is reduced to the order of a few microns. The described microdisk/ring resonators are fixed structures, and have been extensively explored for passive filtering applications. The operation of the microdisk/ring can be modulated by controlling the coupling into the resonator, as has been demonstrated by moving freely suspended waveguides closer to the microdisk (Lee *et al.* 2005), or by reducing the resonator's quality factor, as demonstrated by a metallic plate approaching the cavity and increasing the cavity's propagation losses (Nielson *et al.* 2005). A thermally wavelength-tunable and MEMS bandwidth-tunable microdisk cavity has been demonstrated on a silicon substrate.

(Source: Nielson G N *et al.* 2005 Integrated wavelength-selective optical MEMS switching using ring resonator filters. *IEEE Photon. Technol. Lett.* **17**, 1190–2, © [2005] IEEE.) (b) Micrograph of microdisk with moving waveguides to control coupling coefficient. (Source: Yao J *et al.* 2005 Wavelength- and bandwidth-tunable filters based on MEMS-actuated microdisk resonators. *Optical Fiber Conference (OFC)*, Anaheim, CA, USA, paper OTuM1, © [2005] IEEE.)

Heaters placed near the microdisk increase its refractive index and coupling to the resonator with electrostatic attraction provides a tunable passband between 12 and 41 GHz (Yao *et al.* 2005).

A final class of a tunable resonant devices is based on a thin waveguiding slab with a grating pattern formed on top (Rosenblatt *et al.* 1997). When such a structure is illuminated with an incident light beam, part of the beam is directly transmitted through the structure and part is diffracted by the grating and is trapped in the waveguide layer. Some of the trapped light in the waveguide layer is then diffracted out so that it interfaces destructively with the transmitted part of the light beam. At a specific wavelength and angular orientation of the incident beam, the structure resonates; namely, complete interference occurs and no light is transmitted. For wavelength tuning purpose, the resonant filter is attached to a MEMS tiltable platform (Niederer *et al.* 2004). The reflected wavelength is tuned by changing the angle of incidence of the resonant grating filter. The grating is patterned by holographic recording and dry etching. The demonstrated filter worked over a wavelength range of 1520–1580 nm with a 0.5 nm half-width for a single polarization. The MEMS platform is DRIE processed, and electrostatically actuated over $\pm 4^\circ$ with a driving voltage of about 60 V. Alternatively, a modulated resonant grating structure has been demonstrated, in which a thin suspended silicon layer is etched with the grating structure (Kanomori *et al.* 2006). The gap separation between the patterned silicon layer and the underlying silicon can be controlled with bimorph actuators, resulting in a disruption of the resonant guiding. The silicon layer was patterned in two dimensions, resulting in polarization-independent operation.

3.07.4.2.2 Deformable gratings

A grating-based spectral filtering arrangement utilizes the dispersive property of diffraction to collect a finite bandwidth of light by an aperture, such as an optical fiber. The bandwidth captured by the fiber is a design parameter, influenced by the grating frequency and spatial dispersion. One method for wavelength tuning the filter is to change the grating frequency. The change in grating frequency changes the spatial dispersion, resulting in a different center wavelength impinging on the collecting fiber. Changing the grating frequency is typically impractical, as bulk gratings have fixed ruling. A tunable grating frequency can be achieved by implementing the diffractive element as a movable sequence of grating lines with a constant periodicity that can be continuously changed. The constant periodicity property is important for a

uniform diffraction response resulting in high resolving power; without this uniformity, the filtering response would broaden. Therefore, MEMS tunable grating frequency designs implement identical support structures for the grating elements, such that the displacement is uniformly distributed (**Figure 11**). The displacement can be achieved by thermal expansion of the inter elements' support structure (Zhang and Liu 2000), strain distribution by spring structures upon electrostatic actuation applied to the end point (Torman *et al.* 2006), and distributed expansion by a piezoelectric effect of the support structure (Wong *et al.* 2004). Both the electrostatic and piezoelectric actuation mechanisms achieve submillisecond actuation speeds. An alternative tunable grating frequency implementation uses independent analog control of the position of each of the grating elements (Li *et al.* 2006). The moving elements are blazed at an angle to achieve high diffraction efficiencies, using a process that combines KOH etching and DRIE to realize mirror surfaces with a root mean square (RMS) roughness of 26 nm and stiff structures that resist out-of-plane bending. An optical experiment using the tunable blazed grating with a small number of elements demonstrated their basic filtering functionality. The challenge in using this approach is associated with the scaling to a large number of grating elements, required for high-resolution filtering.

A different technique for controlling the diffraction response of a grating utilizes a 1D micromirror array, where each micromirror can piston out of plane for phase encoding. The independently controllable phase modulators can be set to coherently direct light of a certain frequency to a diffraction direction (Belikov and Solgaard 2003, SasBerg *et al.* 2003). Various synthesis techniques can be employed for designing different filter response functions as a rectangular frequency response. Such filters use very large mirror arrays with simple piston-motion functionality for achieving high-resolution filtering. The 1D phase modulator can also be placed within a cavity to form a segmented Gires–Tournois interferometer (Yu and Solgard 2004). The back reflection plane of the traditional interferometer is replaced with the 1D micromirror array for phase modulation, resulting in both amplitude and phase control for

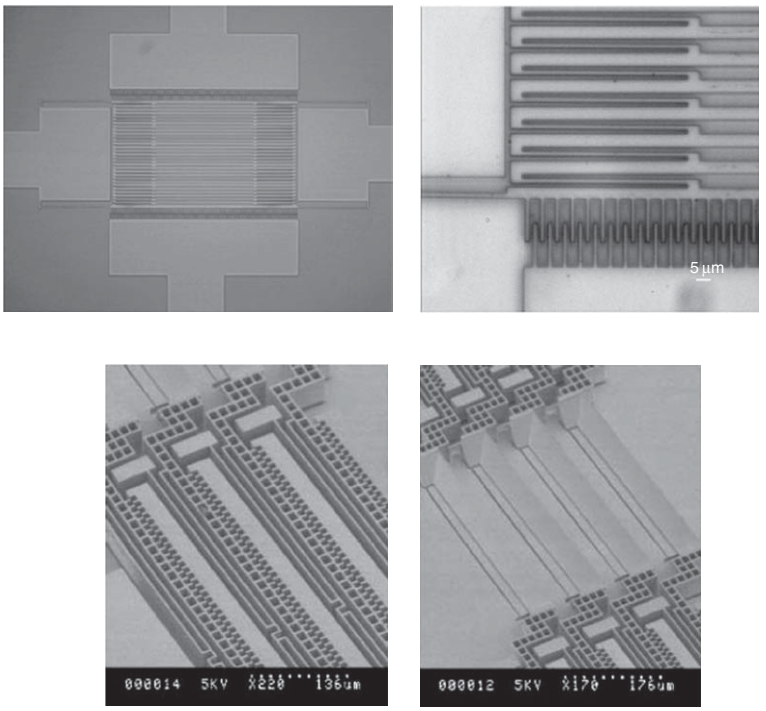

Figure 11 Deformable gratings. *Top*: Micrographs of electrostatic tunable grating frequencies with spring details on right. Opt.* **8**, S337–40, © IOP.) *Bottom*: Tunable grating with independent motion of each grating element. (Source: Li *et al.* 2006 Tunable blazed gratings. *IEEE J. Microelectromech. Sys.* **15**, 597–604, © [2006] IEEE.)

each micromirror reflection. Collecting all the mirror reflections and performing an optical spatial Fourier transform results in a transfer function for the device that has the same form as a transversal filter in digital signal processing. Thus, conventional filter synthesis techniques can be used for tailoring the filter's bandpass as well as chromatic dispersion.

3.07.4.2.3 Spatial filter of spectrally dispersed light

The most common technique for wavelength tuning a grating and lens-based filter is by changing the tilt angle of the grating, resulting in a shift of the spatial dispersion and a selection of a different center wavelength impinging on the collecting fiber. However, as high-quality gratings utilize thick and thereby heavy substrates for stability, they are not compatible with MEMS actuation. However, a shift of the spatial dispersion can be similarly accomplished by a tilting micromirror inserted in the beam path (Berger *et al.* 2003). The resultant passband shape when coupling spatially dispersed light into a single-mode fiber is Gaussian, and the reported implementation achieved a 32 GHz–3 dB bandwidth, tunable over 40 nm. Similar implementations have achieved wider tuning with correspondingly wider passbands as well, demonstrating the interplay between resolving power and tuning range (Kimura *et al.* 2004). The collecting fiber can also be replaced with an apertured photodetector, for implementing a complete tunable receiver (Berger *et al.* 2004). While angle tuning of a bulk grating is difficult to implement in MEMS technology, thin-film filters are much more compatible. A thin-film filter with a 200 GHz bandpass response was mounted on a thermally actuated MEMS rotation stage (Unamuno and Uttamchandani 2005). The measured mass of the filter was 6 g, and the MEMS rotation stage achieved 1.5° rotation for a 700 mW power draw. However, thin-film filters have weak angular tuning range, in the reported case of 100 GHz only.

The Gaussian passband shape associated with the direct coupling of dispersed light to a single-mode fiber is often undesirable. An alternative approach often utilized by WSSs and blockers (see Sections 3.07.4.5 and 3.07.4.5.1) is that of dispersing the light with a grating and filtering by a finite mirror, followed by the reverse process of combining the spectral components with the same grating and coupling to the fiber. The double passing of the grating (first to disperse and second to recombine) removes any frequency dependence for spectral component beams striking the mirror far away from the mirror edges. A filter with tunable passband width and center frequency has been demonstrated using this approach together with a MEMS tilt mirror (Wilson 2006). The MEMS mirror shifts the spatially dispersed light that is incident on the spectral mirror (**Figure 12**). The reflective spectral mirror in this case is triangular, chosen to select the passband width. The center frequency of the tunable filter is selected by shifting the dispersed light along the axis of the dispersion. The passband width of the tunable filter is chosen by translating the dispersed light in the orthogonal direction, such that the dispersed light encounters a broader or narrower segment of the triangular mirror. This filter can also operate in hitless mode, which is a unique distinguishing feature compared to all the above filters. Hitless operation is important for channel add-drop, where the act of channel tuning cannot cause a disruption to the intermediate channels. The MEMS micromirror has to tilt a broad beam in the filter implementation due to resolution requirements, and the experiment used a magnetically actuated mirror with an aperture of 4.5 mm × 6 mm, with an angular range of ±1.5° for a ±2.3 V drive. The filter demonstrated wavelength tuning over 36 nm, and passband width settings from 28 to 210 GHz, with a 4.6 dB insertion loss. Transmission experiments with 10 Gb s^{-1} data rate signal showed negligible power penalty due to the grating double passing arrangement.

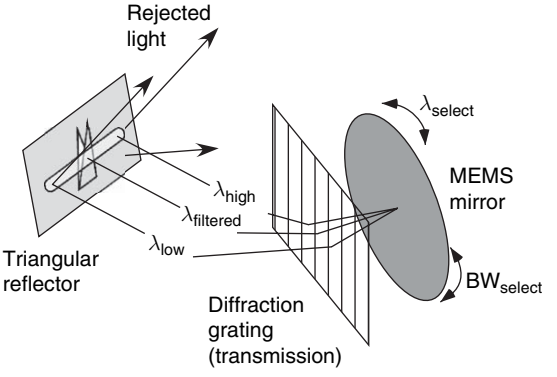

Figure 12 Wavelength and bandwidth tunable filter. Spatially dispersed signals can be scanned with microelectromechanical systems (MEMS) mirror in left–right direction to select wavelength and up–down to prescribe bandwidth. (Source: Wilson G 2006 Spectral passband filter with independently variable center wavelength, bandwidth. *IEEE Photon. Technol. Lett.* **18**, 1660–2, © [2006] IEEE.)

3.07.4.3 MEMS Variable Optical Attenuators

Terrestrial optical communications systems are required to operate over large dynamic ranges, as topography dictates irregular distribution of nodes (or cities) and amplifying stations. The path length diversity of optically amplified systems implies that the optical powers can vary by up to 20 dB, but as these are known system attributes, they can be addressed by placing fixed attenuation elements in the system. Other factors lead to changing conditions, such as the number of wavelength division multiplexing (WDM) channels, which typically increases as the network is required to handle more users and capacity, and less gain per channel is available. Furthermore, the system is designed with extra margin to allow for component aging, resulting in lower transmitter powers and amplifier gain over the lifetime of the system. This leads to a large variation in the incident power that the optical receiver might experience. On the other hand, the optical receiver, comprised of an optoelectronic detector and electrical amplifiers, typically operates over a limited dynamic range. To limit the receiver's impinging optical power to the acceptable dynamic range, a variable optical attenuator (VOA) is normally introduced as part of the receiver. The VOA is a simple device with a single input fiber and a single output fiber, where the experienced optical loss between the input and output fibers can be continuously set. VOA can also be used as replacement for simple 1×2 switches, in an arrangement consisting of a power splitter and a VOA placed on each branch, enabling broadcast and select topology at the cost of higher losses. Other uses, requiring faster VOA in optical networks, are for transient suppression of amplifier dynamics that can wreak havoc on the stability of the network, and for possible low-frequency modulation of the transmission bit stream to encode system signaling information that can be received by a low-frequency response photodetector (a technique known as pilot tones) (Darcie *et al.* 2005).

Because the VOA is integrated into each channel receiver and has additional network uses, it is a high-volume optical component, implying it must be inexpensive, compact, and preferably consume very little power. These attributes make VOA functionality well suited for a MEMS implementation.

3.07.4.3.1 Shutter VOA

Optical loss can be introduced by blocking the light radiating out from the input fiber en route to the output fiber. A movable shutter placed in the beam path can selectively block the light in proportion to the shutter's displacement. The optical arrangement can be very simple by setting a minimal gap between the input and output fibers, where the gap region is intended for the shutter placement (**Figure 13**). Such an arrangement does not require any imaging optics, greatly simplifying the packaging requirements, and has a planar form factor. The intrinsic optical loss of this arrangement is due to light diffraction between the input and output fibers, as well as a possible contribution from lateral fiber misalignment in the packaging process. To minimize the intrinsic optical losses, it is necessary to minimize the gap size; hence, the shutter width should be very small, a requirement compatible with MEMS technology. Counter to the requirement that the shutter width should be small, its lateral dimension should be comparable to the optical fiber diameter, or $\sim$125 μm. The shutter range of motion should preferably be greater than the fiber radius so that the unactuated shutter should be further from the optical fibers during the assembly process. The shutter normal should also be tilted with respect to the fiber axis, so that back reflections will not couple back into the input fiber.

The large lateral dimension and travel range requirements for the MEMS shutter and its orientation normal to the fiber plane impose design limitations. A surface micromachined optical shutter VOA has been demonstrated with the shutter element rotated 90°, normal to the substrate (Barber *et al.* 1998, Giles *et al.* 1999). The shutter element was attached via a lever arm to a parallel plate capacitor actuator. Upon actuation, the shutter elevated further from the substrate via a pivot and hinge structure. A voltage range of 0–28 V applied to the capacitor plate resulted in full attenuation, with a switching speed faster than 100 μs. The fiber-to-fiber gap size of 20 μm yielded a minimal loss of 0.8 dB. An alternative bulk micromachining process optical shutter VOA utilizes DRIE in a thick silicon layer on an insulator wafer (Marxer *et al.* 1999). The VOA uses a comb-drive actuated shutter and fiber placement grooves for simple alignment. To minimize the risk of damage during fiber placement, the large gap size of 60 μm was maintained. To reduce the effect of beam diffraction and subsequent optical losses upon coupling to the output fiber, the entire package including the gap region was filled with index matching oil. The optical losses were reduced from 2.5 to 1.5 dB, with an additional damping benefit provided by the oil, eliminating mirror ringing effects. A voltage range of 0–30 V applied to the comb-drive actuator resulted in full attenuation, with switching speed of 4.5 ms (due to the oil damping effect).

Technol. Lett.* **11**, 233–5, © [1999] IEEE.)

The VOA implementations described above require a steady voltage to maintain the attenuation settings, sometimes coupled with a feedback loop for added stability. A desired alternative is a latching switch, which requires active actuation in order to reach an attenuation state, but can then hold the state indefinitely with no power draw. A Vernier latching technique can be used to hold the shutter in the desirable attenuation state (Syms *et al.* 2004b, Unamuno and Uttamchandani 2006). The Vernier latch attenuation level progresses in discrete steps in one direction, and has a release actuator to return the VOA to the unactuated state. This operation mode is not amenable to active power level control feedback, often necessary for stable operation of optical networks. Moreover, the latch release operation and re-engagement can cause deleterious transient effects in networks.

Some concerns with polarization dependence exist when using the shutter-type actuator, due to vectorial diffraction effect from the shutter's edge. A MEMS iris alternative to the shutter has been demonstrated, with has greater symmetry about the optical fiber mode. The iris consists of four simultaneously moving blades, continuously adjusting the size of a central opening in the beam path (Syms *et al.* 2004a).

A self-powered VOA offers an interesting feature for surge suppression in optical networks (Aksyuk *et al.* 1999, Hirat *et al.*, 2005). The VOA includes a photogenerator, which provides sufficient voltage to drive the VOA in feedback mode. A power tap after the shutter drives the photogenerator in a self-governing mode; as the incident power on the detector increases, so does the photogenerator voltage, engaging the VOA shutter and regulating the output through increased attenuation.

3.07.4.3.2 Beam displacement VOA

An alternative loss-generating scheme to the optical shutter consists of an optical arrangement that displaces the beam emerging from the input fiber, thus controlling the coupling efficiency into the output fiber. The scheme suggests that a more complicated optical system is required compared to the simple fiber gap arrangement of the shutter solution. However, the optical losses associated with a well-designated optical system between the input and output optical fibers can result in lower losses compared to propagation over a finite fiber gap. MEMS micromirrors are well suited for implementing the beam displacement mechanism of the optical system.

One method for imparting beam translation utilizes a tilting micromirror in the beam path. A 3D configuration often used places the input and output fibers side by side with their polished endfaces at the front focal plane of a common lens (**Figure 14**). The MEMS tilting mirror is placed at the back focal plane of the lens. When the mirror is in the unactuated state, light from the input fiber is collimated by the lens onto the mirror, is reflected back, and subsequently focused by the common lens into the output fiber. The intrinsic coupling efficiency of this configuration is limited only by the quality of the lens (antireflection losses and aberrations) and the mirror reflectivity, and can routinely achieve better efficiency than -1 dB. Polarization effects are also minimized because the beam is almost normally incident onto the mirror. When the mirror is tilted, the focused beam is shifted from the output fiber and coupling losses increase according to fiber misalignment calculations. The relationship between the mirror tilt $\Delta\theta$ and beam shift Δx is $\Delta x = 2f\,\Delta\theta$, where f is the focal length of the lens (obtained by geometric optics using small angle approximations). Thus, larger focal lengths require smaller tilt angles for imparting the same loss values. However, the collimated optical mode size at the mirror also increases with the focal length, requiring a larger mirror with greater sensitivity to mirror curvature. The lens focal length is typically kept small (order of 1 mm), resulting in a smaller system size. The collimated beam diameter is $D = 2f\lambda/(\pi w_0)$

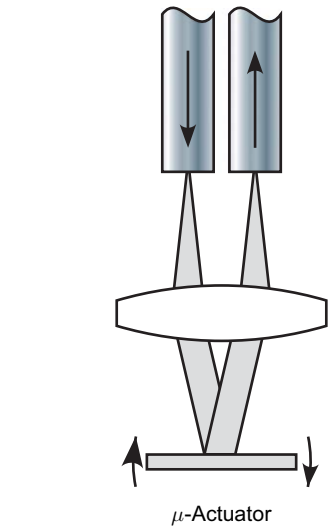

Figure 14 Beam scanning-type variable optical attenuator in a 3D layout. *Top*: Schematic representation. *Bottom*: Micromirror and support details fabricated using silicon bulk micromachining. (Source: Isamoto K *et al.* 2004 A 5-V operated MEMS variable optical attenuator by SOI bulk micromachining. *IEEE J. Selec. Top. Quant. Electron.* **10**, 570–8, © [2004] IEEE.)

($D = 200\,\mu m$ using a 1-mm lens), requiring a mirror size of $1.5D$ (or 300 μm for a 1-mm lens) for minimal insertion losses, a size that is compatible with MEMS technology. A commercial, bulk micromachining, electrostatic MEMS tilting mirror (30-μm-thick, 600 μm diameter silicon mirror) demonstrated 5 V full actuation and a 3 ms underdamped response time (Isamoto *et al.* 2004). The entire VOA package is 5.6 mm in diameter and 23 mm long. Alternative actuation techniques for the tilting micromirror can be employed (Diemeer and Dekker 2002).

A planner beam translation method places one or more micromirrors in the beam path between the input and output fibers (**Figure 15**). Both fibers have a lens attached to their end facets, creating a collimated beam with an extended propagation distance between the two lensed fibers (typically hundreds of microns). A 90° folded geometry with a single MEMS translation or rotation mirror (Bashir *et al.* 2004, Yeh *et al.* 2006), or a 180° folded goemetry with two MEMS translation mirrors have been demonstrated (Cheng *et al.* 2004). In all cases, DRIE must be employed due to the fiber diameter and the planar configuration. The different MEMS designs utilize comb-drive actuators with low driving voltage (up to 30 V) and fast response times (millisecond range). The optical arrangements have low intrinsic losses (<1 dB), but the long beam path is sensitive to fiber placement errors, sometimes requiring active alignment within the alignment grooves. Because the reflective mirror surface is the etched silicon sidewall, surface roughness contribute to the intrinsic device loss and can limit the attenuation range due to scattering.

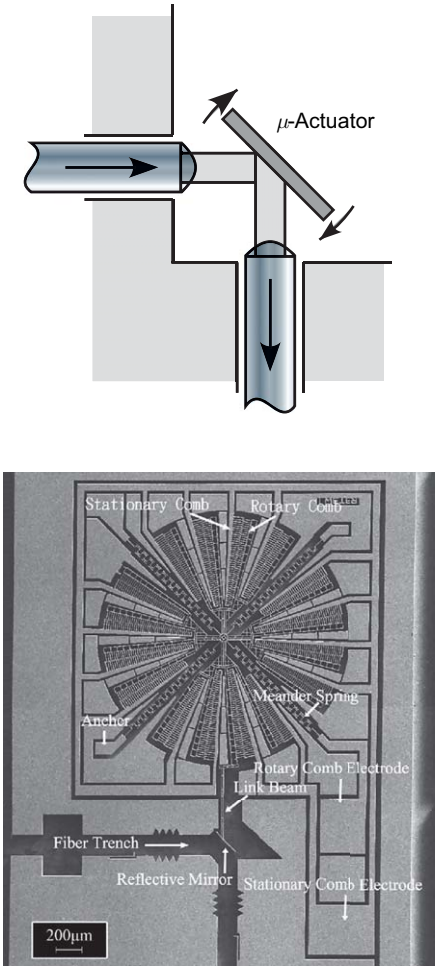

Figure 15 Planar beam scanning-type variable optical attenuator (VOA). *Top*: Schematic representation. *Bottom*: VOA with micromirror attached to a rotation stage, fabricated using bulk micromachining. (Source: Yeh J A, Jiang S-S, Lee C 2006 MOEMS variable optical attenuators using rotary comb drive actuators. *IEEE Photon. Technol. Lett.* **18**, 1170–2, © [2006] IEEE.)

An alternative beam displacement technique to a mirror in the beam path is a displacement of the input fiber with respect to the output fiber with the aid of MEMS actuators (Kanamori *et al.* 2003). One implementation utilized moving silicon waveguides suspended in air instead of optical fibers (Tilleman *et al.* 2005), with the silicon waveguides operating in the multimode regime (having a cross section of $14\,\mu m \times 14\,\mu m$). The moving waveguide is attached to a comb-drive actuator. Due to the multimode structure, the attenuation versus displacement is highly dependent on mode number and polarization. However, the fundamental mode is very well behaved. The small air gap in the waveguide introduces diffraction losses and can also introduce Fabry–Perot effects, in the form of wavelength-dependent attenuation, due to the high reflectivity in the silicon-to-air interface.

3.07.4.3.3 Variable reflectivity mirror

The previous solutions, whether based on a shutter inserted into the optical beam or beam displacement with tilting or moving mirrors, require MEMS devices with a relativity large motion range. An alternative arrangement based on mirrors whose reflectivity is adjustable can be utilized. The simple and low-loss optical arrangement with the common imaging lens is often used, with the variable reflectivity mirror replacing the tilting mirror. The variable mirrors can be based on interferometric and diffractive MEMS (DMEMS) solutions, both requiring a motion range smaller than the optical wavelength.

An interferometric mirror based on the interference between two membranes with a controllable gap size between them achieved tunable reflectivity (Ford *et al.* 1998). The mirror, termed mechanical antireflection switch (MARS), functions effectively as a dielectric coating on a silicon substrate. The active element is a silicon nitride layer one-quarter wave optical thickness, just as for a single layer dielectric antireflection coating (**Figure 16**). This silicon nitride layer is separated from the silicon substrate by $(3/4)\lambda$. At the $(3/4)\lambda$ separation, the antirefection coating becomes a single layer dielectric mirror with up to 72% reflectivity. However, the membrane is deformable. Voltage applied to electrodes on top of the membrane creates an electrostatic force, which pulls the membrane closer to the substrate. When the membrane gap is reduced to $\lambda/2$, the layer becomes an antireflection coating with close to zero reflectivity. Due to the small range of motion and the high silicon nitride film stress, the device can operate at 3 μs response times. A 28 dB attenuation dynamic range was observed for a 0–35 V operating voltage range. The device is nearly polarization independent on account of the normal incidence. However, due to the wavelength dependence in the interference effect, there is a strong wavelength-dependent attenuation. The wavelength dependence is especially pronounced about the peak attenuation value, where perfect destructive interference can only be achieved for a single wavelength.

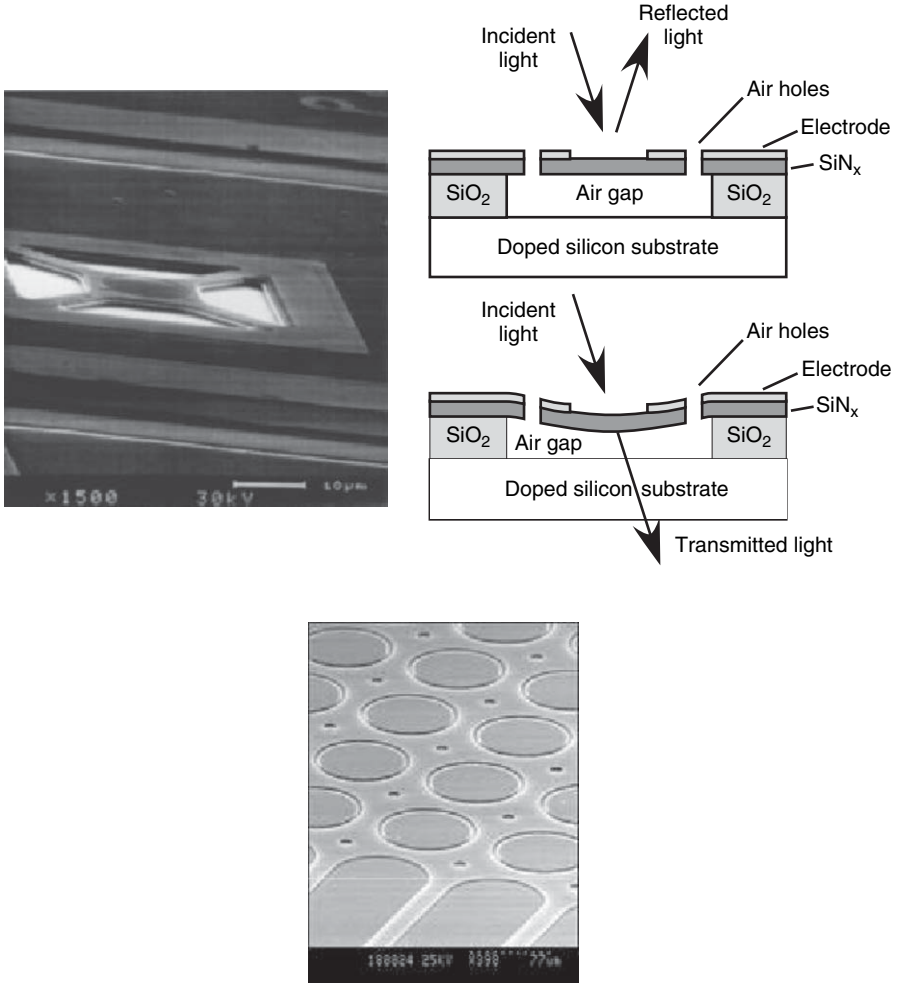

Figure 16 Variable reflectivity mirrors. *Top*: Controlled interference between moving thin membrane and substrate layer. (Source: Ford J E *et al.* 1998 Micromechanical fiber-optic attenuator with 3 μs response. *IEEE J. Lightwave Technol.* **16**, 1663–70, © [1998] IEEE.) *Bottom*: Controlled interference between moving plate and static pillars. (Source: Godil A 2002 Diffractive MEMS technology offers a new platform for optical networks. *Laser Focus World*, May.)

DMEMS mirrors can also be used in a VOA application, by utilizing the zeroth diffraction order for coupling back into the output fiber (Godil 2002). However, the traditional DMEMS, consisting of periodic ribbons where half can be actuated, does not offer the necessary performance for optical communication application. Ignoring the gap region in the DMEMS, the power in the zeroth diffraction order is proportional to $(1/2)\,(1+\cos(\Delta\phi))$, where $\Delta\phi$ is the phase difference between the reflected signal from the actuated versus unactuated ribbons. The attenuation can be set to zero when the phase difference, $\Delta\phi$, is π ($\lambda/4$ translation), but the condition is satisfied for a single wavelength only due to the wavelength dependence in the phase delay. To circumvent the wavelength dependence, the DMEMS device can be optimized taking three parameters into account; the phase and period fractions of the movable ribbons, the stationary ribbons, and the exposed substrate in the gap regions. The extra gap factor allowed for a design that is nearly achromatic in the attenuation state. The ribbon structure gives rise to polarization dependence, due to the inherent orientation asymmetry. By creating a grating structure that is perfectly symmetrical in the two directions, polarization-independent operation is achieved, and the achromatic response criterion is also included in the design. The reflective surface is comprised of fixed round disks, a movable membrane around the disks, and a gap region between the membrane and the disks. Incident light is reflected on all three surfaces, and the geometrical layout ensures low polarization and wavelength dependence. The packaged VOA is 5.4 mm in diameter, and 18 mm long, and operates at a 0–5 V voltage range. According to a commercial press release, as of March 2005, 40 000 VOAs have been shipped to customers, demonstrating the large market demand for VOA modules.

3.07.4.4 MEMS Optical Fiber Switches

Optical fiber switches route the entire guided optical signal from one fiber to another, and scale in size from fundamental 1×2 and 2×2 switches to $N \times N$ switches, where N can be as large as one thousand. When possible, it is more desirable to switch signals in the optical domain due to the cost and power savings over optoelectronic equipment. Their uses in optical communication systems and networks are as diverse as the scale range they encompass. The basic 1×2 switch is often used for protection against equipment failure. For example, metropolitan-scale fiber rings often utilize fiber redundancy using a BLSR (bidirectional line switched ring) topology. The 1×2 switch is used to switch from the main fiber to the backup fiber when a loss-of-signal occurs (e.g., fiber cut). A fundamental 2×2 switching element can be used as a stand-alone switch or within a multistage interconnection network architecture (such as a Benes network) for constructing larger switch fabrics. The 2×2 switch can be used for implementing optical add-drop architecture on a per-channel basis. A $1 \times N$ switch, which routes from one fiber to one of any N fibers, can be used for efficient equipment sharing, such as optical monitoring at an amplification site. Finally, large $N \times N$ switches, often referred to as optical cross-connects (OXCs), are used to establish a desired connectivity pattern across many fibers. An OXC is therefore sometimes referred to as an automated patch panel, whose connectivity can be changed without the need for a technician's visit to the switch site. The OXC can be used to route individual WDM channels at a network node using opaque or transparent operating modes. A transparent switch, also termed OOO, is one where an input *optical* signal is switched in the *optical* domain and exits the switch in the *optical* domain. The photons flow through the switch unimpeded. OOO terminology contrasts the transparent switch to OEO switches, where an input *optical* signal is switched in an *electronic* switch fabric and exits in the *optical* domain again. An opaque switch uses the same switching fabric as the transparent switch, but isolates the optical switch from the optical input and output signals with electronic conversion. Hence, the opaque switch with OEOEO functionality regenerates the optical signal and does not suffer from wavelength contention issues.

While the smaller 1×2 and 2×2 optical fiber switches can be constructed using many competitive technologies, the larger switches are implemented exclusively using MEMS technology. The most common switching method uses micromirrors, yet other MEMS alternatives exist as well. Companies offering MEMS optical fiber switches have received much attention, as well as investment, during the telecom boom years. Very few of these companies survived, as the demand and deployment of large OXC switches never materialized. An opaque OXC architecture, while offering complete freedom of WDM channel routing restriction due to the signal regeneration, was too expensive to deploy. Transparent OXC functionality could be more effectively implemented using WSSs.

3.07.4.4.1 Small lensless MEMS switches

Small switches require simple optical arrangements, and the simplest optical arrangements have no imaging optics between the input and output fibers. The distance between the input and output fiber end faces in such nonimaging solutions has to be very small, so that the coupling losses due to beam diffraction will be minimal. The gap region between the fibers can be minimized if no intervening elements need to be placed in it. Hence, the basis for a simple 1×2 switch is a movable input fiber, which can be laterally actuated to a position in front of either output fibers (**Figure 17**). The positional accuracy or placement in front of the fiber is very important for minimizing the coupling loss. Therefore, moving fiber switches rely on bistable designs with mechanical stops that define the parking positions (Field *et al.* 1995, Herding *et al.* 2003, Hoffmann *et al.* 1999). The optical fibers are placed in alignment grooves, with the single fiber typically placed onto a moving thermal actuator owing to the required large fiber bending forces. While the power consumption of the thermal actuator is high (~1 W), it is only required in actuation, due to the bistable design. Reported switching time is 400 ms, which is too slow for a protection application. An electrostatic switch using a metalized fiber offers an alternative actuation method. The electrostatic actuation at 75 V achieved a 10 ms switching time. One disadvantage associated with the moving fiber switch is that the three fibers are manually inserted into their alignment grooves, and offer no axial alignment mechanism. Hence, the gap region is intentionally larger than the minimal clearance (typical values of 25 μm) and the gap will be different for the two output fibers, resulting in uneven losses. The moving fiber concept can also be implemented with moving waveguides, in which case the gap region can be photolithographically defined (Bakke *et al.* 2002, Ollier 2002, Stuart *et al.* 2003). The moving waveguide approach using electrostatic actuation has been demonstrated in buried glass waveguides with metallization around the cladding region, in polymer waveguides deposited on top of a conducting SOI actuator, in GaAs waveguides, and in silicon ridge waveguides. The moving waveguide approach typically achieves submillisecond switching times and actuation voltages of a few tens of volts. Due to Fresnel reflections at the waveguide–air interface, the gap region forms a Fabry–Perot cavity. The gap region has to be precisely etched to ensure that its width will coincide with the cavity transmission peak.

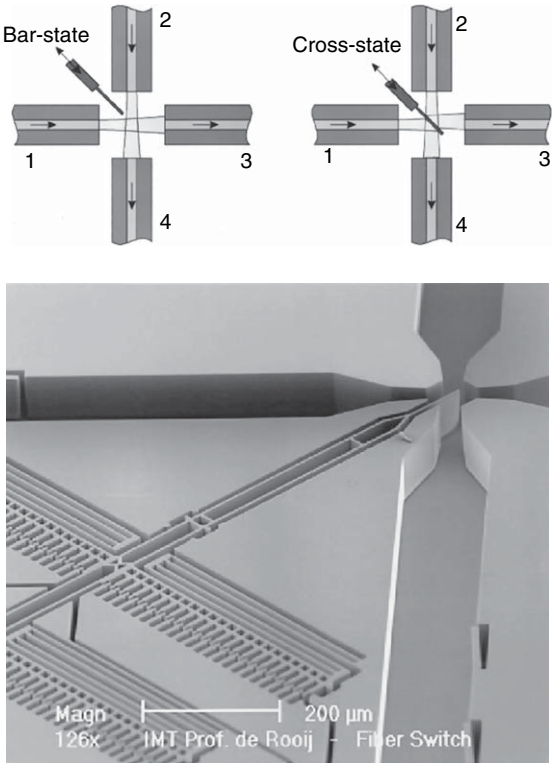

Figure 18 Lensless 2 × 2 fiber crossbar switch with inserted mirror. *Top*: Schematic representation of switch. *Bottom*: Image of microelectromechanical systems (MEMS) switch fabricated in silicon using bulk micromachining. (Source: Marxer C, de Rooij N F 1999 Micro-opto-mechanical 2 × 2 switch for single-mode fibers based on plasma-etched silicon mirror, electrostatic actuation. *IEEE J. Lightwave Technol.* **17**, 2–6, © [1999] IEEE.)

A more complicated arrangement is required for lensless 2 × 2 optical fiber switches, which is counter to the minimal gap requirement. The lensless approach brings the four fibers together in a cross configuration (**Figure 18**). Light from the two input fibers, labeled 1 and 2, can free-space propagate across the junction region and couple to two output fibers, labeled 3 and 4. When a mirror is placed across the junction region, the light is reflected from the mirror and the switch is placed in the cross state. The mirror is inserted into the beam path in a similar fashion to the optical shutter in bulk micromachined VOA. A DRIE in a thick silicon layer on insulator wafer forms the shutter, the comb-drive actuator, and fiber placement grooves (Marxer and de Rooij 1999). The etched silicon layer is 75 µm thick, sufficient to cover the entire core region when standard single-mode fiber is used. The fiber gap size is required to be at least as large as the fiber's outer diameter, due to geometric constraints associated with placing four fibers at 90°. However, the insertion losses due to diffraction after propagation over such large gaps are large. The gap size can be reduced by using fibers with reduced cladding, resulting in a smaller outer diameter. Losses can be further reduced by placing index matching oil in the gap region, reducing the diffraction angles. The index matching oil also serves to dampen the mirror response, eliminating mirror ringing. The mirror's actuation voltage was 60 V, and the response time was about 0.5 ms. Insertion losses at the bar state (no mirror inserted) was below 1.2 dB (best achieved value of 0.55 dB). In the cross state (with mirror reflection) losses increased to a typical value of 1.8 dB (best achieved value of 1.55 dB). The added loss originates from the mirror quality, as a vertically etched mirror will exhibit roughness impacting the reflectively.

3.07.4.4.2 *Sharing 1 × N* fiber switches

As the number of fiber ports in a switch increases, imaging optics have to be introduced in order to collect the light radiating out of the input fiber and efficiently couple the light to the output fiber. $1 \times N$ optical switches, which switch light from an input port to one of N output ports, have an optical system that accommodates $N+1$ optical fibers. Typical values for the number of fibers N is 4 or 8. Such switches are typically used in reverse, as $N \times 1$ switches, for sharing a common resource among the N fibers. Beam displacement with one tilting micromirror in the beam path is an effective switching technique for $1 \times N$ switches. The arrangement is similar to the dual fiber collimator employed by beam displacement VOA, with the $N+1$ fibers in the lens's front focal plane and a tilting micromirror in the back focal plane (**Figure 19**). Each of the N fibers can be addressed by a unique mirror angle. Because the beam size and the micromirror size scale with the lens' focal length, it is desirable to use a short focal length lens. However, as opposed to the two fibers required for VOA, $N+1$ fibers occupy a larger lens field of view that will result in aberrations playing a significant factor in the coupling to fibers that are farther off-axis. One way to reduce this effect is to use a longer focal length, compound lens, which is better corrected for aberrations. This approach has been used in the demonstration of a 1×160 fiber switch (Ford and DiGiovanni 1998). However, as the beam size increases with the focal length, the resulting mirror size is beyond the size of MEMS devices, and enters the realm of precision mechanical mechanisms. A

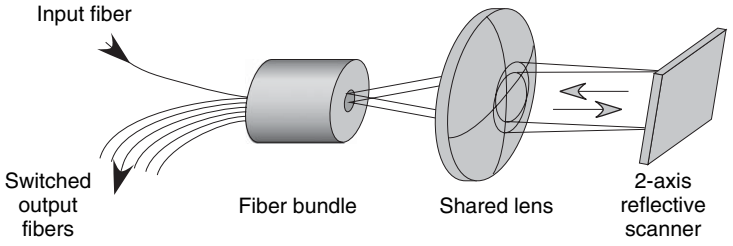

Figure 19 Sharing $1 \times N$ fiber switch. Schematic representation of beam scanning for selecting output fiber. (Source: Ford J E, DiGiovanni D J 1998 $1 \times N$ fiber bundle scanning switch. *IEEE Photon. Technol. Lett.* **10**, 967–9, © [1998] IEEE.)

large switch implementation used galvanometer rotation actuators with prisms in a reflective arrangement to accomplish the beam scanning, with a 20 ms switching time and a worst-case insertion loss of 3.5 dB. A second way to reduce the effects of the off-axis aberrations is to place a deformable mirror instead of the micromirror (Peter *et al.* 2002). The mirror shape can be optimized to reduce the coupling losses for each fiber. The reported demonstration packed 32 fibers in a linear array, placing the input fiber at the array end and on the lens axis for studying the aberration limitations. Thus, the results are equivalent to a 62-fiber switch with 1D packing, or 3019 fibers using 2D fiber packing. Resulting fiber coupling losses ranged from 3 to 6 dB. Possible alternatives to address the aberrations from large count fiber switches include the use of a reduced cladding fiber, for minimizing the fiber bundle lateral extent that is dominated by the fiber's outer diameter, or the placement of a fiber collimator for each fiber. The advantage of placing collimators is that the resulting mode size on the MEMS mirror decreases, resulting in the fiber coupling being less mirror angle dependent.

An alternative approach to the construction of a $1 \times N$ switch is to cascade several 1×2 switches in a binary tree arrangement. The cascade can be from individual 1×2 switches, whereas in the case of moving waveguides the entire switch can be monolithically integrated onto a single wafer device (Ollier 2002).

3.07.4.4.3 Optical cross-connects ($N \times N$)

Large $N \times N$ fiber switches or OXCs were believed to be the best method of managing the exponentially growing traffic in optical networks at the height of the telecom bubble. The established core network vision foresaw these large switch fabrics routing WDM channels at network switching nodes, offering new wavelength services and providing shared protection services (Al-Salameh *et al.* 2002). However, sales of these large switches did not meet the high expectations. The large switches required an upfront investment for handling future traffic demand. Two main OXC designs were pursued by many companies. The first is a beam scanning switch using analog multistate mirrors, starting from sizes of 64×64 and growing to fiber port counts of 1296×1296. The second is a crossbar switch implementation with digital bistate mirrors, most of these switches were 8×8 in size, with some as large as 32×32. The smaller switch modules could be used in a Clos architecture to construct large switch equivalents. Yet even the smaller switch versions saw their viability wither with the downturn in service providers' infrastructure investment and as interest shifted to switching WDM channels using WSSs.

Small optical fiber switches of the crossbar design are planar in structure, with the input linear fiber array arranged at one facet of the switch and the output linear fiber array arranged at a second facet of the switch, at 90° to the first facet (**Figure 20**). The fiber arrays are mated to matching collimating lens arrays, such that the beams from the input and output fibers generate a regular grid. Each beam from an input fiber intersects every beam of the output fiber. For an input/output array of N fibers, there are thus N^2 such beam intersections. Switching from any input fiber to any output fiber in the crossbar design is accomplished by placing a mirror at the respective beam intersection position. Each of these mirrors is bistable; in one state it is not in the beam path, whereas in the second state it is at 45° and completes the connection. Several factors impact the design and performance of crossbar switch. There is no way to fine-tune the mirror position to maximize the coupling efficiency. Because each mirror will have an independent misalignment from an ideal setting, these switches have considerable loss variation for each possible input/output connection. Additionally, even with an ideal mirror position, an additional source of loss variation in the switch is the optical path length

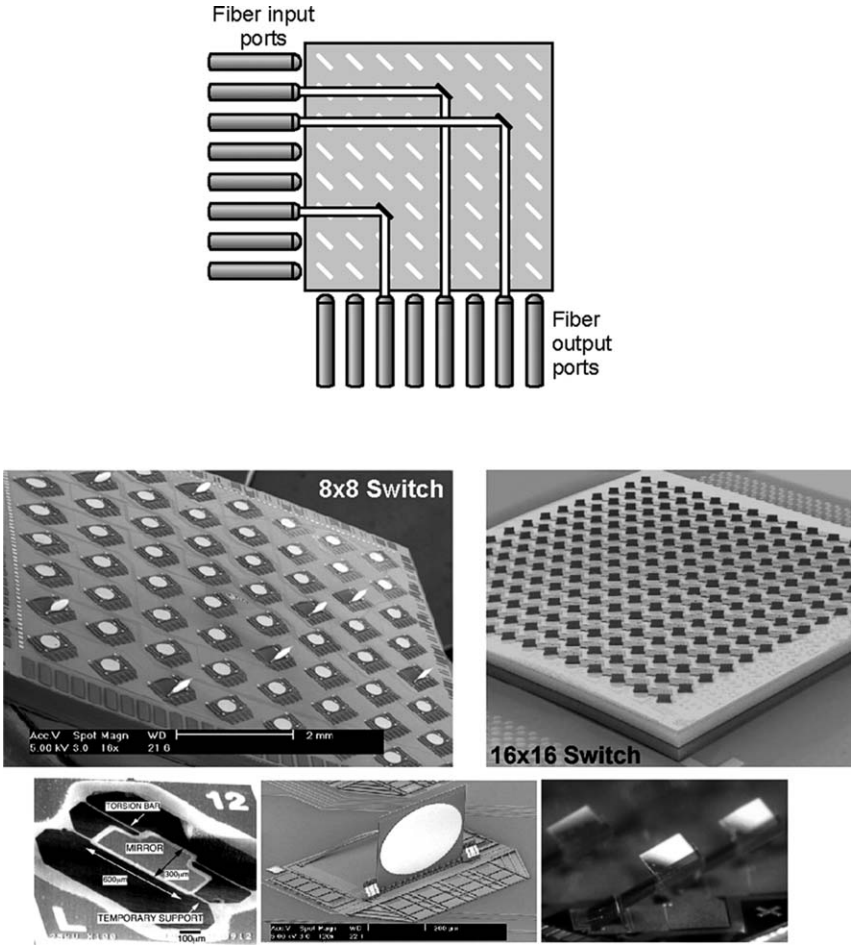

Figure 20 Planar crossbar $N \times N$ fiber switch. *Top*: Schematic representation. *Middle*: Image of 2D matrix of digital microelectromechanical systems (MEMS) mirrors. *Bottom*: Details of exemplary MEMS digital mirrors. Left mirror rotates 90° out of plane with electrostatic actuation, middle mirror rotates with scratch drive, and right mirror lifts with a seesaw actuator. (Source: Lin L Y, Goldstein E L, Tkach R W 1999 Free-space micromachined optical switches for optical networking. *IEEE J. Select. Top. Quant. Electron*. **5**, 4–9, © [1999] IEEE; Toshiyoshi H, Fujita H 1996 Electrostatic micro torsion mirrors for an optical switch matrix. *J. Microelectromech. Technol. Lett.* **10**, 525–7, © [1998] IEEE; De Dobbelaere P *et al.* 2002 Digital MEMS for optical switching. *IEEE Commun. Mag.* **40**, 88–95, © [2002] IEEE.)

differences for each possible connection, with the difference between the shortest beam path to the longest being twice the length of the fiber array. Finally, as the beam strikes the metalized surface of the mirror at 45°, the reflection adds some polarization-dependent loss (~0.4 dB). The optical path length of the crossbar switch scales with the product of the fiber count, N, and the fiber pitch, P. Placing a requirement on the beam size, w_0, to accommodate for the propagation distance, L, one finds that $L \propto \left(w_0^2/\lambda\right) \propto N \times P$. Because the fiber pitch is also linearly proportional to the beam size, we can conclude that $N \propto (w_0/\lambda)$, or that the collimated beam size also scales linearly with N, to accommodate for the longer propagation distance. The major implication of having the fiber array length as well as the fiber pitch scale linearly with N, is that the physical extent of the crossbar switch will scale with N^2, making the crossbar switch impractical for large fiber port counts due to wafer size limitations. An exemplary design of a 16×16 crossbar switch leads to a mirror diameter of 320 μm and a lateral length of 8 mm (Ryf *et al.* 2006). Doubling the fiber port count to a 32×32 switch size doubles the mirror size to 640 μm and quadruples the lateral length to 32 mm. One unique feature of the crossbar switch is the ability to utilize both sides of the micromirror for establishing a second

simultaneous connection (Lin *et al.* 1999). Such architecture has been proposed for implementing add-drop functionality with no additional hardware requirements (**Figure 21**).

The digital MEMS micromirrors of the crossbar switch are required to have large motion comparable to the beam size. Such a large motion is best achieved with long lever arms used to amplify the actuator's motion. The originally demonstrated crossbar switch used polysilicon torsion mirrors supported by long slender rods that enabled the mirrors to rotate 90° out of plane using electrostatic actuation and a mechanical stopper (Toshiyoshi and Fujita 1996). Later pop-up mirrors achieved 90° rotation from the substrate using a translation distance of 22 µm from a scratch drive actuator with submillisecond switching time (Lin *et al.* 1998). The insertion losses of these early research prototypes were 10 dB or higher. Subsequent commercialization of crossbar switches reduced the losses to 2–3 dB by using MEMS micromirrors with better pointing accuracy (Dobbelaere *et al.* 2002). The improvement is provided by decoupling the mirror angle, critical for efficient fiber coupling, from the mirror motion. This was achieved by utilizing mirror translation as opposed to rotation, using a seesaw structure.

Large optical fiber switches of the beam scanning design utilize the free-space volume of the switch, with an input 2D fiber array at one facet of the switch and an output 2D fiber array at the opposing facet (**Figure 22**). The fiber arrays are mated to matching collimating lens arrays, forming light beams from the input fibers onto the output fibers. To establish a connection from any input fiber to any output fiber, the beam from the input is directed to the desired output and then realigned to efficiently couple into the output fiber. Thus, every connection is required to have two beam scanning elements. Because there are N input and output fibers in an $N \times N$ switch, the number of actuators in the switch is $2N$, in comparison to N^2 of the crossbar switch. However, each actuator has to assume one of N possible positions for each switching state. Mirrors can be introduced to fold the propagation length between the input and output fiber arrays, resulting in a more compact switch form factor. When MEMS micromirrors perform the beam scanning, they can be part of the folding mechanism. The path length variation in the beam steering switch is relatively small, as the distance between the input and output fiber arrays, L, is much larger than the arrays' lateral extent. The fiber arrays' lateral extent scales as the product of the pitch, P, and the square root of port count, $\sqrt{N}$, due to the 2D array layout. The beam scanning range $\Delta\theta$ is proportional to the ratio of the lateral extent to the distance between the arrays, or $\Delta\theta \propto \left(P\sqrt{N}/L\right)$. Placing a requirement on the beam size, w_0, to accommodate for the propagation distance, L, one finds that $L \propto \left(w_0^2/\lambda\right)$. Because the pitch, P, is also proportional to w_0, by substitution we find the scaling of the beam scan range $\Delta\theta \propto \left(\sqrt{N}\lambda/P\right)$, of the

propagation distance $L \propto \left(N\lambda/(\Delta\theta)^2\right)$, and of the lateral dimension $P\sqrt{N}$. The physical extent of the switch scale more gracefully with the fiber count N; linearly in propagation distance and as the square root in the lateral dimension. An exemplary design of a 256×256 OXC with a 1 mm pitch requires a propagation distance of 86 mm, a lateral dimension of 16 mm × 16 mm, and a mirror tilt range of ~10° (Ryf *et al.* 2006). Additional optical elements, such as lenses or microprisms, can be introduced in the beam scanning switch to eliminate the tilt angle dependence on the spatial locations of the input and output fibers.

Several methods can perform the beam scanning operation. The most common is the use of two MEMS micromirrors in the beam path, in a folded Z-shaped configuration (Kim *et al.* 2003b, Neilson *et al.* 2004a, Ryf *et al.* 2006). Because the micromirrors are required to rotate about two axes, they are typically supported by a gimbal structure. The gimbal is not a working port of the mirror, hence, the mirror fill factor is reduced. The fill factor impacts the design as the fiber pitch has to increase beyond the limit imposed by the beam size. Moreover, the beam has to be well contained within the mirror's aperture to eliminate beam clipping losses. The MEMS micromirrors can be fabricated using surface micromachining processes of polysilicon or bulk processing of single-crystalline silicon. Typical mirror parameters are 500–800 µm diameter, ~100–200 V electrostatic actuation using three or four electrodes placed underneath the mirror, and 5–10 ms switching times (Aksyuk *et al.* 2003, Chu *et al.* 2005, Zheng *et al.* 2003). When properly designed, the losses of a 238×238 MEMS micromirror beam scanning OXC are in the 1–2 dB range. Loss contributors are the collimators' aberrations and antireflection coatings, and the micromirrors's reflectivity, curvature, and clipping. Other beam scanning methods are based on lateral displacement of the fiber or collimator with respect to each other (**Figure 23**). The collimator lens can be placed on an electrostatically actuated x–y stage

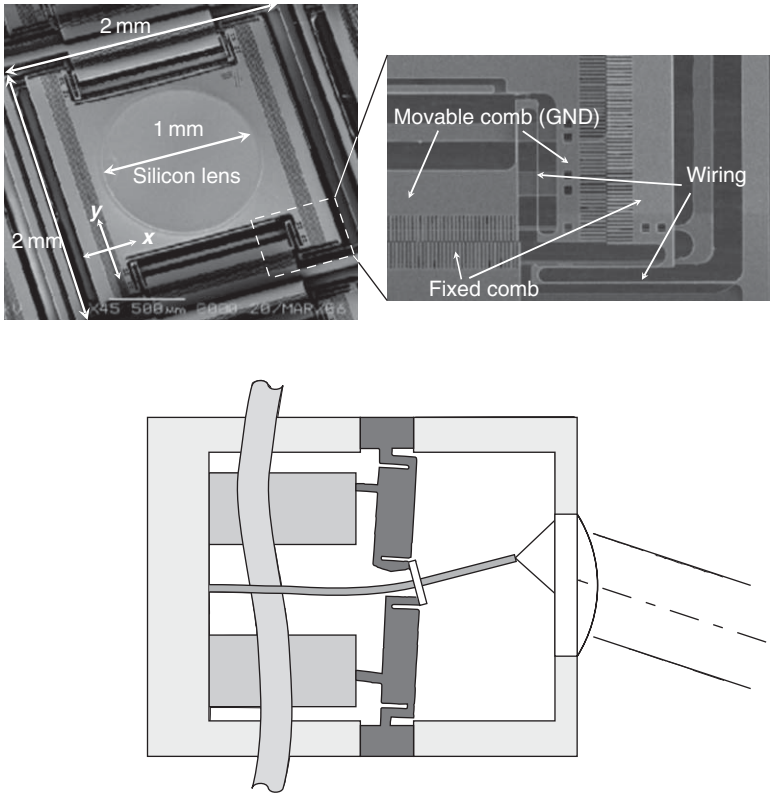

Figure 23 Alternative beam-scanning techniques for $N \times N$ fiber switch. *Top*: Lateral movement of the collimator lens. to achieve scanning (Takahashi *et al.* 2006, Toshiyoshi *et al.* 2003). However, the fill factor of the lens aperture to the fiber pitch is poor due to comb-drive actuation mechanism surrounding the lens, and the amount of lens displacement is limited. As an alternative, the fiber tip can be translated with respect to the lens (Hagood *et al.* 2004, Truex *et al.* 2003). A large displacement of the fiber tip is achieved by tilting the fiber from a pivot point farther away from the lens. Due to the relatively large forces required to bend an optical fiber, piezoelectric actuators are used. The optical path in this arrangement is extremely clear, comprised only of the two collimators. Measured optical losses of the connections average an impressive 1 dB.

3.07.4.5 MEMS Wavelength-Selective Switches

DWDM transmission has provided greatly enhanced data transport capacity on a single fiber, with today's state-of-the-art systems capable of carrying multiple terabits per second. The economic basis behind DWDM is the sharing of the fiber resources, components, and optical amplifiers across many wavelength channels. To maximize the efficiency of the transport layer, the data traffic should remain in the optical regime and undergo optical to electronic to optical (OEO) conversion only when necessary, which is either when the data in a particular channel has to be extracted for consumption or regenerated due to OSNR limitations. The system capability that is required for maximizing the efficiency is the ability to aggregate and disaggregate wavelength channel in the optical domain, allowing the remaining data paths to continue in the optical domain. This function, referred to as OADM, was initially implemented with an optical demultiplexer and multiplexer with a fiber patch panel disposed between them. The requirement to support remote provisioning and fast restoration functions in the OADM were addressed by the more flexible ROADM, which replaced the fiber patch panel with an optical fiber switch fabric. However, the architecture composed of a demultiplexer, switch, and multiplexer suffers from accumulated losses and channel passband filtering, which limit the potential reach of the transmission. A complete ROADM solution should provide wide, flat passband as well as dynamic power equalization across the channels for meeting the physical layer requirements.

WSSs are transparent optical switching subsystems, which can route and attenuate wavelength channel in meeting with ROADM requirements. A WSS contains some means of separating or demultiplexing the wavelength channels at the ingress ports, followed by an optical switch fabric and means of recombining or multiplexing back the wavelengths into one or more egress ports, following the switch function. There is no wavelength conversion or OEO inside a WSS; the switch is optically transparent for the photons carrying the data. The simplest WSS is a channel blocker, with a single input and output fiber, having the capability to power equalize or completely attenuate the WDM channels. The more capable $1 \times K$ WSS has a single input and K output fibers, adding the capability to independently route the individual WDM channels among the K fibers. Finally, the $K \times K$ wavelength-selective cross-connect (WSXC) handles K input and K output fibers with the ability to switch any wavelength from any input fiber to any output fiber, provided there is no wavelength contention. The drawback of the WSXC is its sensitivity to failures; if the switch malfunctions or needs to be replaced, then all the WDM traffic flowing on the K fibers is halted. The $1 \times K$ WSS module, which can be used to construct an equivalent $K \times K$ WSXC, is a more robust solution as the traffic is partitioned according to originating fiber port, and only a subset of the traffic will be affected by a single failure.

3.07.4.5.1 Channel blocker

The channel blocker is based on a free-space optical system that spectrally resolves the optical communication bandwidth, originally conceived for an amplifier gain flattening application (Ford and Walker 1998). However, for independent DWDM channel access, the optical system is designed to provide higher resolution (Neilson *et al.* 2004b). The light from an input/output fiber is collimated by a long focal length lens onto a diffraction grating, such that a large region of the grating is illuminated (**Figure 24**). The diffraction grating generates angular dispersion on account of the wavelength dependence of the diffraction angle. The diffracted light is refocused by the long focal length lens onto the same plane of the fiber tip, but displaced from it, and is incident onto a reflective pixelated modulator. The optical layout is identical to that of a spectrometer, which results in a spatially dispersed optical signal. The dispersive imaging arrangement demultiplexes the input DWDM channels in space, such that the information bandwidth of each wavelength channel is well contained within an active pixel

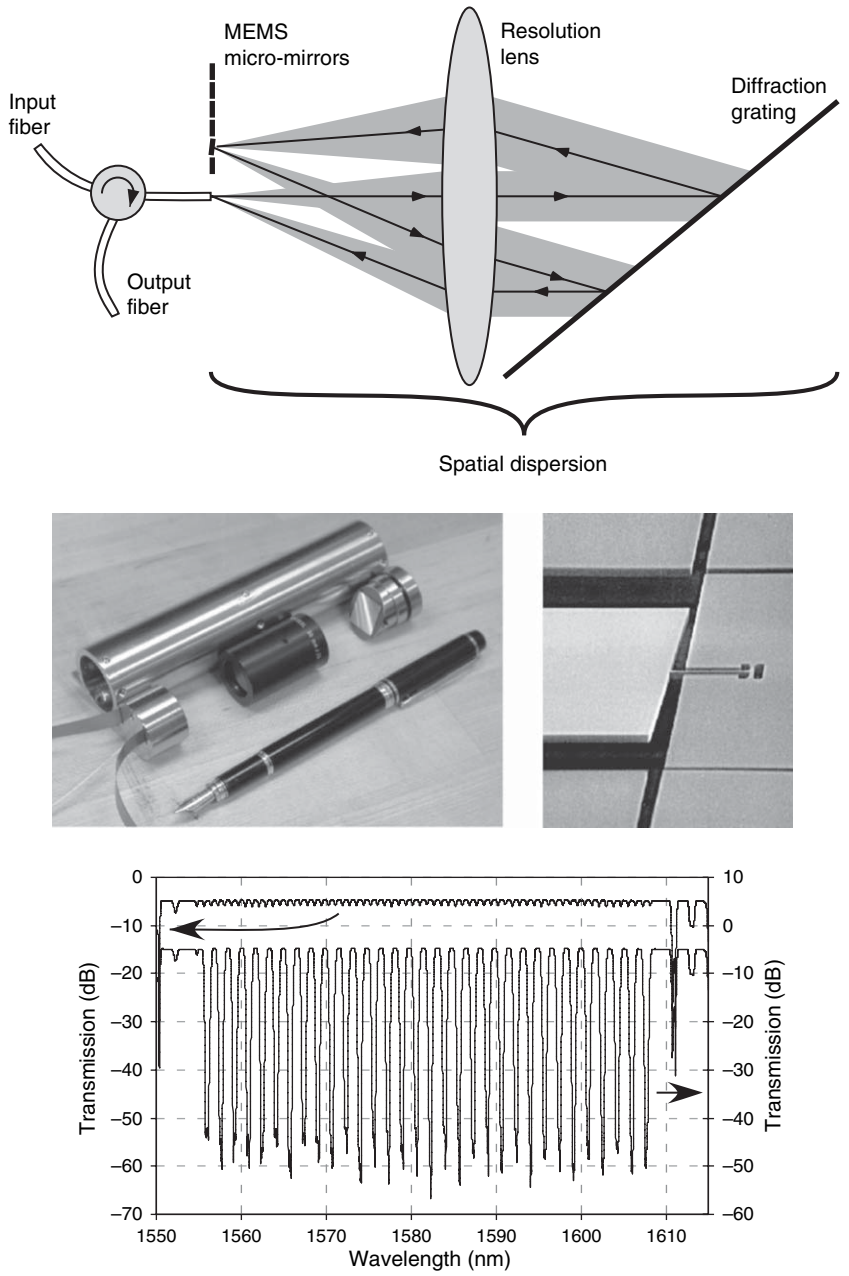

Figure 24 Wavelength blocker. *Top*: Schematic layout. *Middle*: Images of blocker package and microelectromechanical systems (MEMS) torsion mirror array. *Bottom*: Optical power spectrum of all wavelength division multiplexing (WDM) channels in through and alternating blocking patterns. (Source: Neilson D T *et al.* 2004b Channel equalization and blocking filter utilizing microelectromechanical mirrors. *IEEE Select. Top. Quant. Electron.* **10**, 563–9, © [2004] IEEE.)

element. The light is collected back from the active modulating elements and coupled into an output fiber after back propagating through the dispersive arrangement (reversing the original spatial dispersion). Ensuring that the mode size on the device array plane is less than the active pixel width yields the desired wide passband characteristics. This can be achieved by a judicious choice of the diffraction grating frequency and effective focal length of the imaging setup. Furthermore, a wide spatial margin between the incident beam and the pixel edges results in guard bands, which allow for drift in laser

source, optical system misalignment, and provides a more abrupt interchannel transition. The active pixelated device can be chosen from multiple available technologies, although LC modulators (Bouevitch *et al.* 2002, Rhee *et al.* 2001), MEMS tilting mirror arrays (Neison *et al.* 2004), and DMEMS (Ramani 2006) are often the technology of choice. The loss mechanism of each of these technologies is different; MEMS tilting mirrors change the propagation direction of the reflected beams, which introduces a loss when coupling back to the output single-mode fiber, LC attenuates the intensity of the light transmitted through the pixels by polarization rotation and extinction via a crossed polarization (reflective designs are also possible, without loss of generality), and DMEMS control the reflected intensity by adjusting the phase difference between reflective ribbons (with the remaining light diffracting outside the numerical aperture of the optical system).

A 100 GHz channel-spacing blocker based on an array of MEMS tilting micromirrors demonstrates the attractiveness of channel blockers for handling 64 DWDM channels (Neilson *et al.* 2004b). The channel passbands provided by the switch are very wide and flat, and the insertion loss of the switch is less than 5 dB. Channel blocking with greater than 40 dB attenuation was measured. More importantly, the 0.5 dB passband is 58 GHz wide, and the 3 dB bandwidth is 87 GHz. The measured chromatic dispersion within the passband was less than 2 ps nm^{-1}. Polarization-dependent losses were less than 0.35 dB. Such optical channel performance can handle signals with 10 and 40 Gb s^{-1} data rates with minimal impairment, even when the signal traverses several channel blockers in cascade. The MEMS micromirrors of the channel blocker were based on a single-crystal silicon fabrication process, patterned with a 248-nm deep ultraviolet (DUV) stepper to define submicrometer-wide springs and very small lateral gaps between the mirrors (0.4 μm). Torsion rods are used as springs and the 1-μm-thick mirrors have a tilt range of 8° at 150 V. The mirrors are actuated using electrostatic force from electrodes on an electrode chip placed below the mirrors chip. The mirror surfaces are aluminum coated to give high reflectively at 1.55 μm, and exhibit mirror resonant frequencies exceeding 20 KHz. MEMS-based channel blockers have not fared well in the marketplace, as LC-based modulators obtain similar performances with the LC modulating element and drive electronics costing a fraction of the MEMS solution.

3.07.4.5.2 Wavelength-selective $1 \times K$ switches

The $1 \times K$ WSS expands the free-space optical system of the channel blocker to allow for the introduction of $K+1$ fiber ports. The WSS design is based on two major subassemblies; the first used to spatially overlap the beams from the individual input and output fibers, to allow for switching between multiple ports, and the second to spectrally resolve the channels and introduce the wavelength selectivity (**Figure 25**). The role of the first subassembly is to image the input and K output optical fibers end faces onto an angular multiplexed common magnified spot. This subassembly converts the distinct spatial locations of the fibers to unique angular propagation directions. The second subassembly introduces the desired wavelength-selectivity property with the use of a diffraction grating. It spatially disperses the input magnified common spot, consisting of the N WDM channels, onto the MEMS micromirror array, such that each channel is imaged upon a separate mirror in the array for independent addressing. Each micromirror in the array can be tilted to a desired angle, which subsequently determines the selected output fiber array, on a WDM channel basis. The first subassembly determines the optical beam magnification ratio, the fiber array layout, and the required mirror tilts to reach each output fiber. The second subassembly determines the amount of spatial dispersion for separating the WDM channels and obtaining the necessary passband characteristic.

The optical subassembly responsible for imaging the optical fiber end faces onto a common magnified spot is comprised of a fiber array, a matching microlens array, and a condenser lens whose aperture subtends all the beam apertures from the fibers. The fiber array consists of $K+1$ fibers, where one fiber is assigned to carry the input signal and the remaining K fibers are the output fibers. The microlens array and fibers are coaxially aligned and result in collimated beams arranged in a 1D array to accommodate mirrors with a single tilt axis. Gaps are introduced between some of the lens apertures to allow for a variable attenuation feature by the beam scanning method without giving rise to crosstalk. The condenser lens focuses the $K+1$ collimated beams at its back focal plane, where the beams are superimposed and differentiated only in propagation direction. The optical arrangement of the first subassembly implements a telescopic imaging system of the fiber modes via the lenses from the microlens array and the condenser lens. The imaging operation magnifies the

(Source: Marom D M *et al.* 2005a Wavelength-selective $1 \times K$ switches using free-space optics and MEMS micromirrors: Theory, design, and implementation. *IEEE J. Lightwave Technol.* **23**, 1620–30, © [2005] IEEE.)

optical beam emerging from the single-mode fiber by the ratio of the condenser lens to the microlens focal lengths. Anamorphic optics can be introduced into the optical subassembly to increase the number of fiber ports without increasing the magnified spot size in the dispersion direction, which sets the resolution requirements. Additionally, polarization diversity elements are integrated into the optics for use with high-efficiency diffraction gratings that only support one polarization.

The second optical subassembly disperses the magnified mode that was generated by the first subassembly and images it on the micromirror array. Its design is similar to a spectrometer with a Littrow mounted diffraction grating. A single lens collimates the light that is then incident on the grating. The diffracted light, which is propagating back toward the lens and is angularly dispersed, is imaged by the same lens onto the micromirror array. As is well known from classical spectrography, the spectral resolution of the instrument increases with increasing focal length and grating frequency, and with decreasing input slit size. In the WSS, the magnified mode size is equivalent to a spectrograph slit size. The spectral performance of the free-space WSS is directly related to the dimensionless ratio ξ, which is defined as the ratio of MEMS micromirror size to the magnified spot mode size (Marom *et al.* 2005). All the optical system parameters of the WSS contribute to this dimensionless ratio; the focal lengths of the lenses, the grating frequency, and the fiber mode. The ratio measures how well the Gaussian mode is confined within the micromirror. The channel passband performance of the WSS is derived by solving the frequency-dependent, power-coupling efficiency integral. Using a simplifying assumption that the MEMS array has a 100% fill factor, the frequency-dependent coupling efficiency is defined by

$$|\eta(\nu)|^2 = \frac{1}{4}\left\{\mathrm{erf}\left[\sqrt{2}\xi\left(1-\frac{2\nu}{\nu_{\mathrm{ch}}}\right)\right] + \mathrm{erf}\left[\sqrt{2}\xi\left(1+\frac{2\nu}{\nu_{\mathrm{ch}}}\right)\right]\right\}^2$$

where ν is the temporal frequency variable, ν_{ch} is the DWDM channel separation, and erf is the error function. Thus, passband requirements can be accommodated in the design of the WSS by varying the ratio of the mirror size to the magnified Gaussian mode size, which sets ξ, in fulfillment of the optical transport requirements.

The first reported WSS was configured as a 1×4 switch with support for 128 channels on a 50-GHz grid (Marom *et al.* 2002). The switch had a worst-case insertion loss of 5 dB, with 1 dB passband width of 37 GHz, and 3 dB width of 44.5 GHz. The broad flat-top filter shape enables the switch to be cascaded in transparent systems carrying $10\,\mathrm{Gb\,s^{-1}}$ data rates. Further WSS development was focused on 1×4 configuration, based on a 100-GHz grid, with support for 64 channels and $40\,\mathrm{Gb\,s^{-1}}$ data rates, along with 10 dB spectral equalization dynamic range (Marom *et al.* 2003a). These later WSSs were compact and fully packaged, had a 4 dB insertion loss, 77 GHz wide passbands at the -1 dB level, polarization-dependent losses below 0.3 dB, and chromatic dispersion within the passband below $10\,\mathrm{ps\,nm^{-1}}$. Two different MEMS micromirror arrays were designed for the switch; one based on surface micromachining of polysilicon and the other on bulk processing of a SOI wafer (Greywall *et al.* 2003, López *et al.* 2002). In the polysilicon approach, a double-hinge activation mechanism is defined. An actuation plate, anchored at one edge, is tilted to small angles via an underlying parallel plate electrode and a 4 μm gap. The mirror is attached to the free edge of the actuation plate and to the substrate with unequal arm lengths, allowing large mirror tilt angles out of plane via angle amplification. The mirror, actuator plate, and springs are etched in 1.5-μm-thick polysilicon. Spring features are typically 0.5 μm wide, and the gap between adjacent mirrors is 0.7 (~99% fill ratio). In the SOI approach, a 10-μm-thick layer of polysilicon is deposited over the patterned 1-μm-thick single-crystalline silicon and is used to define the actuator electrodes and ground shields. The electrode attracts the short actuator arm via an electrostatic fringe field, resulting in mirror rotation out of plane about the torsion springs. The monolithic structure has a further advantage that it does not exhibit rotational snap-down. Both the polysilicon and SOI micromirrors achieved 6.5° mechanical rotation at a driving voltage of 100 V, and had approximately millisecond scale switching times. Several other free-space WSS and 1D MEMS mirror array efforts have been reported, with similar functionality to that described above (Bernstein *et al.* 2004, Ducellier *et al.* 2002, Marom *et al.* 2006, Tsuboi *et al.* 2004, Wu *et al.* 2002). When using a mirror array with a single rotation axis, transient effects might occur on intermediate fiber ports as the beam is scanned along it (**Figure 26**). To achieve hitless switching, mirrors with two rotation axes have been developed, so that the beam can be first moved off the array, then to the position closest to the desired fiber, and finally moved back to couple only to the desired port. This

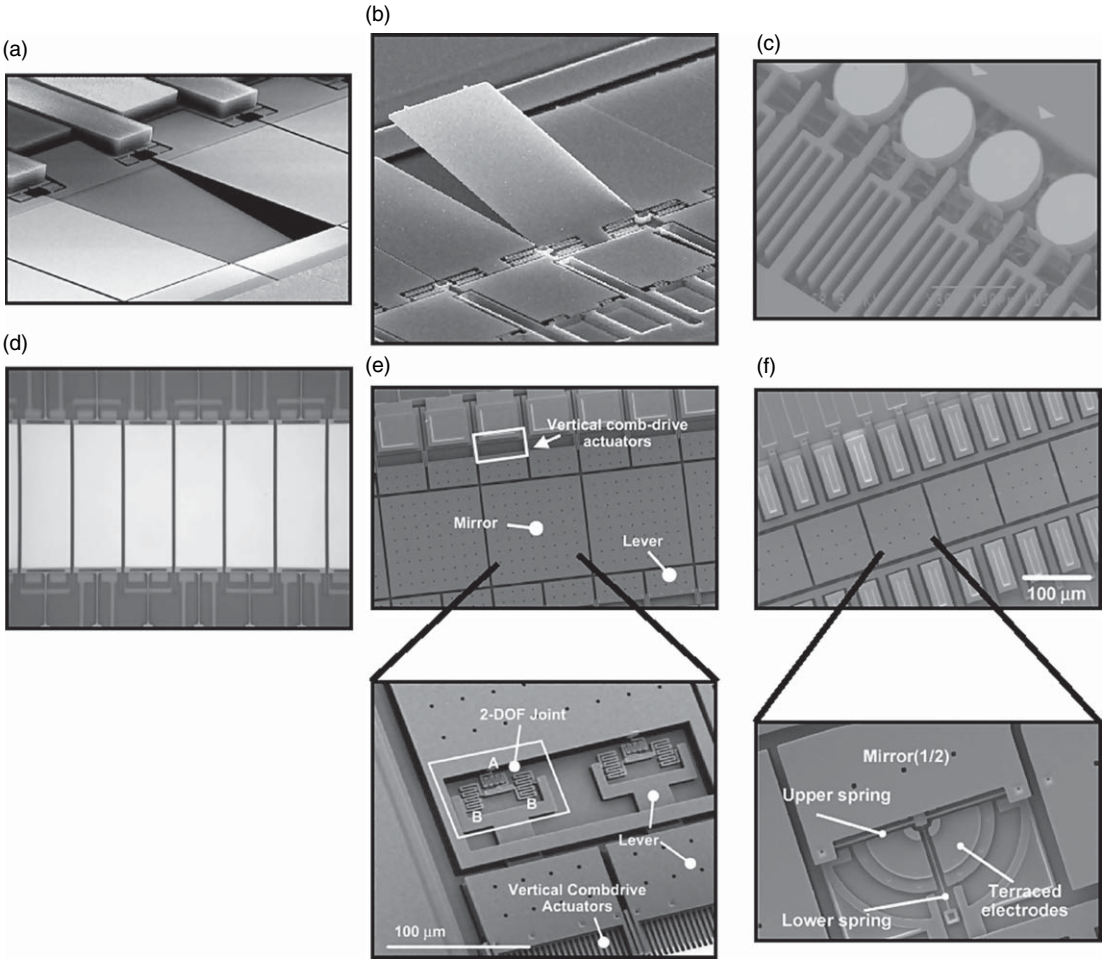

Figure 26 One-dimensional, high fill factor, microelectromechanical systems (MEMS) micromirror arrays for wavelength-selective switching applications. Mirrors can tilt preferentially with rotation axis parallel to dispersion (a–c), or normal to dispersion (d), or in both axis with underlying actuators (e, f) for hitless operation. Technol. Lett.* **18**, 1439–41, © [2006] IEEE.)

poses a design challenge as the mirror array is still required to fulfill the high fill ratio requirement. Several such two-axis micromirror implementations have been reported (Kouma *et al.* 2005, Tsai and Wu 2005, 2006a). Furthermore, with two-axis mirror technology, the number of fiber ports K served by the WSS can be increased by arranging the fibers in a 2D array (Tsai and Wu 2006b, Tsi *et al.* 2006).

While the free-space WSS arrangement performs very well, its size and packaging of discrete optical elements is challenging from an optomechanical point of view. Many of the optical elements can be eliminated by utilizing a hybrid planar lightwave circuit (PLC) and free-space optics arrangement (Marom *et al.* 2004, 2005b, Ducellier *et al.* 2004). The input and output fibers of the WSS are attached to the PLC, which distributes the light into an array of waveguides with constantly increasing path lengths. The light radiating out of the waveguide array is angularly dispersed, and with a single lens is converted to spatial

dispersion that is incident onto the MEMS micromirror array. Reflected light is incident into a desired waveguide array on the PLC for coherently recombining the light into the output fiber. Introducing the PLC platform into the WSS enables to customize each waveguide array, and in one example introduce a demultiplexer directly into the WSS. Other approaches attempt to combine the entire WSS functionality – consisting of the demultiplexing, switching with MEMS micromirrors, and remultiplexing – onto a single PLC (Fuchs 2004, Chi *et al.* 2005).

3.07.4.5.3 Wavelength-selective $K \times K$ switches

The optical switching requirement at network nodes originates from K fibers, carrying N DWDM channels. The number of individually switched channels is therefore $K \times N$, which can quickly scale to many hundreds of channels. For precisely that reason, large port count OXCs were developed. However, the switching functionality can also be provided by using $2K$ modules of $1 \times K$ WSS (or even K modules as in **Figure 27**) (Marom *et al.* 2003b). This elegant solution provides all the switching functionality carried by $K(K-1)$ interconnecting fibers between the WSS modules. If we assume that four fibers are introduced, $K=4$, and each fiber carries 80 channels, $N=80$, then all the traffic is routed on 12 fibers using four WSS modules. The OXC alternative requires $K \times N = 320$ fibers in both input and output sides, a fiber management nightmare! The entire architecture can even be implemented in planar optics with specially integrated free-space tilting micromirrors on a single silicon wafer (Chi *et al.* 2006). Another alternative is the wavelength-selective $K \times K$ switch, or WSXC. The WSXC internally handles the demultiplexing, switching, and

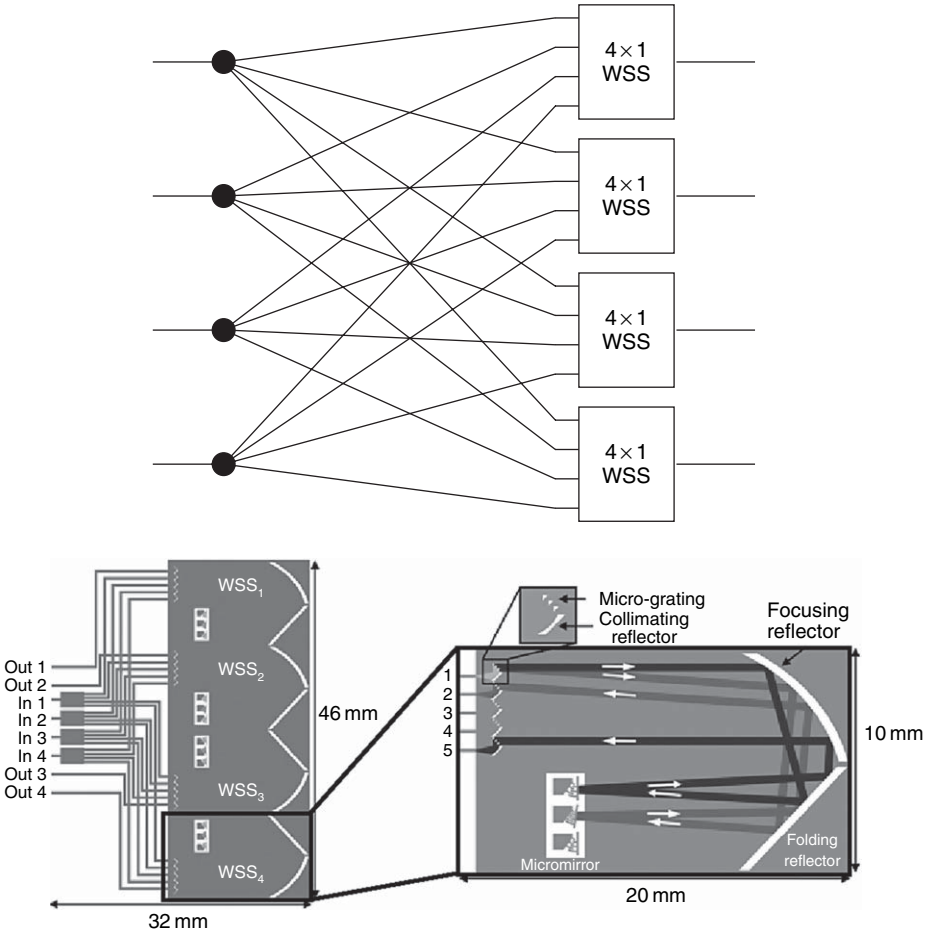

Figure 27 *Top*: Wavelength-selective $K \times K$ cross-connect architecture comprising individual $1 \times K$ wavelength-selective switches (WSSs) in a broadcast and select architecture. *Bottom*: Planar implementation of 4×4 wavelength-selective cross-connect architecture on a single silicon wafer. (Source: Chi C H *et al.* Silicon-based, monolithic, 4×4 wavelength-selective switch with on-chip micromirrors. *Optical Fiber Conference (OFC 2006)*, Anaheim, CA, March 2006, © [2006] IEEE.)

remultiplexing of all K input/output fibers, further reducing the fiber management complexity, at the expense of complex switch architecture.

A demonstrated WSXC introduced PLCs with demultiplexer and multiplexer functionality into a transparent OXC fabric (Ryf *et al.* 2001). The custom PLC placed the demultiplexed waveguides on a pitch $P = 1.25$ mm matched to a microlens array and the micromirror array. The collimated beams were incident onto the micromirrors for switching, much the same way as the collimated beams a from a fiber array are generated. The passband performance of the WSXC is dictated by the demultiplexer/multiplexer implementation, which are typically not as wide and flat as those achieved by regular WSS. Thus, cascadability using this solution is questionable. A reported alternative performs the demultiplexing with a free-space grating, and selects the bandwidth for switching by the MEMS micromirror array (Solgaard *et al.* 2002). With this solution, the bandwidth is defined by the micromirror array fill factor and shape, much the same as for the WSS. However, there is little information on any implementation attempts of this WSXC.

3.07.5 Conclusions

Optical microsystems with MEMS actuators can offer the functionality, flexibility, low power consumption, low insertion loss, and compactness required for optical communication networks. Reported optical microsystems have demonstrated most of the passive and slow active enabling elements for optical networking, such as ROADM, fiber cross-connect switching, channel selection filters for monitoring, and tunable dispersion compensating elements. The maturation of MEMS technology fortuitously coincided with, or even helped to enable, the transition to optical networking, by demonstrating the feasibility of performing the required tasks for reconfigurable networks. This has led to intensive research and development efforts in the last 10 years, by established corporate research centers, academia, and start-up companies. Unfortunately, many of these efforts have since ceased, as the forecasted market demand never materialized and consolidation and investor pull-out resulted in company shut downs. This downturn came as a predictable counter response to the hype and overselling by the investment community, leading to the infamous telecom bubble of 1999–2001.

While most of the private and institutional capital poured into telecom microsystem development may have been written off, the industry effort helped to further advance microoptics, microfabrication, packaging, and related fields. This has benefited the related microsystem scientific and industrial communities, with innovation sprouting out in sensing, bioengineering, and nanotechanology applications. Moreover, telecom industry spending is now experiencing steady growth once again on a more rational base spending level, due to a recovery of the industry (**Figure 28**), with the strongest growth in the metropolitan and fiber access spaces. Companies that have survived the downturn are growing once again, and there are signs of a resurgence of start-up activity. The renewed interest and more stable and sustainable marketplace ensure that optical communication networks will continue to serve as a driving force for innovations in optical microsystems.

Biography

Dan Marom earned the B.Sc. degree in Mechanical Engineering (1989) and the M.Sc. degree in Electrical Engineering (1995), both from Tel-Aviv University. He was awarded the Ph.D. degree in Electrical Engineering by the University of California, San Diego, in 2000. In his doctoral research, under the guidance of Prof. Yeshaiahu (Shaya) Fainman, Dan explored nonlinear wave mixing for optical signal processing of ultrafast waveforms.

From 2000 until 2005, Dr. Marom was employed as a Member of the Technical Staff at Bell Laboratories, then part of Lucent Technologies, where he pioneered the work on Wavelength-Selective Switches (WSS), a critical element for the realization of reconfigurable optical networks using MEMS (Micro-Electro-Mechanical-System) technology.

Dr. Marom joined the faculty of the Applied Physics Department in the fall of 2005, where he is pursuing his research interests in creating photonic devices for switching and manipulating optical signals.

Dr. Dan Marom is active in the scientific community, serving or has served on program committees of leading conferences such as OFC, CLEO, IEEE LEOS, and IEEE Optical MEMS. Dan is the first recipient of the Peter Brojde Excellence in Engineering Award (2006), received the Golda Meir Fellowship (2006), was a Fannie and John Hertz Foundation Fellow during his doctoral studies (1996–2000), and received a Powell Foundation Fellowship (1995).

3.08 Micro-Imaging Systems

Christine Harendt and Heinz-Gerd Graf, Institut für Mikroelektronik, Stuttgart, Germany

3.08.1 Introduction

Visualization is preferred in many technical applications, because the image of a subject or scene provides essential information, which is difficult to obtain with other sensors. Nowadays, digital cameras are available in small sizes and can be integrated in instruments. The rapid miniaturization in semiconductor technology and related techniques enabled the development of miniaturized camera systems. Small-sized imagers are present in everyday life as well as in scientific applications today. In the future various new products can be expected.

This chapter describes miniaturized cameras and their integration into microsystems. First, in Section 3.08.2, general aspects of image sensors such as principles of operation, technology, and general architecture are summarized. System integration and packaging aspects are described in Section 3.08.3. The different applications of integrated microcameras are discussed in Section 3.08.4.

3.08.2 Image Sensors for Microsystems

Image sensors are devices consisting of a photosensitive solid-state sensor array and addressing and readout circuitry. Since the development of the charge-coupled device (CCD) principle at Bell Labs in 1969 (Boyle and Smith 1970) and the demonstration of its first application in Esser (1972), sensors have been developed in small volumes for scientific and space applications (Janesik 2001). In the mid-

1970s, CCDs began to appear in commercial applications such as in fax machines, and later in camcorders.

Some of the initial applications of complementary metal oxide semiconductor (CMOS) image sensors have also been shown by Weckler (1967), but at that time no commercial product was feasible due to the size of CMOS transistor structures. Since then, the advances in performance, image quality, and the price of these imagers made them the major device used in cameras, in photography, and in other imaging applications. The structure of size reduction in semiconductor technology enables the development of miniaturized image sensors and the integration into microsystems. This chapter deals exclusively with silicon photodetectors, which are the major devices used in microimagers.

3.08.2.1 Interaction of Photons with Silicon

The interaction of a photon with silicon can result in the reflection, the transmission, or the absorption of the photon. The following section describes the phenomena briefly and detailed information is given in Tredwell (1995), Pankove (1971), and Sze (1981).

3.08.2.1.1 Absorption

The absorption of a photon and the generation of an electron–hole pair is the effect used for photodetection. Light absorption in semiconductor materials normally occurs by transferring a valence band electron into the conduction band (**Figure 1**). This process depends on the density of occupied states in the valence and the empty states in the conduction band. Also, the absorption coefficient is a function of the transferred energy and the wavelength of the light. Because of the high density of states, the

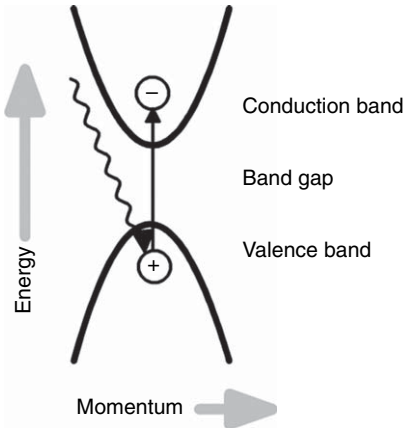

Figure 1 Semiconductor band model.

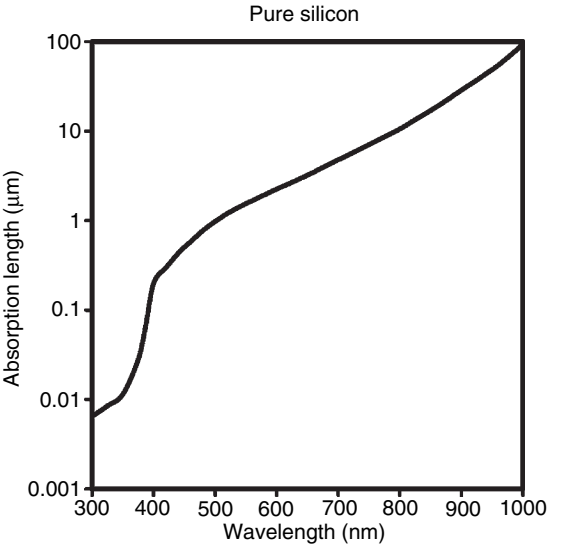

Figure 2 Absorption of light in silicon.

absorption (**Figure 2**) is high for high-energy UV light and low for low-energy near-infrared (NIR) light. For incident light with energies lower than the bandgap energy, there is no transfer between states and no absorption occurs. For single-crystal silicon, the absorption lengths varies between 0.4 μm for blue light (450 nm), 1.5 μm for green light (550 nm), and 10 μm for NIR light (800–1000 nm). There is no absorption beyond 1100 nm because the photon energy is less than the silicon bandgap (1.1 eV). The data demonstrate the possible range of spectral response for a silicon device between 200 and 1000 nm. Only a low NIR response is possible for shallow devices.

The competing process is the recombination of the carriers before detection. The recombination probability depends strongly on the number of interface states and defects or impurities (Auth *et al.* 1977). Therefore, recombination occurs particularly near the surface and can be influenced by defects.

3.08.2.1.2 Reflection

The relatively high index of refraction η of silicon ($\eta = 4$) results for the pure uncovered surface in a reflection of nearly 30% of the visible light (**Figure 3**). Thin layers of dielectric material with lower refractive index serve as antireflection coatings (ARC). A reflection lower than 10% results for layers with a thickness of odd-numbered multiples of a quarter wavelength. This is caused by the interference of the reflected waves on both surfaces. The so-called quarter wavelength layers for antireflection

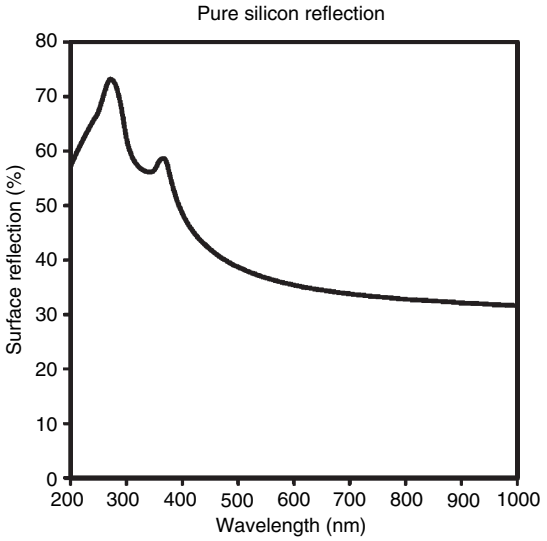

Figure 3 Reflection of light on silicon.

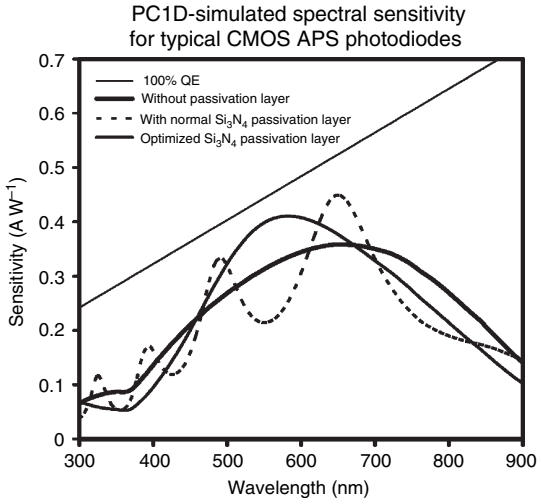

Figure 4 Spectral sensitivity of silicon.

are only effective when the layer is thin (<150 nm). With thicker layers, the interference is disturbed by thickness variations and different incident angles.

3.08.2.1.3 Spectral response

A measure for the spectral sensitivity of the diode is the quantum efficiency (QE), which is the ratio of the charge collected to the number of incident photons. Thus, for QE = 100%, every incident photon generates a detected charge. The QE depends on the transmission of the incident light through the layers covering the junction diode, on the absorption of the light in silicon, and on the probability of the detection of a generated electron–hole pair before recombination. This function describes the major parameters for the optimization of silicon photodetectors: adjustment of the covering layers of the diode to the optical requirements, design of the junction diode (e.g., optimization of the depth of the junction) for optimal absorption of the desired light, and optimization of charge collection, which implies the reduction of recombination probability. The spectral sensitivity is also an indicator of the photon energy, which increases with lower wavelength. In **Figure 4**, the spectral response of a silicon photodiode is shown. The QE = 100% is indicated by the straight line in **Figure 4**. The relatively low values for blue light (400 nm) are because of the lower transmission (i.e., light absorption in the cover layers) and the high recombination probability in the near-surface regions of the junction. Special efforts are needed to improve the near-UV light sensitivity. Infrared light has a low absorption probability due to the low energy of the photons. Consequently, the sensitivity to the IR light is reduced.

3.08.2.2 Image Sensor Devices

3.08.2.2.1 Photodetectors

There are three basic types of structures used for image sensing: the junction photodiode, the photocapacitor, and the photoconductor. While the junction photodiode is generally a single-crystal silicon device, the latter are mostly fabricated in amorphous silicon. In this section, the junction photodiode, the detector widely used in CMOS devices, and the photocapacitor, the typical CCD structure, are described. A detailed description of the devices and their performance is given in Sze (1981) and Tredwell (1995).

3.08.2.2.1.(i) The junction photodiode A pn junction photodiode is shown in **Figure 5**. The photodiode is formed by boron (p)- and phosphorus or arsenic (n)-doped areas in the single-crystal silicon. If a voltage is applied between the p and the n contact in reverse bias, typically between 1 and 5 V, a depletion layer is formed. Photon-generated minority carriers are accelerated in the resulting electric field and collected, if they do not recombine before collection. The depletion layer width depends on voltage and dopant concentration in the junction diode. Typical widths of depletion layers for silicon photodiodes are 0.3–3 μm. Minority carriers generated outside the depletion layers contribute to the

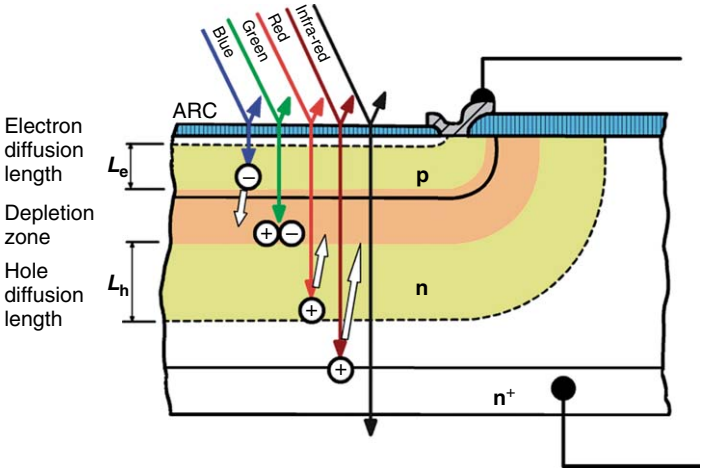

Figure 5 Schematic of a junction photodiode with ARC (antireflection coating).

photo-generated current, if they get into the depletion region. This carrier transport can occur by carrier diffusion or the drift in the small electric fields generated by different dopant concentrations inside the n or p region of the diode.

In many applications, the junction diode is also used for storage of the collected carriers until they can be read out. As a consequence, the reverse voltage on the junction decreases depending on the amount of charge collected until the charge is removed in the readout process. In the case of high light intensities, many charges are collected and the voltage drops to forward bias. Then additional light is compensated by the diode's forward current. No additional response occurs and the sensor is saturated.

3.08.2.2.1.(ii) CMOS image sensors The CMOS device, the major technology used for consumer semiconductor products such as integrated circuits (IC), microprocessors, and memories, is based on transistor structures fabricated in single-crystal silicon. Thus, the integration of a pn junction photodiode into a CMOS technology does not require additional effort.

The first image detector using MOS technology was the passive MOS array, an addressable array of photosensitive junction diodes (**Figure 6**). An individual photodiode is selected by one or two transfer transistors. After selection, the photodiode is recharged to a fixed reset voltage using an integrating amplifier. The charge needed for a given integration time is a measure of the photocurrent.

The rather poor performance of these devices compared to that of the already established CCDs was mainly due to the nonuniformities and noise. Noisy output signals were caused by low signals levels, which were connected to the read line with the large capacitance of many transistor drains.

Consequently, the integration of a gain transistor, which enhances the signal and improves the image intensity and uniformity, was the next step. The device, the active pixel sensor (APS), is the most widely used CMOS imager type today. The schematic of passive (MOS) and active (APS) pixels is shown in **Figure 6**. The APS sensor has an amplifying transistor integrated into each pixel.

The photodiode is manufactured using the diffusions necessary for the transistor. Each diode is connected to the transistors needed for pixel addressing, amplification, and reset. The CMOS APS enables the implementation of desired functions directly at the pixel and allows APSs with flexible readout schemes such as access to subframes or single pixels and many other features. These advantages, however, are limited by the feasible structure size in CMOS technology and the surface area needed for the devices. Both the photodiode and the transistors cover a defined area of the silicon surface, so the part of the surface used by the photosensitive element, the fill factor, is typically 30–60%. The high complexity of the circuitry lowers the fill factor. The minimal transistor size is determined by the minimal structure size, which can be reproduced in the photolithographic processes used in CMOS technology. If this structure size (i.e., gate width) is 0.5 μm, which is the technological limit that was reached in 1993, one

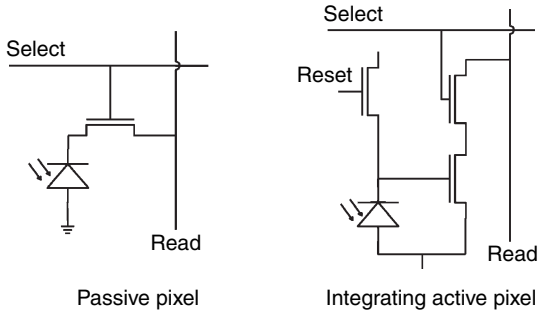

Figure 6 Schematic of metal oxide semiconductor (MOS) and active pixel sensor (APS) pixels.

transistor covers an area of about 2 μm × 3 μm. The resulting pixel consists of three to seven transistors and the photodiode needs at least 20 μm × 20 μm, which gives a 500 × 500 pixel array with an image field of 1 cm × 1 cm. This illustrates the fact that CMOS image sensors could only participate significantly in the image sensor market since submicron CMOS technologies with structure sizes of 0.25 μm and below are available.

One major goal when designing image sensors for microcameras is the achievable pixel size. Thus, in most cases, only three transistor cells are used. Advanced pixel designs share transistors (1.5 transistor cell) in order to reduce the pixel pitch.

In CMOS technology, the photosensitive element can be combined with a number of devices (transistors, resistors, and capacitors). Thus, different pixel types and readout schemes are possible. The most widely used type is the integrating linear sensor.

The photodiode is precharged to a fixed voltage using the reset transistor. After the integration time used for collecting photo-induced currents, the output voltage change on the photodiode is measured using the fixed voltage or a stored dark pixel output as reference. The capacitance of the noise-limiting node is build by the photodiode, reset transistor, and amplifying readout transistor only. But each pixel readout path forms an individual assembly of circuit elements resulting in variations of gain and offset.

This approach reveals good results for medium-contrast scenes and enables, by an increase of the integration time, a high sensitivity for low light conditions. Typically, the dynamic range of these sensors is 60–80 dB, the adaptation to the different illumination levels is done by mechanical apertures. For high-contrast scenes, saturation in the bright spots cause a loss of image information.

Another concept, the pixel with logarithmic response, uses a nonlinear shunt for continuous reset. The photon-induced voltage on a subthreshold transistor, which has an exponential rising current versus the linear rising source/drain voltage, is detected (**Figure 7**). The resulting response for different illuminations shows a logarithmic increase of the output signal with the incident light, rather similar to the sensitivity of the human eye. The dynamic range of this type of image sensor (high dynamic range CMOS (HDRC)) is >120 dB, allowing the saturation-free detection of scenes with a variation of illumination over six and more decades (spot welding, light bulbs, near-field illumination, and reflection of light sources) (HDRC, 1996, 1997, Seger *et al.* 1993, 1999). Compared to linear sensors, the lower sensitivity for low light conditions and a higher fixed pattern noise (see Section 3.08.2.2.1.(v)) are the disadvantages of the logarithmic approach. The LinLog sensor (www.photonfocus.com) combines both sensor types and the advantages of logarithmic and linear sensors. But an increased complexity of the device restricts its performance for many applications.

CMOS image sensors differ in the pixel design; also, there are a number of different addressing and readout schemes. In principle, each individual pixel could be addressed and read out separately. In practice, the readout is triggered by a clock signal and the charge measured at each pixel is transferred by a multiplexer to the output. The time needed for the complete readout of an image determines the number of images, which can be transferred per second: the frame rate.

A typical addressing scheme is the line-synchronous sampling. It is simply the sequential readout of one pixel row after the other, often called rolling shutter. This principle is widely used in consumer applications. Additionally, variations of this method are possible, i.e., the readout of subframes or single lines.

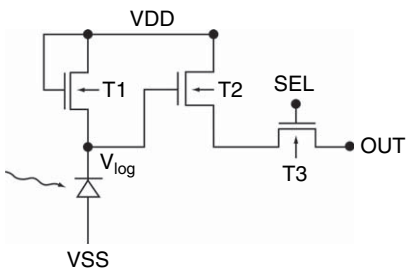

Figure 7 Schematic of log-compressing pixel with VDD (positive supply voltage), VSS (ground voltage), SEL (select pulse), V_{log} (illumination dependent voltage with logarithmic response), OUT (output voltage), T1, T2, and T3 (transistors).

For some applications, the rolling shutter proves disadvantageous, for example, for observing fast-moving objects. As the imager detects images during readout, the rolling shutter image changes within the process with the consequence that the images show smeared figures. An alternative readout scheme is field-synchronous sampling. This approach, also known as global shutter, freezes the information at each pixel at the same time. The readout itself is done sequentially, but the image information is stored once, resulting in good image quality independent of the movements. This scheme requires an additional transistor at each pixel, thus requiring a larger pixel size.

In order to obtain the desired functionality, each image sensor has a number of circuit blocks (clock generator, addressing logic, etc.), which are located outside the photosensitive area. Other camera functions such as analog (A)/digital (D) conversion, image data processing (fixed pattern noise (FPN) correction), or color conversion are in many cases integrated in the CMOS imager too. This is one advantage of the CMOS technology and helps to reduce the number of additional boards, interconnects, package efforts, and cost. In microcamera applications such as endoscopy, where the chip size correlates directly to the system size, the integration of additional functionality and the chip size optimization are a trade-off.

3.08.2.2.1.(iii) The photocapacitor The photosensitive element used in CCD imagers is the photocapacitor. As shown in **Figure 8**, an optically transparent conductive electrode forms one plate, the silicon substrate is the other plate, and a thin oxide layer is the insulator of the photocapacitor. A voltage applied to the transparent electrode results in the accumulation of the majority carriers in one direction and a depletion layer in the opposite direction. This depletion layer is formed by the fixed (nonmobile) ionized dopants. A large depletion layer thickness and thus a low capacitance is observed immediately after applying the voltage. After that, the photon-generated minority carriers are formed in the depletion layer or enter it by diffusion. These carriers are transferred and collected near the silicon–oxide interface (*cf.* **Figure 9**). As a consequence, the depletion layer shrinks and the total capacitance rises. The total collected minority charge in this depletion, the so-called bucket, is the charge Q, which depends on the voltage U and the difference between the oxide capacitance C_{ox} and the minimal capacity of the

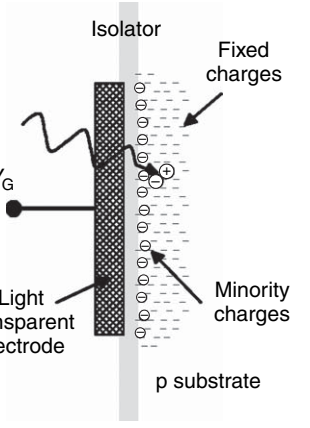

Figure 8 Schematic of a photocapacitor.

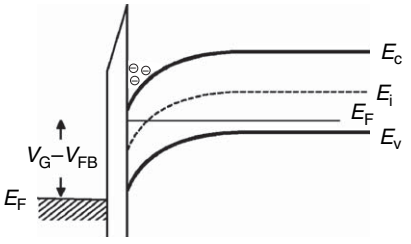

Figure 9 Bandmodel of the semiconductor–insulator interface. The energy levels of the valence band (E_V), the conduction band (E_C), the intrinsic energy (E_i), and the Fermi level (E_F) are shown as well as the gate voltage V_G and the so-called flatband voltage V_{FB}, which depends on the material.

device C_{min}. This is the storage capability of the device:

$$Q = (C_{ox} - C_{min}) \times U$$

Only a very slow recombination of minority carriers in this bucket occurs because of the absence of recombination partners. This type of capacitor is also an ideal device for the collection and storage of a limited number of photon-generated minority charges. Excessive charges are injected in the non-depleted substrate area or are collected by neighboring pixels (blooming).

3.08.2.2.1.(iv) CCD image sensors In a row of connected photocapacitors (**Figure 10**), the collected charge can be transferred from one capacitor to its neighbor. By applying the depleting voltage to both electrodes, a larger depletion bucket is formed,

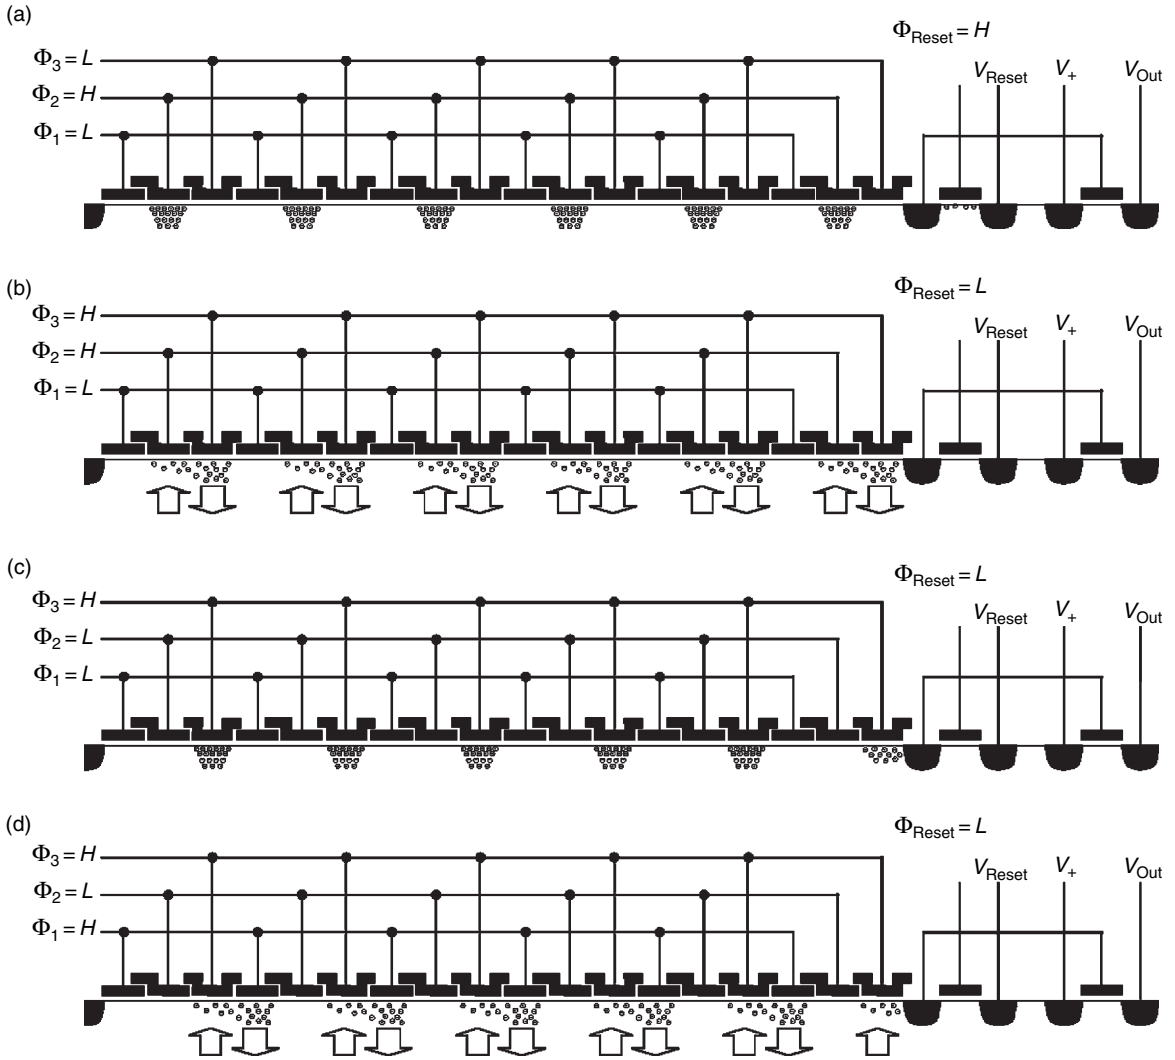

Figure 10 Schematic of charge-coupled device (CCD) readout principle.

holding the collected charge from the first capacitor. By the subsequent reduction of the depletion voltage on the first electrode, the collected charge is transferred to the neighboring capacitor. This is known as the CCD principle.

By means of three phase-shifted overlapping voltages, a number of N charges can be collected and transferred in a line of $3N$ capacitors. A diffused diode at the end of the line works as a contact to the amplifying transistor. This diode is periodically precharged to a fixed voltage by the reset transistor. After arrival of the transferred charge, the gate voltage changes on the amplifying transistor. This results in modulations of the transistors source/drain current.

For 2D arrays with M rows and N columns, arrangements of one horizontally oriented CCD line with N vertically arranged CCD lines are used. One bucket from each vertical CCD is transferred to the horizontally arranged CCD before this CCD is read out from the whole line. After $3N$ transfers reaching the end of the line, the next bucket of the vertically arranged CCDs is transferred to the horizontal CCD. This way the whole image is sequentially read out row by row.

Different types of arrangement of photosensitive and nonsensitive buckets are used for the storage of integrated charges during readout.

In an interline transfer CCD, all charges integrated in the photosensitive buckets are simultaneously

transferred into a metal-shielded nonphotosensitive CCD (Figure 11).

In the frame transfer CCD, the vertically arranged CCDs double their length. The first half of this CCD is photosensitive, the second half is covered with metal. All collected charges from the photosensitive part are transferred vertically to the metal-covered storage part by $3M$ short transfers. After this first step, the photosensitive part is set to charge integrating conditions. Only the second half transfers the image content to the horizontally arranged CCD (Figure 12).

CCDs provide a very sensitive picture cell with the lowest possible capacitance and the best noise performance. All image contents are transferred to the same output, resulting in a high homogeneity of the image. The photosensitive electrodes, however, show strong oscillations in the spectral sensitivity. The high sensitivity of the device is correlated to a limited charge transfer. Overexposure can cause charge detection in neighboring pixels. The signal-to-noise (S/N) ratio and the limited dynamic range lead to image artifacts such as saturation, blur, or smearing.

A major advantage is the CCD process technology. Because to its lower complexity, it needs less lithographic steps. Additionally, a smaller pixel size and a higher fill factor can be achieved especially for the frame transfer organization. Therefore, image sensors of this type have been used successfully in most of the image sensor applications since the early 1990s and still dominate the markets for camcorders and digital cameras.

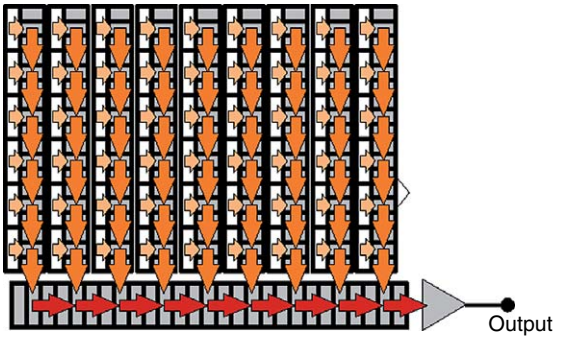

Figure 11 Interline transfer charge-coupled devices (CCDs). Small horizontal arrows (orange) indicate the charge transfer from the photosensitive cells to the column CCDs. The next step is the transfer of the first charge packet of every column CCD into the row CCD. This is shown by the vertical arrows (light red). Then all charges from the first row are transferred to the output (horizontal arrows, dark red). This sequence is repeated until all charges are read out.

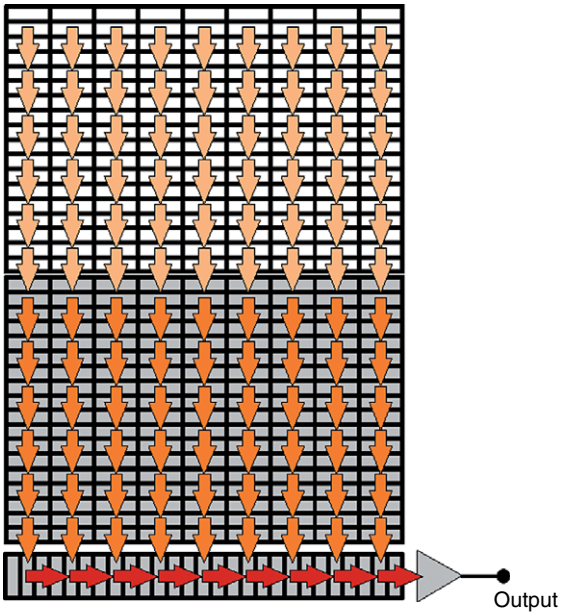

Figure 12 Frame transfer charge-coupled device (CCD). The integrated charges are transferred simultaneously into the light-shielded storage area (vertical arrows, orange). For readout, the stored charges are transferred to the horizontal row CCD (vertical arrows, light red). Then all charges from the first row are transferred to the output (horizontal arrows, dark red).

For some applications, very large and highly sensitive backside illuminated sensors can be fabricated and assembled on glass or ceramic substrates. Operating on low temperatures and with multisampling, they offer a nearly unlimited low light sensitivity and a good dynamic range for long-time exposure.

3.08.2.2.1.(v) Limitations of image quality For both device types, there are a number of parameters limiting the image quality obtainable. First, different sources of noise cause signals, added to the photo-induced signals. The major sources of temporal noise are photon noise, reset and readout noise, and the dark current. The photon noise is caused by the statistical variation of the incident photons. This noise depends on the light intensity and cannot be affected by the performance of the imager.

Reset and readout noise are caused by noise generated in the circuitry. Strategies in design optimization for reduced noise are applied in image sensor design using low-input node capacitance and

high gain. In CCDs and some CMOS APS, the reset noise can be compensated by the difference between the reset voltage and output voltage of the each pixel.

The dark current affects the low light sensitivity, which is the major task in image sensor technology optimization. Even in the absence of light in every photosensitive element, a number of electron–hole pairs are generated resulting in the dark current. It restricts the minimal illumination detectable by a photosensor and is an important criterion for the device quality. The dark current limits the applicable integration time. Even if a dark current compensation is applied, the dark current shot noise reduces the S/N value of the devices.

Major sources of these charges are defects and impurities in the silicon and interface states at the $Si–SiO_2$ interface. Typical values of dark currents for silicon junction diodes are 10–100 pA cm^{-2}.

The dark current depends significantly on the temperature: it doubles approximately at every 10°C rise in temperature. This is the reason for using cooled devices for high-performance imaging. On the other hand, this indicates the difficulties to obtain good image quality for applications with higher ambient temperature (human body, sensors, and robotics in the production environment). Self-heating of the device is another concern, which might cause an unintended rise in temperature and thus in increased dark currents.

Another source of noise, the static noise, is caused by nonuniformities of the device parameter. A dark image of a pixel array shows a variation of dark signal intensity known as fixed pattern noise (FPN). This FPN pattern is constant for every device. Normally, a subtraction of the dark values is implemented in the image processing (FPN correction).

For a more detailed discussion, the FPN can by split into different parts: the dark current value of each photosensitive element depends on the overall material properties of the semiconductor; it also shows slight variations from pixel to pixel caused by technological imperfection in structure size and defect density. A measure for the dark current variations is the dark signal nonuniformity (DSNU) value of the image sensing device.

The same applies for the values of the photoresponse and gain of each pixel. This is measured in the photoresponse nonuniformity (PRNU) given for a signal near saturation level and the photoresponse nonlinearity (PRNL).

The effects influencing the signals in neighboring pixels are known as crosstalk. This can be caused by carrier diffusion in CMOS sensors or by charge overflow in CCDs (blooming). During the carrier transport, crosstalk along the readout path causes a bright line (smearing). Image lag is caused by incomplete discharge of the pixels at reset. The resulting image of a moved bright object shows a trace.

For both device types, improvements of image quality and the noise reduction strategies are major tasks in the development of devices and technology. The optimization of the QE and the reduction of the dark current require efforts to improve the properties of the material (minimization of defects, optimization of top layers). Additionally, some efforts in device design and correction circuitry are needed for miniaturized image sensors.

3.08.2.2.1.(vi) CMOS vs. CCD While the CCD imagers dominated almost all solid-state imaging applications from the beginning in 1972 until a few years ago, CMOS imagers have been acquiring a growing market share since the late 1990s (Fossum 1997, Mendis *et al.* 1994). This is due to the fact that only with the advanced submicron CMOS technologies (minimal lithographic structure size <0.5 μm), acceptable pixel sizes were achievable. The CMOS technology improvements pushed by the mainstream products (processors and memories) enabled the development of CMOS imagers. Major advantages are certainly the flexibility of the approach, allowing random access readout, active pixel sensors, and the integration of additional features. The CMOS process as the mainstream technology enables high-volume and thus low-cost production. Additionally, the various devices and design blocks available in libraries facilitate the implementation of new features. The CMOS technology itself, however, has a number of disadvantages for photosensitive devices.

The reduction in pixel size is going on for both device types. CMOS image sensors with 3.3 μm pixel pitch are available (www.tsmc.com). For 2007, a value of 2.2 μm (Nummela *et al.* 2006, www.tsmc.com) is expected. Thus, the achievable pixel size even with the most advanced CMOS technology is bigger than that for CCDs, which is an important issue especially for microcameras. The fill factor, normally <50% for small pixel sizes, limits the sensitivity of the sensor. Additionally, standard CMOS processing result in devices with low performance of the photosensor in terms of dark current, light absorption, and sensitivity. In order to reach the requirements of the photodiode, CMOS processes have to be optimized

for image sensors (see Section 3.08.2.3). For advanced CMOS technologies, illumination levels of 5 mlux to 5 lux can be detected at normal videoframe rates.

CCD technology, on the other hand, is still the champion in pixel size and achievable fill factor. A CCD with 1.56-μm pixel (Oda *et al.* 2005) has been reported. The QE in the visible range, especially for blue light, is better and the special and less complex CCD process technology has more degrees of freedom for the optimization of optical parameters (i.e., the top layers). An experience of more than 20 years in device optimization and image quality improvements is another advantage of the technology.

The main restriction is the fixed readout scheme. The process incompatibility with CMOS technology anticipates the integration of additional features. For microsystem approaches, the higher power consumption and the relatively high number of inputs/outputs (I/O) are drawbacks.

The performance of the CCD depends mainly on the charge capacity and the charge transfer efficiency of the device. Typical values for the charge handling capacity of microcamera CCDs are 10 000 electrons per pixel. This allows the detection of 1-mlux signal on the device surface. The major limitations are saturation and blooming for high light intensities.

3.08.2.3 Technology Aspects

3.08.2.3.1 CMOS technology

As stated above, the manufacturing of pn junction diodes is integrated in the CMOS process. There are two diffusion processes available for the formation of the diode: the relatively deep diffusion of the well of the transistor and the shallow diffusion of the source and drain contact. Depending on the junction depth, the spectral response of the diode is modified (*cf.* Section 3.08.2.1). Generally, when developing submicron CMOS processes, the depth of the well has to be reduced to meet the lateral size requirements. It is not possible to manufacture photodiodes having deep junctions (>3 μm) by advanced standard processes. Extra process steps are needed to obtain the full spectral sensitivity.

The performance of junction diodes fabricated by standard CMOS technology is in many cases low, because reduction of dark current and low defect densities in the diode are not the major optimization criteria for process engineers. The reduction of the dark current, the optimization of the spectral response, and the reduction of the recombination probability are the tasks for a good imager process technology. Thus, the reduction of defect densities and the adaptation of junction depth and optical performance of cover layers are the issues in process engineering. With the growing market for CMOS imagers, special imager processes with these optimized parameters for photodiodes have been developed and are now provided by most foundry services.

3.08.2.3.2 High fill factor processes

The performance of the photosensitive element depends also on the optical parameters of the layers covering the sensor surface. In advanced CMOS technologies, up to five metallization layers are used for wiring. These layers are separated by dielectric layers, mainly deposited oxides, which are planarized by chemomechanical polishing in order to reduce the topography. Thus, the silicon diode surface is covered by a stack of dielectric layers that are several microns in thickness, which might vary over the wafer due to polishing process variation. As shown in **Figure 13**, this is a problem for the transmission of light; it also reduces the field of view. Additionally, reflected light might be transmitted in the horizontal layers resulting in crosstalk. The other major limitation of CMOS technology is the relatively low fill factor, which reduces light sensitivity and device performance.

One approach to enhance the photosensitivity is the concept proposed in the fill factory patent. An additional diffusion collects the photon-induced electrons generated below the photodiode and in silicon areas covered with transistors.

Another concept, the vertical integration of the photodiode and the CMOS readout circuitry, has been proposed and several approaches have been shown (Fischer *et al.* 1992, Harendt *et al.* 1998, Neidlinger *et al.* 1999). One straightforward process is the low-temperature deposition of amorphous silicon photodiodes on top of CMOS image sensors as shown in **Figure 13**.

These Thin-Film-on-CMOS (TFC) diodes have a p–i–n layer structure of amorphous silicon-based photodiodes. It mainly consists of an undoped (i.e., intrinsic i) absorber layer sandwiched between very thin doped layers generating the required electric field across the intrinsic layer.

Because of the short diffusion length of charge carriers in the amorphous Si:H-based semiconductors of typically 100–150 nm, no pixel separation is

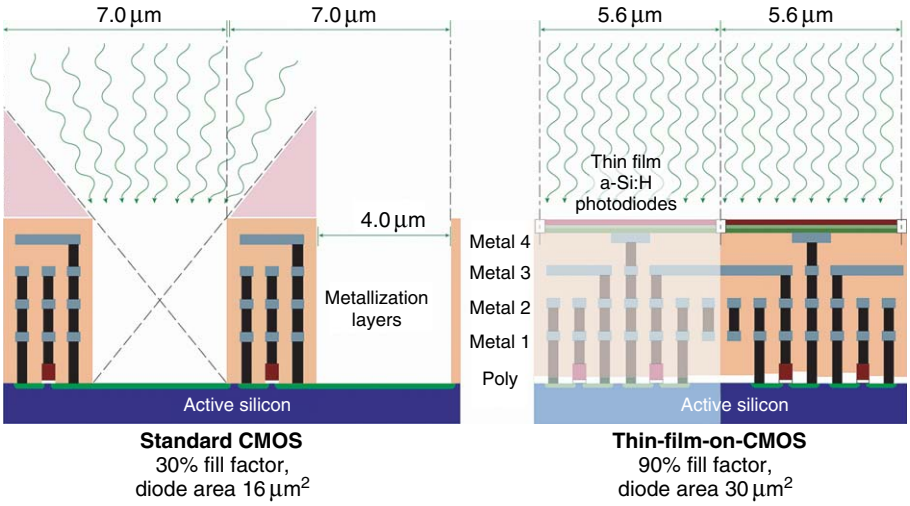

Figure 13 Cross-section view of a pixel in bulk silicon and the Thin-Film-on-CMOS (TFC) photodiodes.

needed in the upper photodiode layers. Down to a back contact spacing of 1 µm, the crosstalk between adjacent pixels outperforms CCDs by a factor of 5–10. Moreover, the small diffusion length determines the layer structure of the thin film photodiodes. In contrast to crystalline semiconductors, diffusion-based carrier collection is almost impossible in these amorphous materials. Therefore, a built-in electric field must serve the purpose of separating the photon-generated charge carriers. The TFC process is an add-on to the standard CMOS production process. The wafers are fabricated in a 0.25-µm CMOS process by using a wafer foundry service. Before depositing the TFC diodes, an additional layer with metal contacts is patterned for each pixel. The manufacture of the amorphous p–i–n diodes is done via plasma-enhanced chemical vapor deposition (PEVCD) at low temperatures of 100–150°C. Subsequently, a layer of zinc oxide is deposited, forming a transparent conductive top electrode, which is contacted via an alumina layer that is patterned at the edge of the image field. Deposition of an antireflection coating and opening of the bond pads completes the wafer-level processing.

3.08.2.3.3 Color technology

For many applications color imaging is preferable. The majority of color image devices in use today use color filters on top of the sensor. The filter material is normally an organic resist containing color pigments. The wafers are spin coated with the color resist and the color filters are patterned using lithographic processes. The pixels are coated with the three color filters (red, green and blue or yellow, magenta, and cyan) in a regular pattern, i.e., alternately red and green or blue and green. For some applications also, black filters for pixel grid and circuitry covers are used. These absorbing grid structures help to avoid the detection of scattered light in neighboring pixels and thus reduce crosstalk.

Often color processes include planarization layers to reduce surface topography. The color filter material is typically stable up to temperatures slightly above 200°C. Color degradations after sterilization processes in medical applications have been observed. The color process is often combined with the fabrication of microlenses on top of the coating, requiring additional planarization layers. Finally, antireflection coating is necessary to obtain good performance. In total, the color process consists of three to five lithography steps and a similar number of layers resulting in a significant increase of processing costs. So far, this technology with organic color filters has been used in most microcameras. For very small pixel sizes, however, the resist thickness required for the color separation and the size of the pigments limit the performance, mainly the device sensitivity.

Recently, amorphous silicon has been tested as a color filter material (Kasano *et al.* 2006). The color separation is determined by the different absorption length of the light in the amorphous silicon, which is

used as a filter material with a different thickness on top of the CCD or CMOS device. The deposited amorphous silicon layers can be easily patterned lithographically and thinned by dry etching processes. These layers are only 40–80 nm thick and reveal a better transmission than do organic filters.

The color information obtained from each pixel is processed in the software resulting in a color picture. Although software processes such as interpolation between the pixels improve the quality, the color image has significantly lower resolution due to the combination of three pixels. Additionally, the color filters absorb light and thus increase the minimal detectable illumination. As a consequence, images may show moiré pattern, increased noise, or color seams in low light conditions.

The restrictions of the color filter technology led to a number of different approaches. The sequential illumination with colored light (using mechanical or electrical shutters) is one of the earliest techniques. The resulting color images have the full image resolution, but suffer from reduced image quality for moved scenes (color seams).

Another approach is the separate color detection in one pixel presented by Foveon (Lyon and Hubel 2002, www.foveon.com). This concept uses different absorption lengths for photons of different wavelengths (*cf.* Section 3.08.2.2.1) for separate detection. The pixel contains three vertically stacked subpixels formed by diffused p and n wells. While blue light is detected in the upper junction diode, green and red light is absorbed in the lower parts of the stack. Compared to color filters, however, the color separation is less optimized.

In the past, a three-color pixel technology has been demonstrated using amorphous silicon photodiodes (Eberhardt *et al.* 1995, Neidlinger *et al.* 1996, Zhu *et al.* 1994). Again, a different absorption length is used for the color separation, but within the amorphous silicon photodiode stack on top of the CMOS device. The drawback of this approach is the time constant for the charge collection in each section, limiting the frame rate.

A promising technology for the future might be a detection principle somewhat similar to that of organic light-emitting electrodes (OLEDs) for pixel image sensors. Recently, in a press release from Fuji, a new color image sensor technology has been announced using organic pigments as photodetectors (Tanaguchi and Takada 2005). Three different layers of organic material are forming a color sensor. Products in this technology are expected in 2010.

3.08.2.3.4 Microlenses

In the sections above, the fill factor problem has been addressed. With the reduction of the pixel pitch and the size reduction in technology (both CCD and CMOS) the photosensitive detector is located at the bottom of a stack of transparent layers (**Figure 14**). For small pixel sizes, the aspect ratio could be 8:1 or more. By positioning a lens on top of each pixel, the amount of light detectable at the sensor increases. A schematic of such a device is shown in **Figure 14**. Typically, these on-chip microlenses are fabricated using a layer of organic material with the desired optical performance, which is patterned with a grid. The microlenses are formed in a thermal molding step. In process optimization, the focus of the lens has to be adjusted to the photodetector, e.g., by transparent planarization layers. The combination of microlenses with the optics and the camera, however, can reduce the aperture angle. An offset between microlenses in the center of the sensor and at edge positions reduces the effect.

3.08.2.4 Scanning Sensors

While CMOS and CCD sensors are self-scanning systems, scanning sensors consist of a row of photosensitive elements and a scanning system. The advantage of this principle, which is used in many volume products such as fax machines, is the reduced complexity of the image sensor. It requires, however, a moving part for the scan. This can be either the sensor itself or a movable mirror. Microscanners use movable mirrors fabricated using microelectromechanical (MEMS) technology, which can be precisely controlled by electrostatics. Single-crystal silicon, often covered with a metal coating in order to improve the reflectivity, is a common material for mirrors.

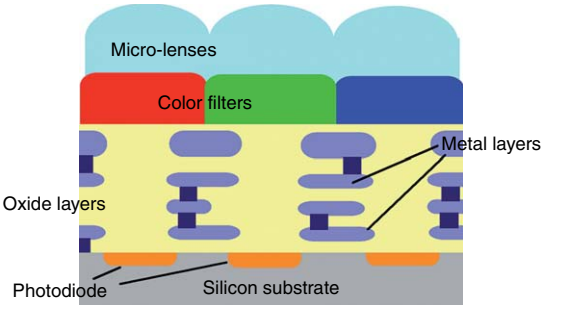

Figure 14 Schematic of an image sensor with color filters and microlenses.

For scanning systems with a control for x- and y-movement, the detector can be a single photodiode or a photomultiplier. The detector determines the sensitivity and can be optimized for the application. The resolution obtainable depends on the scanning system.

One application in microscopy is a confocal laser scanner (Knittel *et al.* 2001, Albrecht *et al.* 2006). Confocal laser scan is used in microscopy for biological samples, because this method provides much better images than does conventional microscopy.

3.08.3 Packaging and Integration

3.08.3.1 Packaging for Image Sensors

The integration of the image sensor chip with other necessary components into a camera or a more complex system such as a cellular phone or an endoscope requires packaging. Although the focus seems to be on improvement of pixel size and performance of the sensor, packaging is one of the most important issues for microcamera development. It affects the system size, the reliability, and the performance of the sensor and is a critical task for cost reduction.

There are various packaging technologies for silicon chips ranging from relatively high-price ceramic package for advanced products to plastic package used for volume production (Menz *et al.* 2001, Tummala 2001). For image sensors, however, many of the standard technologies are not applicable because the photosensitive part of the chip surface has to be exposed to light. Additionally, the image field of the chip must not be damaged or contaminated with particles and, for organic color filters, not treated at temperatures above a limit of approximately 230°C. Thus, many of the standard packaging technologies, mainly the plastic packages common for volume production, cannot be used.

One standard packaging approach is the ceramic package. After thinning the silicon wafer and sawing, the good tested bare dies are placed in a ceramic housing. Depending on the need for the device, a conducting or insulating glue is used to fix the die. After a heat treatment for the bake of the adhesive, the pad connections on the chip are wire bonded to the pads on the ceramic package (**Figure 15**). Instead of the metal cover, which is soldered on top of the ceramic housing in the standard process, a transparent glass cover is used for image sensors. This glass lid is glued to the ceramic. Often the glass is replaced by a special filter (e.g., an IR filter to reduce the NIR response).

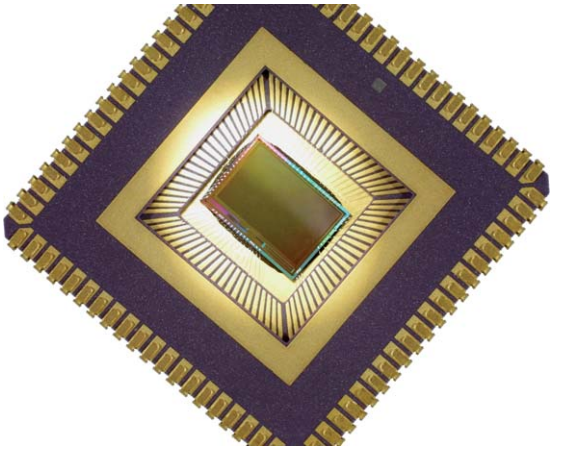

Figure 15 Image sensor in a ceramic package.

The technology is used for many image sensors, mainly in the low-volume and advanced product market. There are, however, a number of drawbacks limiting this approach. First, ceramic packaging is not a low-cost technology. The price for ceramic packages is in the range of US$10–30 per device, which excludes volume markets such as cellular phone cameras. Additionally, many processing steps are critical in terms of particle generation or performance reduction. The processes used in wafer packaging such as wafer thinning, which is done by grinding, generate many particles. In the sawing process, the silicon particles are directly washed onto the chip surface and remain to some extent on the photosensitive area. There are organic protective covers and cleaning procedures, but the removal of both the protective covers and the particles remains a challenge. This is especially difficult for imagers covered with delicate layers of organic color filters or microlenses. These organic top layers can also degrade by thermal treatments such as glue bakes. Particle contamination or even damage of the top layers of the sensor might occur in the pick-and-place process, when the die is placed into the cavity using a front-side tool.

The cover glass lid must be free of particles too. Additionally, the optical parameters of the glass are important for the image quality. Reflections on the glass can cause ghost images, absorption will reduce the sensor sensitivity. Therefore, a strategy to avoid the cover glass is the application of an epoxy resin to protect the wire bonds. The glob top is a semifluid

epoxy material, which is applied on the wire bonds and hardened thermally. Because of the protected bond wires, these packages can be handled without an additional cover. The optimization of the glob top process is not easy and requires special tools and experienced staff.

In a similar way, the image sensor can be mounted as a bare die on a circuit board or ceramic plate. As demonstrated for the miniaturized endoscope sensor, the chip on the ceramic plate is wire bonded to pad connectors on the holder. The glob top cover avoids contacts and damage of the bond wires during further assembly.

For volume applications, the costs of ceramic packaging are not acceptable. One approach is to adapt the plastic package technology to the requirements of the image sensor. Open or semiopen plastic packages have been developed. Elmos Advanced Packaging (www.elmos.de) offers plastic packages with glass openings for optical applications. Another packaging service describes a technology, where a film is used for the cover of the photosensitive surface during molding (www.boschman.nl). The film functions as a seal and protects the image sensor surface. As described for the ceramic packaging, the requirements of image sensors in terms of temperature sensitivity and particle contamination differ from the standard IC processes. For plastic packaging, the molding process has to be adapted to some extent to the needs of the special device, i.e., temperature limitations. Developments in this field are driven by volume market products such as image sensors for cellular phones. Thus improvements in terms of size and cost are to be expected.

For a next generation Nokia cell phone camera there is another approach. In order to meet the size requirements for this mobile phone application, the mounted camera module should have a similar height of about 2.5 mm as the other components on the board (e.g., the display). Chip packages used at present are more than twice the size. If the chip is mounted directly on the board, the height can be reduced to the desired dimensions. That implies, however, the application of the reflow process with high temperatures above 250°C, a risk for the temperature-sensitive organic components (color filter, microlenses) (Nummela *et al.* 2006).

A technology using a glass–silicon–glass sandwich for the package of image sensors has been presented by Shellcase in 2000 (www.shellcase.co.il). The wafers with image sensors are mounted upside down onto a glass substrate and subsequently thinned and separated. Metal interconnects from the front-side pads to the back are fabricated in several steps. The resulting device has a size almost identical to the dimension of the bare die. Additionally, the delicate image sensor surface is protected after the first processing step, which certainly reduces the particle contamination. The complexity of the process, however, seems to limit this approach to applications in advanced products.

Generally, in image sensor packaging front-side wire bonds are disadvantageous for the assembly process. They increase the package size and obstruct simple assembly techniques for the optics. The straightforward approach of flip chip mounting instead of wire bonding is impossible because the photosensitive surface has to be exposed to the light. Thus, a front-to-backside via would be the desired technology for microimager packaging. With a plain front side, the optics can be directly positioned on the image sensor chip. Cost reduction in assembly with plastic or glass optics and a gain in reliability is expected.

Some approaches for front-to-backside interconnects have been described (Rasmussen *et al.* 2003) but the high aspect ratio of the interconnects, which have to be hundreds of microns deep and only 5–50 µm wide, is a challenge. The improvements in MEMS technologies will certainly support process developments in this field.

A wafer-level packaging (WLP) concept seems to be successful in the high-volume market of image sensors (Leib and Töpper 2004). The processed silicon wafers are bonded to a glass wafer and thinned to about 100 µm. Via interconnects to the front-side metal layer and backside bumps are fabricated after wafer thinning (**Figure 16**). The resulting chip package has a similar size as the chip and meets the height requirements for videophone applications.

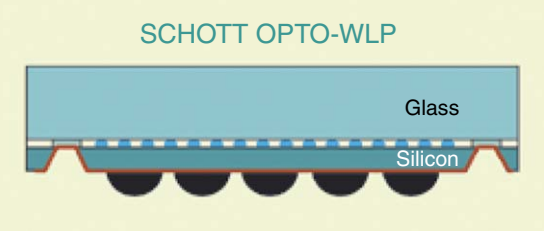

Figure 16 Schematic of wafer-level package for optical devices (Courtesy: Schott).

3.08.3.2 Integration of Micro-optics

Miniaturized cameras frequently consist of small-sized components similar to those used in larger devices. Thus, lenses assembled in lens holders are mounted on the image sensor package located on a circuit board. In the assembly process, the optical system has to be adjusted in order to reach the desired optical performance (i.e., focus and position of the optics). For advanced products such as endoscopes, these optimization processes are done separately for each device.

In a microimage sensor, the optics can be integrated in the cover of the device, e.g., in the metal cap of an endoscope or in a separate optics socket such as the dome in the capsule (**Figure 17**). Examples of integrated optics in capsule endoscopy are shown in Section 3.08.4.4.

For microcameras provided with illumination, special attention has to be paid to the position of the light source, because improper shielding of the sensor reduces the image quality. In volume production, cost and size are the major optimization criteria. Plastic lenses are mainly used. The reduction of the height of the lens stack is a major issue. For cost reasons, automated processes are used for focus and position control. For better manufacturability, wafer-level fabrication technologies for optics have been reported (WLP Optic patent).

One approach used in consumer microcameras today is a combination of digital image data processing (Nummela *et al.* 2006). These opto-digital systems enable a wider focus range without mechanical components (Mait *et al.* 2003). Recently, compound-eye optics have been proposed for image sensors (Duparre *et al.* 2004). These optics are very thin (0.2 mm) compared to the lens stack system, but the performance needs to be improved.

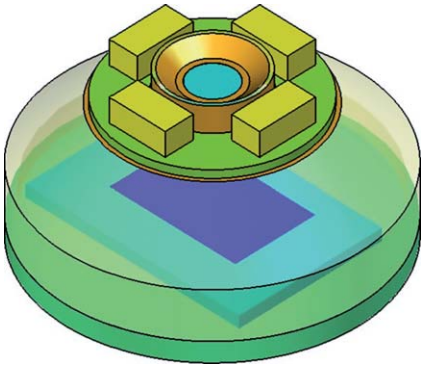

Figure 17 Optical dome with a lens and a circuit board with light-emitting diode (LEDs), a component of a videocapsule.

3.08.3.3 Integration with Micromechanical Components and Electrical Systems

The trend to further reduction of size of the devices will certainly lead to the integration of more functions in the camera chip. The electrical functions can be subdivided into four parts:

(1) Digital circuits
(2) Wireless transceivers
(3) Power systems
(4) Illumination

For CMOS image sensors, the integration of additional digital functions such as signal processing is straightforward. The functional blocks of many of the circuits are available in the CMOS libraries. The increase in chip size and complexity is compensated by the reduction of interconnects and the size of the system. Generally, the reduction of chip-to-chip interconnects increases the reliability of the system because of the higher failure probability of wire bonds. The reduction in size of a one-chip approach compared to a solution with several chips on a board is another argument for the integration. In many CMOS imagers, functions located earlier on the camera board are now integrated on-chip. For applications such as endoscopy, where the size of the camera chip is an important factor for the system size, two or more chip solutions may be advantageous. For CCD devices fabricated using a different technology (see Section 3.08.2.2.1.(iv)), the integration of other functions is not possible.

The benefits of a combination of cameras provided with wireless image data transmission were demonstrated in camera capsules. The integration of these functions into the camera chip has been prevented to date because of the difference in technologies.

Self-powered microcamera systems would be a major step toward autonomous microsystems. The examples in capsule endoscopy (see Section 3.08.4.4) show the technologies available at present. There is a gap between the power consumption of the devices and the energy provided by miniaturized power supplies, but the activities in low-power CMOS process technology and the research in power systems indicate, however, the progress in this field. Some of the power systems such as thermogenerators in silicon technology have the potential to be integrated into the silicon device. Again, the CCD

imagers are unlikely to participate in these developments because of their power consumption.

Only some of the microcameras such as endoscopes need illumination, typically LEDs. These diodes are fabricated in special technologies and mounted on the board. The integration of these devices is unlikely because of the differences in technology. To reduce size, on-chip mounting of bare LED dies would be the best solution.

The major issue for the integration of mechanical components in microimaging systems is the focus and the zoom for the optics. Different approaches have been shown ranging from magnetic drive for zoom lenses (Uehara and Hoshina 2003) to liquid zoom lenses (Berge and Peseux 2000). These components are located on top of the image sensor. Therefore, the integration of the driver circuitry for such a device in the imager is more likely than the integration of MEMS devices.

3.08.4 Microcameras

3.08.4.1 Overview

Digital still cameras and camcorders became products in the 1980s. At that time, the consumer market was still dominated by photographic film and videotube cameras. Miniaturized cameras were exclusively developed in the field of military applications.

Within the last three decades, the feature size reduction in semiconductor process technology was driven by major product memories and ICs. This also enabled developments in market segments of smaller volume such as image sensors. Because of the lower complexity of the process, CCD image sensors were the first to become small enough to be integrated in small-sized cameras. Examples were small systems (so-called finger tip cameras) for various applications such as inspection, technical endoscopy, toys.

The major field of development was medical endoscopy, except for military applications, where microcameras have been used in combination with other devices, but access to state-of-the-art results is impossible. Developments and results in endoscopy are described in Sections 3.08.4.3 and 3.08.4.4.

3.08.4.2 Consumer Applications

In digital photography, the major trends were performance improvements in resolution and sensitivity; the size of the device was a minor topic. For both digital still imagers and videocameras the market has roughly two segments: products for consumer applications and high-performance cameras for professionals. While developments of the latter were concentrated on performance optimization (more and smaller pixels, better sensitivity, color quality, and low noise levels), the cost reduction was a major issue in consumer products, resulting in improved device yield and lower packaging costs. With the technical improvements, devices and systems became smaller and the reduction of size and weight was an important factor in the market. Nevertheless, cameras were far from being microsystems and miniaturization was important but not essential.

The situation changed when cameras where integrated into cellular phones. The commercial success of a mobile phone offering the possibility to make snapshots and transmit the images via a phone to friends started the volume production of microimagers. While the first were popular among Japanese youngsters, today about 500 million camera phones are used (Nummela *et al.* 2006).

As a consequence, miniaturization of devices and components became an issue not only for the semiconductor industry, but also for companies specializing in packaging and optics. Because camera phones are the fastest-growing market for consumer products, their needs determine the tasks for the process development, and the major tasks apart from image quality are size reduction and cost reduction.

The cost per device is determined by the price of the image sensor with integrated electronics, the package with the connector and the optics. In 2006, this price was reported to be about US$5 per camera module (Nummela *et al.* 2006), and further reduction is expected. This demonstrates the need for high-volume and low-cost processes such as automated assembly with plastic packages and lenses. Also processes so far done manually or semiautomatically like quality control or focusing have to be automated. Cost reduction is also the driver for the definition of packaging and interface standards for mobile phones.

The other important parameter, the size of the camera module, does not depend only on the image chip size. Package and optics determine in a similar way the final size of the product. A typical module size for a 1 mega pixel image sensor is 10 mm × 10 mm × 7 mm (Bosiers *et al.* 2006). The package thickness for the next generation of small cameras in the common intermediate format (CIF) or in the videographics array (VGA) format will be only 2.5 mm (Nummela *et al.* 2006), which demonstrates the challenges for size reduction.

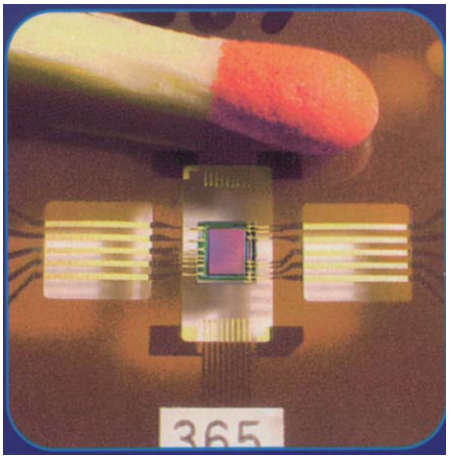

Figure 18 Miniaturized charge-coupled device (CCD) image sensor.

An example of a small-size image sensor in comparison to a match is shown in Figure 18.

3.08.4.3 Videoprobes in Endoscopy

Visualization of the status of an organ's health is one major task in medical diagnosis and therapy. Endoscopy and minimal invasive surgery are techniques for this purpose in medical applications. Endoscopy emerged in the beginning of the 20th century as a method in medical diagnostics and became increasingly important with the development of techniques for minimally invasive surgery.

Most endoscopes use optical lens systems (rigid endoscopes) or fiber bundles (flexible endoscopes) to transmit the images to the viewer's eye or a camera located at the proximal end of the system (Buess 1990). At the distal end, wide-angle optics are used usually in order to obtain images with a reasonable depth of field. Additionally, endoscopes comprehend an illumination source, normally a fiber bundle connected to an external light source, and a number of additional functions (support channels for air or water, biopsy, or medication). There is a special endoscope type for each medical application ranging from colonoscopes for inspection and treatment of the colon (10- to 15-mm diameter) to bronchoscopes for the inspection of the lung with a diameter <5 mm. Fibroscopes used in neurosurgery have diameters in the range of 2 mm and lower. Details on medical endoscopy are given in Buess (1990) and Vilardell (2006), the available instruments and technical details are described by the major endoscope manufacturers (e.g., www.olympus-europa.com/endoscopy/427.htm, www.karlstorz.com, www.richard-wolf.com, www.pentaxmedical.com).

For applications in minimal invasive surgery, more than one endoscope is needed. A typical setup consists of an endoscope with wide-angle optics to have a complete view of the scene and one or more endoscopes for a detailed view. Often stereoendoscopes are used. In some cases, overview and detailed view endoscopes are combined in one instrument, which has a diameter of not more than 15 mm.

Developments in endoscopy have focused on improvements of image quality, on size reduction, and better flexibility of the distal part (Irion 2005). For flexible endoscopes, the resolution is limited by the number of optical fibers used. Endoscopes with diameters of about 4 mm consist of fiber bundles with 30 000 fibers. Thus, there is a trade-off between image resolution and the diameter of the endoscope. On the other hand, thick fiberglass bundles limit the bending property of the system, a drawback for many applications. A typical value for the bending radius of a fiber is 25 times its diameter. Additionally, the loss of image intensity over the distance of up to 2.5 m between optics and camera restricts the sensitivity of the endoscope.

Because of the development of small-size image sensors, the integration of the camera chip into the tip became feasible. Such a videoendoscope or videoprobe contains a microsystem with an image sensor chip, optics and illumination, and electrical wiring at its head. Image data are transmitted via cables, providing the power for the system. The requirements for the medical application, i.e., the secure encapsulation of all microparts and the stability of the whole system in sterilization procedures, are additional challenges for the technical realization.

The first videoprobes demonstrated for this application contained CCD image sensors, which are still used in the majority of products today. In the mid-1980s, the first prototype of a videoendoscope was presented by the American company Welsh Allyn. It had a black and white CCD image sensor with 36 000 pixels. Color images were obtained by sequential color illumination.

Typical CCD sensors in use for videoendoscopes have 480 000 pixels (chip size 4 mm × 4 mm) or 250 000 pixels (chip 2 mm × 2 mm). A drawback, however, is the need for at least 10 external connections (*cf.* Section 3.08.2.2), which makes packaging, wiring, and interconnects more complicated.

Today the complexity of device fabrication, packaging, and system integration limits the

Figure 19 Tip of a laparoscope (10 mm) with a charge-coupled device (CCD) image sensor (chip-on-a-tip, www.richard-wolf.com).

application of these videoprobes to the field of advanced and high-price products (**Figure 19**).

The integration of CMOS sensors into small-size videoprobes has been demonstrated recently (Arena *et al.* 2005, http://ivp.ims-chips.de/start.html). General aspects of the development of a CMOS imager for this application are:

- The minimization of the pixel size to allow acceptable dimensions for the sensor.
- The reduction of the number of pad connections, because bonding pads with its area and the required sizes for pad circuitry cover a significant area of the chip. Additionally, each bond also requires size on the package.
- The minimization of the chip size by area optimization and reduction of functionality.

The reduction of the pixel size is always a trade-off between the complexity of the circuitry and the area reserved for the photosensitive element, the fill factor (*cf.* Section 3.08.2.3). The image sensor developed in the European joint research project IVP (intracorporeal videoprobe) (http://ivp.ims-chips.de/start.html) could be designed with a pixel pitch of 4.6 µm in a 0.25 µm CMOS technology. Although the number of transistors per cell was reduced to the minimum necessary for addressing and readout, the fill factor remains below 30%. The fill factor can be improved by using microlenses (*cf.* Section 3.08.2.3) or the TFC technology.

The number of pad connections is a crucial issue for both the chip and the package size: Each bond pad with a size of 50 µm × 50 µm to 100 µm × 100 µm requires a significant area of the chip with pad driver circuitry, circuits for electrostatic discharge (ESD) protection, and minimal spacing between structures defined by design rules. This area can easily have a size of 150 µm × 300 µm per pad. Besides, the number and position of the bond pads increases the size requirements in the package (*cf.* Section 3.08.3.1). For the IVP image sensor, the number of I/Os could be reduced to four pads (power and signal lines).

The minimization of the overall chip size requires again a trade-off between functionality and size. Although the optimization of the configuration of functional blocks can result in a significant area reduction of the complete chip, the integration of additional functions such as A/D conversion or FPN correction is difficult for these applications. The on-chip A/D conversion is advantageous, because digital signals are less noise sensitive. Chip size restrictions, however, make a two-chip solution favorable in this case. For the IVP sensor the signal output is analog, A/D conversion and other features (FPN correction) are executed in a circuit board located in the hand piece of the videoprobe. This approach enables simple solutions for the micro-camera head; it implies, however, the risk of noise superimposition to the analog signal. Additional screening is necessary to reduce the problem.

The CMOS image sensor developed in the IVP project is an HDRC sensor with a logarithmic response function (*cf.* Section 3.08.2.1). The resulting sensor has an image field of 200 × 180 pixels with a pixel size of 4.6 µm. The overall chip size is 1.7 mm × 1.3 mm and the device has four connections. The image sensor is coated with color filters (red, green, blue). **Figure 20** shows a color image of a human eye obtained with an IVP image sensor. Although the bright reflection in the center seems to be saturated,

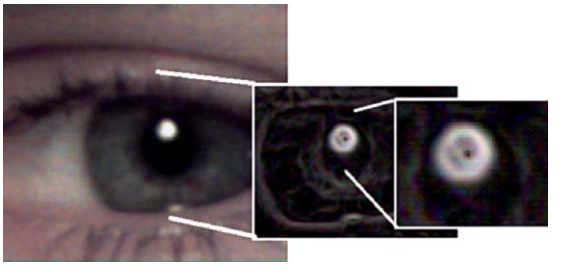

Figure 20 Color image obtained with a miniaturized High Dynamic Range-CMOS (HDRC) image sensor.

more details are visible in the enlarged images, being processed with an edge detection software. The details are the shape of the light bulb used for the illumination during the shot. The image demonstrates the obtainable quality and resolution of the sensor. The complete system is shown in **Figure 21**; details of the image sensor package are shown in **Figure 22**.

Colonoscopy is a very important part of endoscopy due to the high number of patients dying of colon cancer (in Germany about 30 000 patients per year). Early diagnosis could reduce this number significantly since efficient treatment is available. Thus, colonoscopy is a widely used diagnosis, and there are about 25 million colonoscopies worldwide per year. The unpleasant and in some cases painful colonoscopy procedure is one drawback for a wide acceptance among the patients.

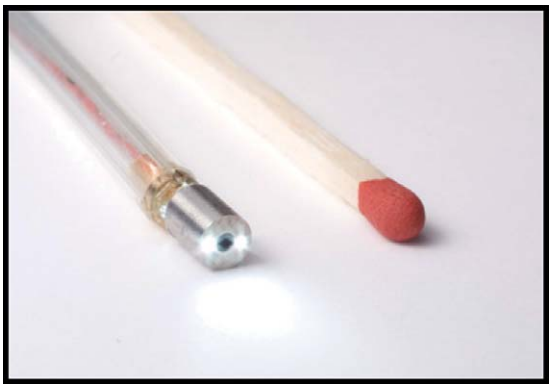

Figure 21 Videoprobe IVP1 (outer diameter 3.5 mm).

Different approaches for advanced colonoscopes using miniaturized cameras have been shown. An instrument intended for single use has been developed by STM Medizintechnik (www.stm-medizintechnik.de). In order to realize this product, the cost reduction of components has been a main objective. The imager is a CMOS sensor with 512×512 pixels and a pixel size of 6 µm. The chip size is 9 mm^2. The sensor is integrated into plastic optics. In the colonoscope, it covers only a part of the system, which has a diameter of 15 mm. It is also equipped with LEDs for illumination and channels for biopsy necessary for the diagnosis. The advantage of the system is not mainly the reduction of size but the single use. The absence of sterilization costs and the higher acceptance by the patients are the major benefits.

The colonoscope robot is another more advanced concept. The focus here is the improvement of the locomotion of the distal part of the colonoscope, one major source of pain for the patient. Colonoscope robots using the inchworm movement principle have been evaluated and first products are entering the market (Dario *et al.* 2004, Kim *et al.* 2006). The camera integrated is a CMOS sensor similar to the ones used in capsule endoscopy.

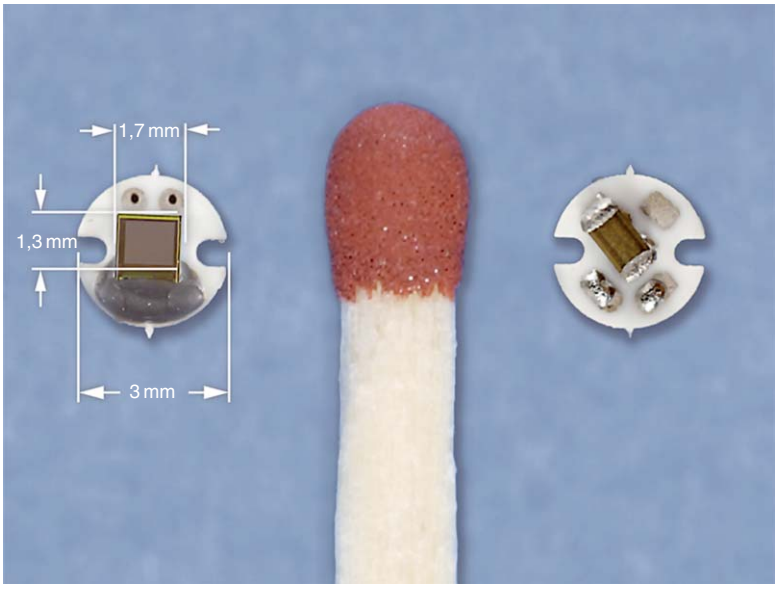

Figure 22 Miniaturized image sensor mounted on a ceramic plate with openings for the fiber optics (left). On the right the backside with four connectors and a capacitor.

The examples of the applications in endoscopy show again the competition between the CCD and CMOS technology. In comparison, the CMOS approach suffers from the bigger pixel size, thus reducing the resolution that can be obtained for small-size imagers. However, the integration of CMOS image sensors in videoprobes has a number of advantages compared to CCDs, which are today certainly the best solution for high image quality. For CMOS devices, the possibility to minimize the number of pad connections and the relatively low cost per device together with improved packaging technologies will make low cost, possibly even disposable videoprobes feasible. The trend to integrate sensors in instruments and the desire to avoid sterilization procedures will be the reasons for proceeding in developments of miniaturized CMOS sensors in videoprobes. Additionally, with the flexibility of the CMOS technology, the possibility to design sensors with special features, and the structure size reduction driven by the mainstream CMOS developments will make these types of microcameras the future devices for videoendoscopy.

3.08.4.4 Videocapsules

A much more sophisticated approach in the field of medical videoprobes is the capsule endoscopy. An autonomous system equipped with a microcamera, a battery or powering system and a transmitter moves through the body and sends image data wireless from inside the body to the outside world. Early examples of wireless capsules for capsules for medical diagnosis were shown in the 1950s (the radio pill) for pressure measurements and in the mid-1960s for pH detection.

The integration of cameras and the transmission of image data were presented by Iddan *et al.* (2000) and Meron (2000). The product based on the invention, the M2A capsule fabricated by the Israeli Company Given Imaging Ltd., started clinical trials in 2000 (www.givenimaging.com). After approval in various European countries, the US (FDA approval in 2001) and Australia, the technology attracted attention worldwide. Already by the year 2004, over 122 000 patients were treated with the capsule.

The M2A capsule has a diameter of 11 mm and is 23 mm long. Its contents are a color CMOS image sensor with optics and camera boards, four LEDs for illumination, an antenna, a transmitter, and two batteries. The CMOS image sensor has a resolution of 256×256 pixels with a pixel size of $10\,\mu m \times 10\,\mu m$. The sensor with an on-chip A/D converter has a power consumption of 2 mW (Krymski 2002). The principle of the capsule is shown in **Figure 23**, a schematic of the new capsule PillCam™. As shown in the figure, image sensor packaging and system integration have been challenges in the development.

During an operation two images per second are transmitted. The overall operating time of the capsule is limited by the battery power; it has been reported to be 7–8 h. The electronic devices are sealed in a biocompatible capsule cover. The capsule is designed for single use; a recovery after use is necessary because of the batteries. The receiver is located in a belt, which also contains a storage system. Image sequences can be analyzed by the physician after the patient's data have been transferred to a computer processing the images.

The major application of capsule endoscopy is diagnosis of diseases in the small intestine. The movement of the videoprobe is caused by the natural

contraction of the intestine. No locomotion is provided. Thus, the direction and the orientation of the capsule during movement are not controlled. Recently, Given Imaging presented a capsule for the diagnosis in the esophagus. This PillCam ESO capsule is equipped with two image sensors, one at each end of the pill. For the inspection of the esophagus the patient is in a supine position; this reduces the velocity of the capsule and enables, in combination with the possibility to catch two images, the full inspection (www.givenimaging.com). Results for diagnosis in the large intestine have not been shown yet using capsule endoscopy. This might be due to complexity of the organ topography; the battery lifetime is another restriction for this application. Microrobots (*cf.* Section 3.08.4.3) with videocameras and steering options are the better choice for colonoscopy.

Since the first product release in 2000, technical improvements of both the capsule and the peripheral instruments have led to a number of new features. Today the next-generation capsule, the PillCam, with a new generation of CMOS imager provides a higher resolution (**Figure 23**). A smaller videocapsule for children is offered (Arguelles *et al.* 2003) and many additional features and accessories are provided. Because of the success of this approach, capsule endoscopy is an increasingly accepted technique in medical diagnosis now.

There are, however, other developments of videocapsules. The Korean Intelligent Microsystem Center (IMC) demonstrated in 2003 a capsule MIRO #1, also with a CMOS image sensor (Park *et al.* 2003). The major difference to the Given Imaging concept is data transmission. The MIRO system monitors the localization of the capsule and transmits images in real time to a PDA. The IMC, which works on robot colonoscopy using inchworm locomotion (Kim *et al.* 2006) (see Section 3.08.4.3), is developing various multifunctional endoscopic microcapsules on the basis of the MIRO #1 system with diagnostic and therapeutic functions and locomotion.

In 2001, the Japanese Company RF Norika presented on the web a capsule with different features (www.rfnorika.com); the details are described in Uehara and Hoshina (2003). A miniature CCD camera has been integrated in a videocapsule based on the developments for space applications. The energy of the capsule is provided by microwave power transmission. The rather high-energy consumption of the CCD camera required special efforts in the power system optimization. The camera system itself consists of the CCD imager with 410 000 pixels, a magnetic focus system for the optics, and four LEDs for illumination. For the CCD, the driver circuitry within the capsule has been reduced to the minimum necessary; functions such as digital signal processing (DSP) are done outside the capsule. In order to increase the field of view, the camera chip is positioned in an angle to the front. The whole inner part of the videopill can be rotated around the axis of the capsule. For this movement miniaturized permanent magnets are located in the pill. The rotation is controlled by three coils located in a vest the patient wears during treatment. Many additional features of the capsule such as integrated tanks for drug delivery or variation of the illuminating light (e.g., by integration of IR LEDs) are reported. Up to now, the product has not been available on the market. In 2006 a new model, the Sayaka capsule, was presented (**Figure 24**).

A capsule development in Europe, the IVP2 system, uses a HDRC camera for image detection (http://ivp.ims-chips.de/start.html). The results obtained in a joint research and development project in the European IST program between 2001 and 2005 (Arena *et al.* 2005) demonstrate the feasibility of this approach. The capsule contains a CMOS image sensor with camera, optics and illumination, a transceiver, a system control with image data compression unit, and a power supply using radio frequency inductive powering (**Figure 25**). The optical part is located on a tiltable plate driven by a wobble motor. The camera chip is a color image sensor with a pixel pitch of 4.6 μm, an address decoder logic, and an integrated A/D converter. The chip dimensions are 4.4 mm × 3.5 mm; it has VGA resolution and provides about 40 frames per second. For illumination four LEDs are used and the wide-angle optics in combination with the movable plate guarantees a field of view of 120°. During the operation the transmission of at least 10 color images per second is needed to secure sufficient information. With about 3 Mbits per image a data compression was necessary to reach the desired frame rate. A special compression chip (ENDOCOM, Turgis and Puers 2004) was developed for this purpose. The system is shown in **Figure 25**.

Recent publications and announcements demonstrate the interest in the field of capsule endoscopy. The Japanese endoscope manufacturer Olympus announced in 2005 a new endoscope pill with many features such as localization and control of the capsule (www.olympus.co.jp/en/news/2004b/

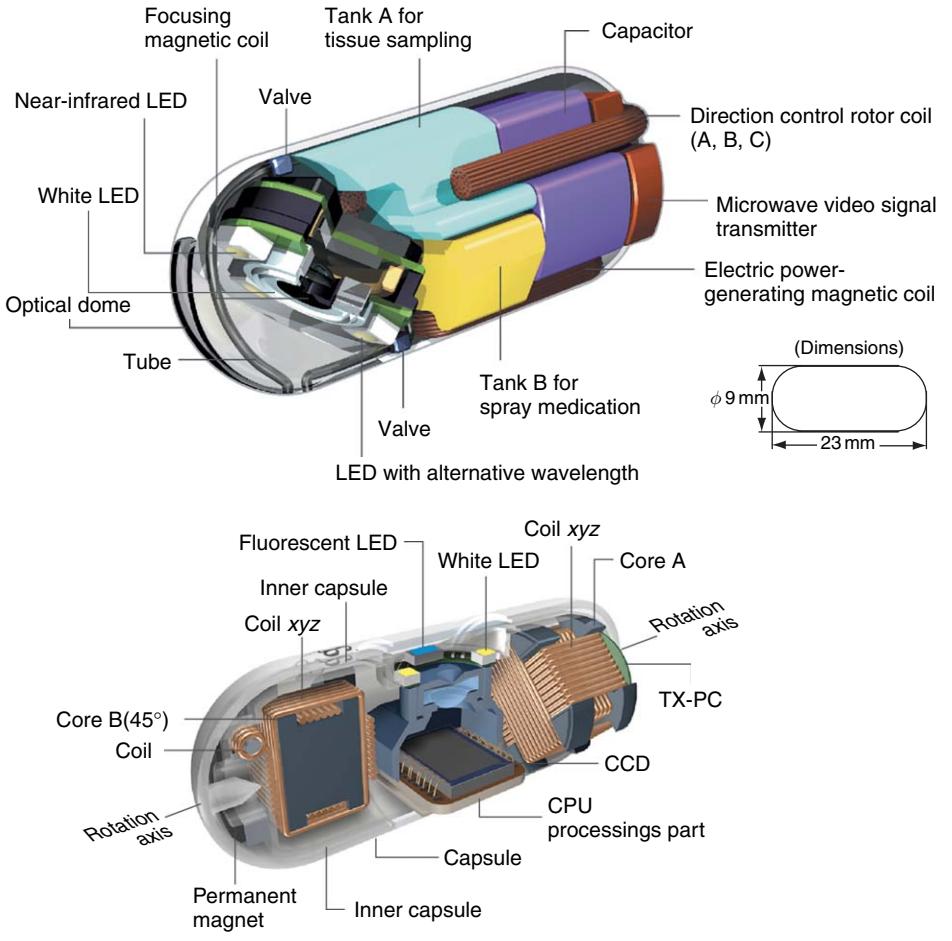

Figure 24 Schematic of RF-NORIKA capsule (top) and the new SAYAKA capsule. (Courtesy: RF System lab).

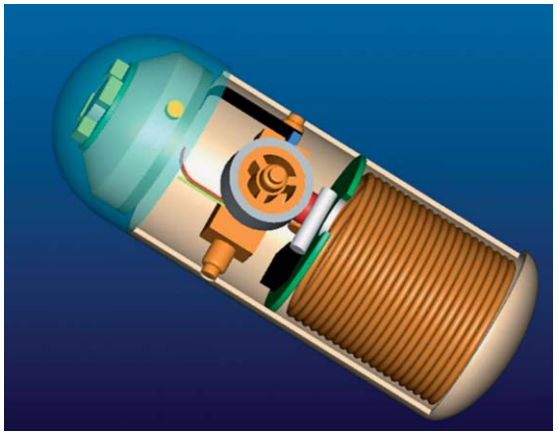

Figure 25 Videocapsule IVP2.

nr041130capsle.cfm). A capsule camera development in China was reported in 2004 (Meng *et al.* 2004).

3.08.5 Summary and Outlook

The development of miniaturized cameras started from products for special applications, such as instruments for medical diagnosis, but the fabrication of products for volume markets was the driver for the fast optimization and size reduction. The input from progress in other technologies, mainly the IC industry and telecommunications, was essential for miniaturization.

The rapid development of microcameras and the trend to integration and miniaturization will continue in future. As demonstrated for the growth of the camera phone market, the combination of technologies generates new types of products and changes the behavior and desires of customers.

The next step for new fields of applications will be the development of autonomous systems with wireless communications. So far the power demand of

circuitry limits the technology, but the progress in low-power CMOS devices and the developments in power generation for small-sized systems indicate that solutions are to be expected in the near future. The integration with MEMS systems and different types of sensors such as chemical or biochemical sensors will lead to many new products.

Wireless systems for health and care with functions for control of medical parameters as well as support for elderly or handicapped people will be a major application. Viewing functions, i.e., cameras, have to be integrated in many of these devices. The same is true for the large market of robotics ranging from production, where cameras are already integrated, to consumer and household applications.

In summary, with the further integration of functions, mainly electrical circuitry, a number of new products are feasible. The future imager will be integrated in smart autonomous systems, which communicate wireless with the outside world. These sensors will most probably be CMOS devices.

Christine Harendt heads the department Add-On Processes at the Institut für Mikroelektronik Stuttgart, Germany (IMS CHIPS). She is involved in the development and application of new technologies in combination with CMOS processes. In 1988, she received her Ph.D. in Physical Chemistry from Freie Universität, Berlin. The same year she joined IMS CHIPS. She has participated in several national and international research programmes (IST, PROMETHEUS, German Research programs). From 2001 to 2005, she coordinated the European Research Project (IVP) dealing with the development of miniaturized videoendoscopes.

Heinz-Gerd Graf heads the Microsystems Department of the Institut für Mikroelektronik Stuttgart, Germany. He was a member of the research staff of the Department of Electrical Engineering at the University of Dortmund and a researcher in the Advanced Physics Group of Messerschmitt-Boelkow-Blohm GmbH. He received the diploma in physics from the University of Dortmund. CMOS Image Sensors, IR Detectors, IC Packaging, and SOI-CMOS technologies are his main research activities.

3.09.1 Introduction

Biophotonics is concerned with the interaction of light and biological material. While the use of light for analysis, manipulation, and modification of biological specimens, from cells to organisms, has a long history, developments in microsystems engineering have made new types of optical components available, and also allow strong miniaturization of the optical systems involved (Motamedi 2005). The fields of photonics (Iizuka 2002), frequently defined as that in which lasers and semiconductor-based components, such as laser diodes, photodetectors, modulators, and waveguides, play an essential role, along with that of micro-optics (Herzig 1997, Sinzinger and Jahns 2003), have thus become of great importance in biology. As a result, the term biophotonics is used to refer to optical systems for biological analysis and modification, which employ laser technology, with particular emphasis on miniaturization and incorporation of microelectromechanical systems (MEMS) technologies.

This chapter provides an overview of microsystems technologies as they are applied to biophotonics (Prasad 2003). In correspondence to the focus of *Comprehensive Microsystems*, the coverage is restricted to those aspects of biophotonics in which microsystems play a decisive role; macroscopic imaging or laser-based systems, while of great significance to the field, are not considered here. Other chapters in *Comprehensive Microsystems* that deal with biophotonics include Chapters 3.06 and 3.14.

Beginning with an overview of the nature of the interaction of light with biologically relevant materials, ranging from individual molecules and cells to tissue and entire organs, a brief summary of the optical techniques employed by the biologist or the physiologist for analysis and alteration is provided. Following this introductory summary, the focus is on four areas in which biophotonics has seen particularly rapid and fruitful development:

1. Microscopic imaging systems, which take advantage of advances in micro-optics to allow the fabrication of strongly miniaturized microscopes and interferometers.
2. Optical biosensors, which frequently employ integrated or fiber optical structures for the measurement of biologically relevant parameters

3. The combination of microfluidics and photonics technology for enabling flow cytometry, essential for highly parallel measurement of individual cells.
4. Microarrays, the workhorses for genomic or proteomic analysis, in which highly parallel measurement of fluorescence is accomplished by means of the so-called biochips, in which the complete system has benefited from miniaturization of its components.

3.09.2 Photobiology

This section gives a brief description of the interaction of light with biologically relevant matter. In the context of biophotonics, light means electromagnetic waves from the near-ultraviolet, over the visible and near infrared, to the far-infrared, or Terahertz, frequency range. The interaction of light with biochemical and biological species of interest is described as the interaction of photons with a complex molecular energy level structure, including electronic, vibrational, and rotational levels. Virtually all these molecular energy levels play a role in biophotonics and are used for qualitative and quantitative analysis of biochemical species. For a description of the interaction of a system with discrete energy levels with a light field, only two energy levels directly involved are conveniently considered. Einstein identified three fundamental processes, i.e., absorption, spontaneous emission, and stimulated emission, in the interaction of a photon with a two-level system, which occur when the energy $h\nu$ of the photon equals the difference in the energies of the upper (E_2) and lower (E_1) electron state. Of these processes, only absorption and spontaneous emission are considered in this section.

3.09.2.1 Absorption

In the absorption process of a single molecule, the energy of an incoming photon is transferred to the molecule, leaving the molecule in its electronically excited state. A light wave traveling through a sample of thickness x containing an ensemble of absorbing molecules with a concentration c experiences attenuation of its initial intensity I_0. The intensity after passing through the sample, $I(x)$, is given by Beer–Lambert's law:

$$\frac{I(x)}{I_0} = \exp\{-\alpha(\lambda)x\} = \exp\{-\zeta(\lambda)cx\} \qquad [1]$$

Here, α is the absorption coefficient (cm^{-1}). In analytical chemistry, the molar extinction coefficient ζ (in units of $\mathrm{l\,mol}^{-1}\ \mathrm{cm}^{-1}$) is generally preferred over the absorption coefficient α, because the concentration of the molecules c can be determined from an absorption spectrum when ζ is known. Both the absorption coefficient and the molar extinction coefficient show a strong dependence on the wavelength λ. For typical biological materials, such as tissue and blood, their values differ to a great extent among individuals and with environmental conditions. Absorption spectra of water, oxygenated, and deoxygenated hemoglobin are given in Figure 1.

3.09.2.2 Fluorescence Emission

When a molecule is excited, a number of decay processes of the excited state decay due to the complex energy diagram of molecules. In all these mechanisms, conservation of energy, momentum, and angular momentum have to hold. This implies that not all transitions are necessarily accompanied with photon emission. Fluorescent dyes are frequently used in biophotonics to label molecular species of interest; examples of typical absorption and emission (fluorescence) spectra of two rhodamine dyes are shown in Figure 2.

Fluorescence is a radiative transition from a vibrational level of an excited electronic state (usually the first) into a vibrational level of the electronic ground state of a molecule (Figure 3). The emission spectrum of a fluorescence transition is usually shifted to longer wavelengths compared to the absorption spectrum,

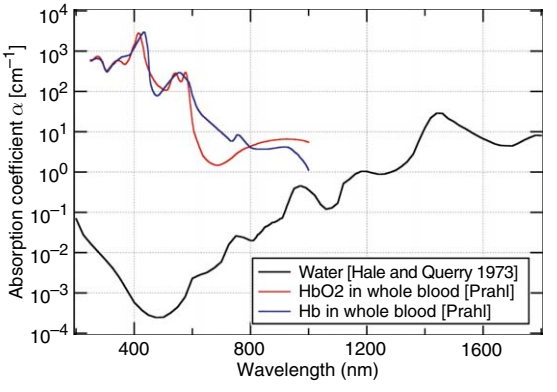

Figure 1 Absorption spectra of water (Hale and Querry 1973), oxygenated and de-oxygenated hemoglobin (Prahl 2006) in the visible to near-infrared wavelength ranges.

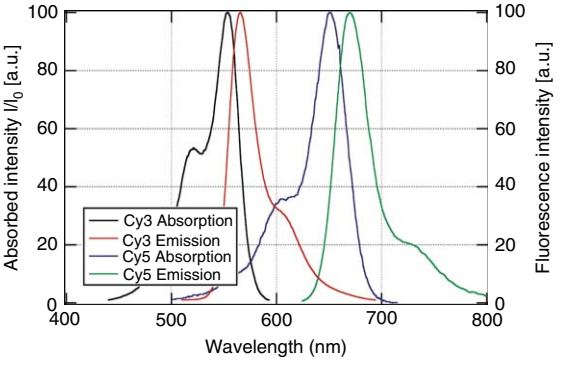

Figure 2 Absorption and emission (fluorescence) spectra of two rhodamine dyes.

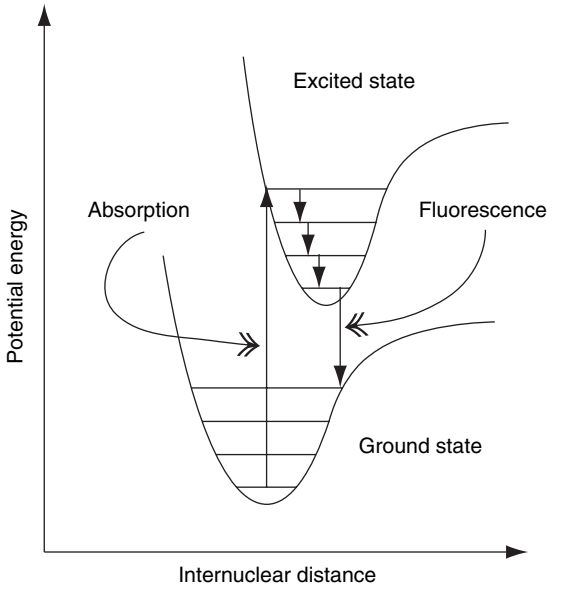

Figure 3 Absorption and fluorescence due to absorption and emission from the energy levels of a typical molecule.

because some vibrational energy in the excited electronic state is dissipated to the environment. Hence, the upper level in fluorescence emission is usually the lowest vibrational level in the excited electronic state (Atkins and de Paula 2006). This so-called Stokes shift between the maxima of the absorption and the emission spectra is typically some tens of nanometers in wavelength. The excitation energy of a fluorescent molecule can be provided not only by direct irradiation but also by coupling an evanescent light field to the fluorescent molecule; this mechanism is discussed in Section 3.09.2.4.

Practically every material shows endogenous fluorescence in the UV spectral range. Therefore,

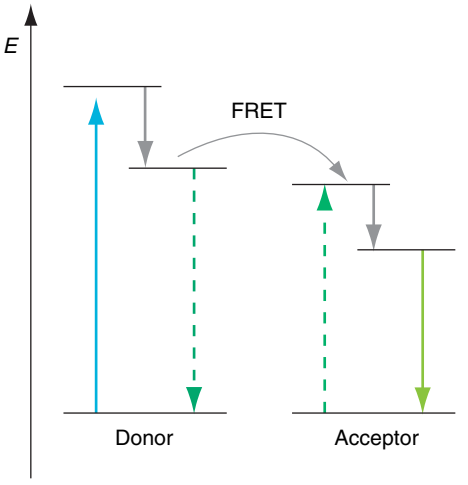

Figure 4 The FRET process: the energy from an excited donor molecule is transferred to a second fluorescent molecule in close physical proximity.

materials for fluorescence-based systems have to be chosen carefully to reduce background fluorescence. In that respect, COC have proven to be superior to glass as substrate materials for many biophotonics applications. On the other hand, endogenous fluorescence can be advantageously used for label-free fluorescence analysis.

Collision of an excited molecule with molecules in its surroundings can lead to dissipation of the excitation energy without photon emission. This effect is known as fluorescence quenching and is usually considered detrimental in biophotonic analysis.

Organic fluorescence dyes generally suffer from a limited lifetime due to photobleaching, i.e., a photon-induced irreversible damage of the molecule. Therefore, inorganic dyes such as semiconductor nanoparticles (quantum dots) are currently much in favor. Besides their stability, semiconductor nanoparticles as fluorophores offer the advantage of tailoring the emission and the absorption spectrum by their size.

Nonradiating transfer of excitation energy between molecules has a prominent application in Förster (or fluorescence) resonant energy transfer (FRET). In this technique, a primarily excited donor molecule transfers its excitation energy to an acceptor molecule in its vicinity. In a simple classical model, illustrated in **Figure 4**, both the donor and the acceptor molecules are described as interacting oscillating dipoles with characteristic r^{-6} dependence of the interaction energy on the distance r between both molecules. The efficiency of the FRET process depends furthermore on the relative orientation of the donor emission

dipole moment and the acceptor absorption dipole moment and on the spectral overlap of the donor emission spectrum and the acceptor absorption spectrum. The latter condition affects the appropriate selection of donor and acceptor molecules for a particular application. Because of the strong dependence on distance and orientation, the FRET process is efficient only for very close distances in the range of a few nanometers. FRET has turned out as a powerful tool for spectral imaging in biomedical research. Its main utility is in the visualization of interactions between proteins and nucleic acids in fluorescence microscopy and in the quantitative measurement of the concentration of nucleic acids.

3.09.2.3 Scattering

From a physical point of view, scattering is a very complex problem and is dealt with in standard textbooks on optics (Born and Wolf 1999) and a number of monographs (Bohren and Huffman 1998, van de Hulst 1982). We restrict ourselves here to a few aspects of relevance to biophotonics. Scattering is a frequently encountered effect in biophotonics; many natural materials (of which blood and tissue are the only two prominent examples) contain soft particles (micelles, vesicles, or cells) with a typical size in the micrometer range and with dielectric properties different from the surrounding host material; these act as scattering centers when light is transmitted through such materials.

Scattering generally occurs when an incident electromagnetic wave interacts with a particle of a size comparable to the wavelength λ. In the simplest case, a scattering particle can be modeled as an infinitely small oscillating dipole driven by the electromagnetic wave. This is a reasonable model for scattering particles of a size much smaller than the incident wavelength (known as Rayleigh scattering). The scattered field then has a typical dipole radiation characteristic of scattered intensity proportional to λ^{-4}. For scattering particles of a size comparable to or larger than the incident wavelength, full Mie scattering theory is taken into account. In Mie theory, the scattered intensity and polarization depends in a complicated way on the ratio of particle size and wavelength and on the scattering angle. For both these scattering mechanisms and nonfluorescent materials, the scattered light is at the same frequency as the incident light.

The intensity and polarization of the scattered wave depend strongly on the optical material properties, size and shape of the scattering object, and on the direction and angle of observation; possible absorption mechanisms can further complicate the problem. A rigorous treatment of the scattering problem of metal spheres is presented in Born and Wolf (1999). Unfortunately, scattering objects such as erythrocytes exhibit an even more complicated scattering behavior due to their irregular shape. If only the extinction of a light beam by an absorbing and scattering sample is considered, the effect of scattering can be summarized in a scattering coefficient $\sigma\,(\mathrm{cm}^{-1})$, which is added to the absorption coefficient α in eqn [1].

The frequency of scattered radiation can be different from that of the incident wave due to a number of inelastic scattering processes. An important example is Raman scattering: here, a molecule is excited to an unspecified (virtual) electronic state with a lifetime of zero (Atkins and de Paula 2006). From this excited level, radiating transitions occur to a vibrational or a rotational level of the electronic ground state. The energy difference of the scattered radiation is provided by or absorbed by the energy present in the molecular rotations or vibrations. The Raman effect is frequently used in spectroscopy and is as such a means for discrimination and identification of molecules; Raman microscopes that provide optical imaging and spectral information are commercially available.

3.09.2.4 Reflection

A frequently encountered situation in biophotonics is that of a propagating electromagnetic wave impinging onto the interface between two media, e.g., tissue layers as imaged by optical coherence tomography (OCT). The simplest way to model this is by a layer sequence of homogeneous and isotropic dielectrics with a certain refractive index; the interfaces between these layers then give rise to reflection.

At every interface between two media, with refractive indices n_i (from which the wave is incident) and n_t (into which the wave is transmitted), part of the incident light is reflected and the reflectance R defines the intensity of the reflected light as a fraction of the intensity of the incident light. In the case of normal incidence onto the interface, i.e., at an incidence angle θ_i of zero, R is given by

$$R = \left\{\frac{n_\mathrm{t} - n_\mathrm{i}}{n_\mathrm{t} + n_\mathrm{i}}\right\}^2 \qquad [2]$$

and for arbitrary incidence angles, the Fresnel equations define the resultant reflectance (Hecht 2003).

In addition, in the case of non-normal incidence, i.e., for $0 < \theta_i \leq 90°$, the angle of the transmitted beam with respect to the interface normal is described by Snell's law:

$$n_t \sin\theta_t = n_i \sin\theta_i \quad [3]$$

for which the special case, when $n_t < n_i$, is of particular interest. In that case, for a range of input angles, θ_i, greater than a critical angle, defined as

$$\sin\theta_c = \frac{n_t}{n_i} \quad [4]$$

the transmitted angle is predicted to be $\theta_t > 90°$. This situation is known as total internal reflection (TIR) implying that the incident wave is completely reflected at the interface. Nevertheless, there is an electric field behind the interface, the so-called evanescent field, which decreases exponentially with increasing distance normally from the interface (Born and Wolf 1999, Hecht 2003). Associated with the exponential decrease is a characteristic length or penetration depth, which is of the order of the wavelength, typically several hundred nanometers.

In the evanescent field, no net energy is transferred across the boundary to the less dense medium. However, if fluorescence dye molecules are present in the vicinity of the interface (i.e., within the penetration depth of the evanescent field), energy is transferred from the incident beam to the fluorophores by the evanescent field, as is shown schematically in Figure 5. The fluorophores are excited and as a consequence, the intensity of the reflected beam is smaller than that of the incident beam. This situation is called frustrated or attenuated total reflection (ATR). Total internal reflection fluorescence (TIRF) microscopy is based on this mechanism. It is a powerful technique for fluorescence imaging of processes in biophotonics with a pronounced surface sensitivity due to the exponential dependence of the evanescent field on the distance from the interface.

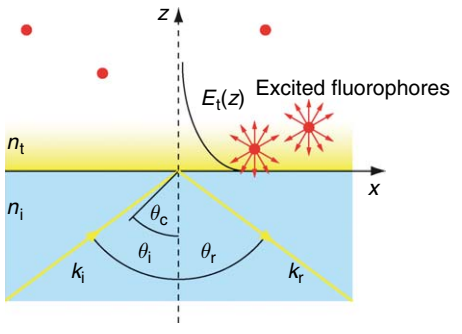

Figure 5 Total internal reflection (TIR) at an interface between two dielectrics; the material with the higher refractive index is at the bottom. The evanescent field extends beyond the interface and can be used to excite fluorescent molecules.

3.09.2.5 Optical Forces

In many applications in biophotonics, molecules, cells, small organisms, and tiny amounts of liquids have to be manipulated. Well-established standard tools for the exertion of forces to such soft or biological micro-objects are optical traps and optical tweezers based on dipole forces and radiation pressure (Ashkin 1992, Visscher and Brakenhoff 1991, 1992). Since these are macroscopic systems and well known for two decades they are not discussed here in more detail. Instead, the focus of this section is on the recently developed techniques based on wetting and surface forces.

In all the techniques for transportation of liquids involving wetting, the interfacial energies of the involved surfaces play a decisive role. In thermal equilibrium, the contact angle θ of a liquid drop on a planar surface is given by the balance of the interfacial energies γ_{sg} (substrate–gas interface), γ_{sl} (substrate–liquid interface), and γ_{lg} (liquid–gas interface; this is the surface tension of the liquid) by Young's equation

$$\gamma_{sg} - \gamma_{sl} = \gamma_{lg}\cos\theta \quad [5]$$

This balance of interfacial energies can be influenced by electric fields, as shown in Figure 6. In the electrowetting on dielectrics (EWOD) setup (in Figure 6, *left*), a conductive (or polar) liquid rests

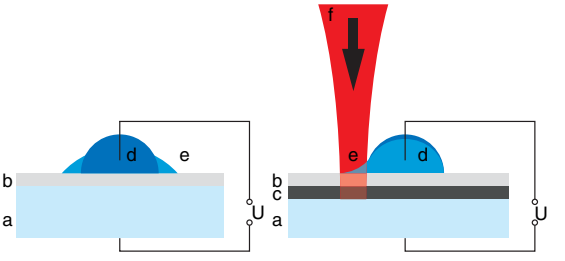

Figure 6 (*Left*) Principle of electrowetting and (*right*) optoelectrowetting; a, conductive substrate; b, insulating coating; c, photoconductive layer; d, liquid at zero voltage; e, actuated liquid droplet; f, light beam; U, driving voltage.

on an insulating layer (thickness d and dielectric constant ε) deposited on a conductive substrate. If a voltage V is applied, a term accounting for the electrostatic energy stored in the system must be added to γ_{sl}, namely

$$\gamma_{sl} \rightarrow \gamma_{sl} - \frac{1}{2}\varepsilon\varepsilon_0 \frac{V^2}{d} \quad [6]$$

By inserting this expression into Young's equation (eqn [5]), the Lippmann equation is obtained, describing the contact angle as a function of the applied voltage V as

$$\cos\theta(V) = \cos\theta(V=0) + \frac{\varepsilon\varepsilon_0}{2\gamma_{lg}} \frac{V^2}{d} \quad [7]$$

Here, $\theta\,(V=0)$ is the zero-voltage contact angle as given by Young's equation. Eqn [7] shows that the contact angle can be reduced by the applied voltage. Since a lower contact angle always means an energetically more favorable state for a droplet, a droplet always move toward those regions on the substrate on which its contact angle is smaller. For a recent review on electrowetting, see Mugele and Baret (2005).

A local reduction of the contact angle can be accomplished by using an array of individually addressable electrodes under the insulating layer and can be used for moving droplets across a surface along a path defined by the electrode array by wetting forces. Another possibility of moving droplets across a surface but without an array of electrodes is by optoelectrowetting (OEW). The experimental setup of OEW (see **Figure 6**, *right*) is a modification of the EWOD configuration with an additional photoconductive layer (e.g., hydrogenated amorphous silicon) deposited between the substrate and the insulating layer. By irradiation with light, the conductivity layer of the photoconductive is increased by several orders of magnitude such that the effective thickness of the insulator is that of the insulating layer and the contact angle of the liquid is reduced by the applied voltage. In contrast, the photoconductive layer acts as an additional insulator in the dark state such that the electrical field in the capacitor is small and does not significantly affect the balance of interfacial energies. Therefore, the contact angle is not changed in the dark state.

In summary, OEW can be used for transportation of liquid droplets by light-induced surface forces on a substrate. Since micromachined spatial light modulators (SLMs) are becoming commercially available, OEW is an attractive effect for use in MEMS-based biophotonics. Experimental demonstrations of electrowetting approaches for droplet manipulation are discussed in Section 3.09.6.3.

3.09.3 Macroscopic Biophotonic Systems

Photonic systems employ light for analysis or for modification of biological material. The use of laser technology for biological applications is virtually as old as the laser itself, and many of the applications that employ these components are decidedly macroscopic. A number of areas in biophotonics have profited from developments in microsystems and MEMS technology. In particular, miniaturized imaging systems and optical sensors have seen significant developments in this regard, as have new microsystem approaches for flow cytometry and microfluidics-based microarrays. The following sections provide an overview of some of these microbiophotonic systems.

3.09.3.1 Imaging

One of the first uses of the microscope developed by Anton van Leeuwenhoek (1632–1723) was to image the complex biological system found in a drop of pond water. Microscopy remains one of the most essential tools in biology, as it allows 2D and 3D imaging of biologically relevant samples. Illumination is by incoherent or coherent sources and the image is formed by reflection or transmission. Limitations in feature resolution are due to the illumination wavelengths employed, possible lack of contrast between the feature and its background, and scattering from the surrounding material, the latter especially if the feature of interest is below the surface.

Microscopy techniques have been developed to partially offset these inadequacies; dark field, phase contrast, or interference contrast microscopes employ scattered light to reveal features with too little contrast using conventional imaging. The confocal microscope (Semwogerere and Weeks 2004) uses a pinhole in the optical path to limit the depth of the field of the image, thereby strongly reducing scattering from layers above and below the feature to be imaged. A variation of this approach is 4Pi imaging, in which confocal approaches are used for illumination and imaging (Hell and Stelzer 1992) (the technique is called 4Pi microscopy because the

full solid angle ($= 4\pi$) of the wavefront generated from a fluorescent object is collected by the setup. The setup includes at least two microscope objective lenses). Miniaturized confocal microscopes are discussed in Section 3.09.4.3.

Fluorescence imaging restricts the image to that of a fluorescent feature, so that either the autofluorescence of cellular components or tissue may be selectively imaged or regions with certain functionality may be stained using fluorophores and thus made visible. The excitation illumination is filtered out and the result is strongly increased in contrast. Imaging using FRET takes advantage of the energy transfer between an optically excited molecule and the one at a lower energy level, thereby permitting an analysis of molecular functionality based on the proximity to known fluorophores. Multiphoton microscopy results in images only from regions in which two or more photons need to be absorbed to generate the detected fluorescence. Two-photon absorption is strongly intensity-dependent, so that optics with a narrow depth of field can be used to image features embedded in the scattering tissue; however, high-power pulsed laser sources are generally required. Both these latter techniques provide enhanced contrast and may reveal features not otherwise visible; they may also allow functional imaging.

A further means to image features below the surface of a scattering medium is through OCT in which a low-coherence light source is used in a Michelson interferometer in which the sample is placed in the measurement arm (Bouma and Tearne 2002). The reference arm contains a scanning mirror such that a detector signal is given only when the arms are balanced and is thus restricted to emission from a single point; the scan then allows slice-by-slice imaging of several millimeters below the surface with micrometer resolution. Optical coherence tomography systems have benefited greatly from advances in microsystems.

Optical near-field techniques use wavelength-sized apertures to circumvent the diffraction limit and image features smaller than the illumination wavelength (Betzig and Trautman 1992). When either the illumination or the image is situated close (within a wavelength) to the aperture, typically a lensed and apertured fiber with an opening in the 50 nm range, imaging is accomplished in the optical near field; resolution better than 100 nm is achievable.

3.09.3.2 Spectroscopy

Measurement of the absorption, transmission, or fluorescence spectra of biological materials (as discussed in Section 3.09.2) is often a direct approach to determine their composition. Whereas standard imaging microscopy provides structural information, spectroscopy can yield compositional data and provides clues as to the functional characteristics of the sample.

Two approaches for spectroscopic analysis can be defined. The first approach uses natural absorption or emission features, inherent to the molecules being measured. All molecular species have absorption spectra corresponding to their structure; most of these are in the near- to mid-infrared frequency range, and manifest themselves as distinct absorption lines at certain wavelengths. Alternatively, some materials show natural fluorescence emission, excited at higher energies and the characteristic emission lines can be used to analyze the sample.

The second approach uses fluorescence from specialized marker molecules or dyes that are selectively hybridized with the biological compound of interest. The fluorescent markers are typically attached to molecules that selectively bind to components in the analyte, thus providing an optical signal proportional to its concentration. This method is widely used for materials that have no easily excitable natural fluorescence.

Spectroscopic analysis can be imaging or nonimaging. The former case corresponds to microscopy approaches in which fluorescent emission is mapped two- or three-dimensionally using either steady-state or time-dependent analysis; a precise spatial distribution of a particular analyte in a larger sample (such as tissue) can be determined. Nonimaging spectroscopy relies on absorption in or emission from the bulk of a sample, e.g., oxygen in a gaseous medium (Zappe *et al.* 2000). Scanning probes allow an analysis of spatial distribution, and interferometric approaches are often used to improve sensitivity. For materials with multiple emission lines, spectroscopic analysis relies on dispersive or wavelength-selective elements, such as bandpass filters, gratings, or prisms, in the optical system to allow spectral separation of various fluorescent signals.

3.09.3.3 Microarrays

At present, one of the most industrially and scientifically significant areas in biophotonics is that of genomic or proteomic analysis. Significant progress in DNA sequencing and in the analysis of the

genomic structure of humans and other species has been made using microarrays. As discussed in Section 3.09.7 in greater detail, microarrays are 2D arrays of immobilized DNA sequences or proteins that selectively bind components of a fluorescence-marked analyte. Upon illumination, optical imaging or scanning measurements are used to determine the positions of fluorescence.

A microarray, sometimes referred to as a biochip, consists of a glass slide on which a 2D array of DNA fragments is immobilized; the spots, formed by variants of ink-jet printing (Chapter 3.11), are typically 50–100 μm in diameter and an array typically consists of 1000–10 000 spots. The sample to be analyzed consists of mRNA or cDNA fragments, labeled with a fluorescence marker; following hybridization of the sample fragments with the spots, the entire chip is imaged and the distribution of fluorescence peaks is determined, thus allowing conclusions to be drawn concerning the structure of the analyte protein or DNA.

A wide range of variations on this approach has been developed, including the photolithographic assembly of oligonucleotides on the microarray itself or hybridization that takes place in on-chip cavities using advances in microfluidics (Whitesides 2006) and lab-on-a-chip technology as discussed in Chapter 2.13. In addition to the analysis of DNA sequences, antibody or protein sequences can be determined, and highly parallel microarray characterization of cells and tissues that express certain DNA sequences is under development.

3.09.3.4 Sensors

Optical sensors form one of the mainstays of biophotonics. Determination of the presence of and the concentration of biologically relevant compounds using optical techniques also has a long history and miniaturization has allowed implementation of optical biosensors in applications not previously feasible. A more general discussion of microsystems-based sensing can be found in Chapters 2.11 and 2.12.

With the notable exception of gas sensing systems based on absorption spectroscopy as discussed in Section 3.09.3.2, which are frequently based on free space optics, most miniaturized optical sensor systems are based on guided wave optics; this technology is the subject of Chapter 3.05. Fiber- or waveguide-based optical fields can be used for excitation and detection of fluorescence, and evanescent wave-based configurations (recall Section 3.09.2.4), employing unclad waveguides or sections of stripped fiber, are employed for the measurement of refractive index changes. Attenuated total reflection (ATR) or surface plasmon resonance (SPR) concepts also employ an evanescent optical field, but they are generally macroscopic approaches with limited prospects for miniaturization using MEMS technologies.

Integrated optical or fiber-based guided wave systems can benefit greatly from interferometric measurement approaches. Michelson or Mach–Zehnder type interferometers can be miniaturized and fabricated in arrays, and the sensitive phase measurements possible with these can be used for high-resolution optical sensing of biological or chemical parameters. These systems allow on-chip referencing and highly integrated approaches provide the means for temperature compensation and exclusion of nonspecific changes in phase.

Transduction of optical biosensors is accomplished using a wide variety of methods; the simplest method is by the measurement of an unspecific change in refractive index, a measurement which is of limited value without sensor calibration. Concentration measurements of specific compounds are generally accomplished by selective binding of analytes to molecules immobilized on the waveguide core. The change in effective waveguide index due to adhesion of a surface layer can be measured with high sensitivity using an interferometric approach. Likewise, fluorescence intensity, either autofluorescence or that of dyes, or change in optical absorption or polarization can be used for optical biosensing. The details of microsystems-based optical biosensors are discussed in Section 3.09.5.

3.09.3.5 Optical Tweezers

Of increasing importance in macroscopic biophotonics systems is the use of light fields for manipulation of microscopic particles, including cells and organelles (Rohrbach *et al.* 2003). Using relatively high-power laser light sources, generally Nd:YAG emitting at 1064 nm or diode lasers with emission in the 780 nm range, tightly focused light fields can be used to capture, move, and analyze cells or their components; the effects considered in Section 3.09.2.5 can also be employed. Using advanced optics and data evaluation techniques, the elastic properties of cells can be measured directly.

Chiou *et al.* (2005) have shown that directly or holographically generated light field distributions can be used to guide, manipulate, and ultimately

sort particles such as cells, suggesting future directions for optical flow cytometry. Optical tweezers and related techniques are undoubtedly promising for a variety of biophotonics applications, but the prospects of benefit from microsystems technologies are limited.

3.09.3.6 Tissue Engineering

A final area in which biophotonics has become firmly established is in tissue engineering, a collective term implying slicing, drilling, dissecting, cauterizing, coagulating, or welding tissue using intense light fields. The relevant technologies, generally employing truly macroscopic laser systems and frequently requiring femtosecond laser pulses, have become standard in various surgical specialities, predominantly ophthalmology.

Related to radical surgical approaches, photodynamic therapy uses considerably lower optical powers for destruction of undesirable tissue, generally tumors. These selectively absorb the illumination, low-power lasers or high-power lamps, due to the presence of a sensitizer, which is optically activated. Activation yields a high concentration of elemental oxygen leading to destruction of the tumor.

As high optical powers and macroscopically sized delivery systems are required, tissue engineering also remains a facet of biophotonics just beginning to benefit from MEMS technology in the near term.

3.09.4 Microimaging

Optical imaging is one of the most significant areas in biophotonics: the use of light to create an image of a biological specimen ranging in size from a molecule to an entire animal. It has a long history and is exceptionally well established. Advances in microsystems have allowed extreme miniaturization of many of these optical methods and thereby permit imaging (particularly *in vivo*) in locations not previously accessible. Imaging is in direct contrast with sensing (discussed in Section 3.09.5), which is typically a point measurement; an image is usually 2D or 3D.

Microimaging is used in the development of tools for minimally invasive surgery and diagnostics (Haga and Esashi 2004), and it has benefited greatly from advances in microcameras (Chapter 3.08). Closely related, but outside the focus of this chapter, is the development of biomimetic systems, which use microsystems technologies to fabricate structures inspired by nature; an advanced example is an artificial compound eye (Jeong *et al.* 2006).

3.09.4.1 MEMS Components for Imaging

In many cases the incorporation of microsystems technologies into biophotonic imaging systems has occurred stepwise; individual miniaturized components frequently become essential parts of imaging concepts that still use classical (macroscopic) technologies. The most useful MEMS components in this regard have been microlenses, micromirrors, and optofluidics.

3.09.4.1.1 PDMS lenses

Making smaller microscopes allows their implementation in areas for which a classical apparatus is not suitable; using microlenses, particularly tunable microlenses, allows fabrication of novel miniaturized microscopes. Using poly(dimethyl siloxane) (PDMS), a microstructurable elastomer, a rubber microscope has been fabricated (Gambin *et al.* 2006). A solid immersion lens, with which numerical aperture (NA) > 1 is possible, was manufactured from PDMS and combined with spherical lenses, a light emitting diode (LED) light source, and a charge-coupled device (CCD) imager yielding a system that is only 10 cm long. This novel application of low-cost MEMS technology yielded a microscope with which fluorescent cellular imaging could be performed. Further integrating a microfluidic channel into the device has shown that a handheld flow cytometer is feasible.

Elastomer materials such as PDMS can also be structured as membranes, and they open opportunities for a new class of tunable micro-optical components suitable, for example, for incorporation into new generations of endoscopes (Werber and Zappe 2005). A 50-μm-thick membrane is suspended over a silicon micromachined fluidic cavity; filled with an optically transparent liquid with a suitably high refractive index, the distensible membrane forms a convex lens and controlled changes in pressure allow tuning of the radius and thus the focal length. An example of two distended lenses on a silicon substrate is shown in **Figure 7**.

Lenses fabricated using this technology, with typical diameters of 400 μm, are tunable in the range $0.4\,\text{mm} \leq f \leq \infty$. Concave lens structures can be made by applying negative pressure relative to the ambient pressure. Pressure-actuated tunable microlenses such as this are of particular value in endoscopic zoom optics, since classical optical

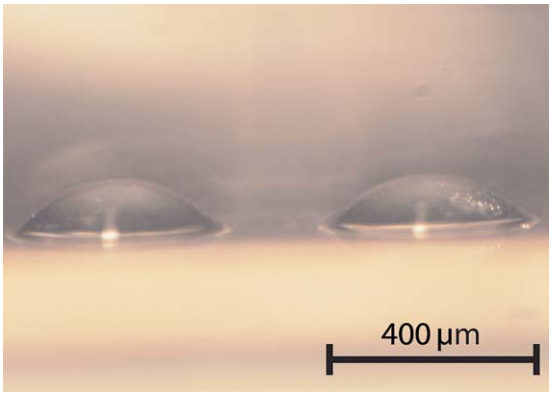

Figure 7 A pair of PDMS membrane lenses extending from a silicon surface; pressure variations in the liquid filled cavity below allow dynamic tuning of the focal length.

systems at the required size scales are impractical and pressure actuation implies that no high voltages are required at the distal end of the endoscope. Tunable microlenses are also of interest in OCT systems, allowing a more effective depth scan.

3.09.4.1.2 Micromirrors

Micromachined mirrors, such as the one shown in Figure 8, not only are well established in communications technology but are also finding an increasing number of application domains in biophotonics. As discussed in Chapter 3.01, OCT systems rely on 1D and 2D scanning mirrors to enable complete scanning of tissue sections. Micromirrors have also expanded the utility of endoscopes, allowing a larger field of view for a compact optical system. Advanced applications (Fu *et al.* 2006) include an invasive two-photon fluorescence microscope, which employs a compact imager based on a silicon micromirror capable of 6° angular motion with only 5 V required for electrostatic actuation. A gradient index (GRIN) lens was used for imaging and a photonic crystal fiber was used to separately guide excitation and fluorescence light to and from the imaging area.

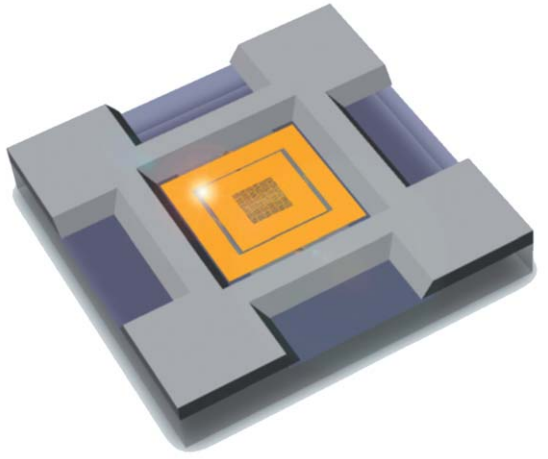

Figure 8 Sketch of a dual-axis silicon-based micromirror developed for endoscopic scanning; the size of the central mirror region is 500 µm × 500 µm. The mirror rotates about two perpendicular axes parallel to the mirror edges.

An alternative approach to two-photon microscopy features two-axis scanning using Si-based micromirrors with an area of 750 µm × 750 µm and 16° angular motion (Piyawattanametha *et al.* 2006). With an acquisition rate of 3.5 kHz, this and the previous example represent technologies useful for both endoscopy and portable imaging systems.

3.09.4.1.3 Optofluidic imaging

Ultracompact imaging can also be accomplished by using a completely different approach without a macroscopic analogue. Microfluidics can do more than transporting liquids or particles suspended therein; the field of optofluidics uses microscopic fluidic structures or flows to perform optical functions. Tunable liquid lenses (Krogmann *et al.* 2006) represent one such application; another application is the use of microfluidics for high-resolution imaging directly (Psaltis *et al.* 2006). Using a fluid system to transport a particle of interest, for example, a cell, over an arrangement of micromachined holes through which the sample is imaged, flood illumination leads to a sequence of partial images of the object, which can be reassembled after it flows through the system.

The micrometer-sized holes are arranged such that the entire sample is scanned as it moves past, and illumination in the visible wavelength range leads to image resolution better than 100 nm. The structure is very simple and compact, requires no classical optical components such as objectives or other lenses, and can conceivably be manufactured using replication such that low-cost, disposable microimagers for cellular analysis are feasible.

3.09.4.2 Adaptive Optics

Adaptive optical systems are well established in astronomical applications, in which they are used to compensate for atmospheric distortion of the incoming optical wavefronts from stars. The concept, illustrated schematically in Figure 9, relies on the measurement of wavefront distortion using a wavefront sensor,

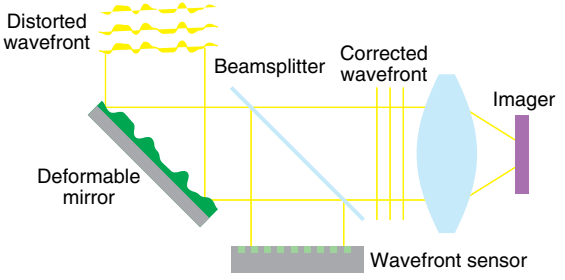

Figure 9 The principle behind adaptive optics: a distorted wavefront is incident on a deformable mirror, which compensates the wavefront distortion. Part of the signal is directed to a wavefront sensor, the output from which defines the mirror shape dynamically. The image is then of the corrected wavefront.

frequently a Shack–Hartmann sensor. Output from the sensor provides an input to a dynamically deformable mirror, whose reflective surface is modulated to compensate for the distortion. When placed in a feedback loop with the appropriate control electronics, the result is a corrected wavefront and thus a higher resolution image (Tyson 1997).

Macroscopic adaptive optical mirrors, typically with apertures ranging from 50 to 150 mm, driven by piezoactuators and with up to 4000 segments, are industrial products, but of a size and cost that makes them unsuitable for biophotonic applications. In contrast, MEMS-fabricated adaptive optical mirrors have recently become available (Doble *et al.* 2002), using electrostatically deformed silicon membranes (Vdovin *et al.* 1999) or highly resilient photostructurable polymer membranes (Friese *et al.* 2004) as mirror surfaces. These microfabricated mirrors, an example of which is shown in **Figure 10**, are not only considerably smaller than their macroscopic counterparts, but also require lower operating

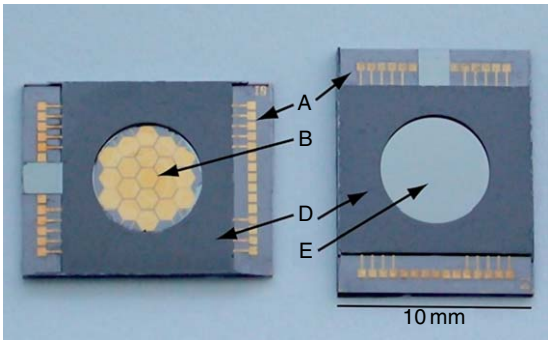

Figure 10 A polymer-based adaptive optical mirror with a diameter of 5 mm and 39 actuation electrodes. A, Power input; B, electrodes; D, silicon frame; E, reflecting membrane.

powers, switch faster, and are usually significantly less expensive.

As a result, microfabricated adaptive optical mirrors are increasingly being used for medical imaging, particularly in ophthalmology (Liang *et al.* 1997). Adaptive optical wavefront correction has recently been applied to laser scanning ophthalmology, confocal microscopes, OCT systems, and two-photon fluorescence microscopy. In ophthalmological examinations, in particular of the retina, the inhomogeneous optical structure of the lens, tear fluid, the vitreous humor, and the cornea make high-resolution imaging of the eye difficult. Adaptive optics has improved the imaging capabilities to the point where individual rods and cones can be discerned on the retina of a live eye (Roorda and Williams 1999).

One example of a typical MEMS-based adaptive optical system for ophthalmology has a 4.4 mm × 4.4 mm aperture and consists of 144 individually movable mirror segments (Zhang *et al.* 2006b). With 3.5 µm of stroke for each mirror, the wavefront can be corrected to 0.1 µm, which, in a confocal arrangement, led to an axial resolution better than 100 µm with laser diode illumination at 655 or 840 nm. When combined with a method for retinal tracking, which compensates for the movement of the eye using a low-power, long-wavelength tracking laser, an image resolution of 10–15 µm has been obtained (Hammer *et al.* 2006).

MEMS-based adaptive optical mirrors have also been used to improve the resolution of standard microscopy techniques (Potsaid *et al.* 2005); when added to a scanning microscope, adaptive optics resulted in higher resolution with an increased field of view when compared to a standard configuration.

3.09.4.3 Confocal Microscopy

As briefly described in Section 3.09.3.1, a confocal microscope uses a pinhole aperture to limit the depth of the field of light reflected and scattered from the tissue and thus improves signal contrast. Most confocal microscopes use a laser beam for illumination and this is scanned over the surface to be imaged.

A microsystems-based implementation of a confocal microscope consisting of a micromachined scanning head fabricated from silicon and fused silica has been demonstrated in Dickensheets and Kino (1998). Input and output of light is through optical fibers, which are passively aligned to a scanning mirror structure using physical alignment features. The light is directed through a transmission phase

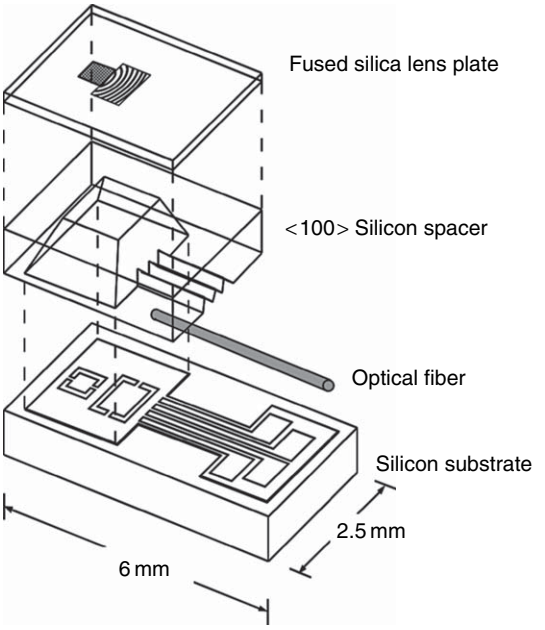

Figure 11 Diagram showing the structure of the silicon-based microfabricated confocal microscope. (Source: Dickensheets D L, Kino G S 1998 Silicon-micromachined scanning confocal optical microscope. *IEEE/ASME J. Microelectromech. Syst.* **7(1)**, 38–47; Diagram courtesy: David Dickensheets, Montana State University.)

grating etched into silica, which focuses the beam off-axis onto the sample, by using a reflecting silicon-based cavity. The reflected light is directed through the same system back to an external photodetector through an external fiber coupler.

As shown in **Figure 11**, the entire confocal sensor head has external dimensions of 6.5 mm × 2.5 mm × 1.2 mm; all light sources, detectors, couplers, and electronics are external such that the fiber-connected measurement unit can be used endoscopically. Using illumination at 633 nm, submicrometer resolution was achieved at a 20-Hz frame rate over a 90 µm × 90 µm field of view. Similar approaches, using a forward-looking optical configuration with a diameter of 3.4 mm and employing a scanning MEMS mirror and standard off-the-shelf lenses, have also been demonstrated in Furihata (2001).

3.09.4.4 Optical Coherence Tomography

Optical coherence tomography is one of the most advanced and useful forms of structural bioimaging, and microsystems-based miniaturized OCT imagers are the subject of Chapter 3.01. OCT allows the generation of 3D images up to several millimeters below

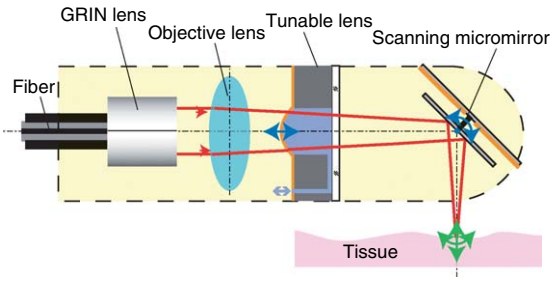

Figure 12 Schematic of an endoscopic OCT system; a tunable lens is used to dynamically change the focus with varying spacing of the tissue sample and the two-axis micromirror is employed to scan across the sample surface.

the surface of the tissue and has therefore become an essential tool for nondestructive diagnostics. Endoscopic OCT systems, which benefit from MEMS technologies such as scanning mirrors (Xie *et al.* 2003), ultra-miniaturized motor-rotated scanners (Tran *et al.* 2004), or tunable lenses (Divetia *et al.* 2005), now allow this type of imaging to be accomplished *in vivo* with a minimum patient discomfort; a schematic view of such a system is shown in **Figure 12**.

3.09.4.5 Imaging Microrobots

An increasingly important task in biophotonic imaging is to provide visual feedback prior to and during surgical procedures, and to combine diagnostics with high-resolution real-time imaging; microsystems technology is providing the means to accomplish extensive intracorporal diagnostics with highly functional systems with increasing autonomy (Dario *et al.* 2000a, b, Haga and Esashi 2004).

Imaging microrobots represent a semiautonomous system; it is used inside the body but attached to the outside world through wires or fibers. For colonoscopy, for example, a pneumatically actuated microrobot has been developed for imaging inside the colon with minimum patient discomfort (Dario *et al.* 1999). Illumination is through a fiber optic bundle and imaging is accomplished using a CCD-based microcamera of the type described in Chapter 3.08. Whereas this system is still controlled externally, current work is focusing on the use of MEMS technologies for autonomous actuation (Menciassi *et al.* 2005), power scavenging, and improved diagnostics tools, which permits the development of more highly functional microrobots of this type. All aspects of microsystems engineering are likely to play a role in these systems.

3.09.4.6 Capsule Endoscopy

It has long been a dream of many surgeons, and not a few film directors, to have a truly autonomous, ultraminiaturized system for diagnostics and therapeutics inside the body; of primary interest is the gastrointestinal tract. Moving from fiction to science, microsystems technologies have provided the methods to realize wireless systems, which transmit diagnostics data as they move through a patient. The idea is not new; first trials were performed in the 1950s (Zworkin 1957) and electronic capsules, which move through the gastrointestinal tract and monitor parameters such as temperature, pH, and oxygen concentration, have been clinically tested (Johannessen *et al.* 2004).

Optical imaging in the gastrointestinal tract using a wireless video capsule has been demonstrated in Iddan *et al.* (2000) and Meron (2000); the 11 mm × 26-mm capsule has no external wires or fibers, is swallowed by the patient, and moves by peristalsis through the bowel. The short focal length of the optics implies that no inflation of the intestine is necessary. The capsule is fully self-contained, and includes a complementary metal oxide semiconductor (CMOS) imager, application-specific integrated circuits (ASICs) for data processing, and white LEDs for illumination; data is transferred to an external receiver via UHF telemetry (Glukhovsky 2004). The capsule can operate for up to 6 h, and it images the regions of the tract that it faces; external manipulation of position is not yet possible. FDA approval for the video capsule, marketed by the Israeli company Given Imaging, was granted in 2001 and numerous other laboratories, including Olympus and Norika in Japan, are developing prototypes of a similar nature, incorporating increasing amounts of microsystems technology into the imager.

3.09.5 Optical Biosensors

Diagnostics of biological samples are most often performed with biosensors, whereby optical sensing techniques offer a wide range of measurement capabilities unmatched by electrical or other means. Hence, biosensors have been developed to measure a wide variety of analytes, often in array form to permit highly parallel or multimodal analysis (Ligler and Rowe-Taitt 2002, Vo-Dinh *et al.* 2001). Much of the work in this area has benefited from and promoted developments in micro total analysis (μTAS) systems (Janasek *et al.* 2006), cell chips (El-Ali *et al.* 2006), and the long history of fiber optical sensors (Mehrvar *et al.* 2000) as well as recent developments in semiconductor processing technology (Zappe 1999).

3.09.5.1 Integrated Optical Approaches

As mentioned in Section 3.09.3.4, a large fraction of optical biosensors use an integrated optical approach, confining the optical field to waveguides (see, e.g., Zappe 1995 and Chapter 3.05). Most implementations use a section of waveguide with the core exposed (analogous to a section of stripped optical fiber) for which a change in the external refractive index, Δn_{ext}, or the adhesion to or change in thickness of a surface layer, Δt, gives rise to a change in the effective index of the waveguide, ΔN (the effective waveguide index, N, should not be confused with the refractive index of a material, n). The task of most optical biosensor systems is to sensitively measure this change.

3.09.5.1.1 Mach–Zehnder interferometer

One of the most sensitive methods to measure a change in waveguide effective index is by means of an interferometer. ΔN gives rise to a phase shift $\Delta\phi$ of the field in the waveguide and this latter parameter is best determined interferometrically. Integrated optics technology allows strong miniaturization of interferometers, so that compact, highly functional sensor microsystems can be produced using this approach.

The Mach–Zehnder interferometer, illustrated in **Figure 13**, translates the phase shift in one arm into an intensity change. The sensor region is a section of waveguide of length L with the core exposed; a change in the effective index of the waveguide ΔN in this region results in $\Delta\phi$ with respect to the reference arm (which has a phase shifter to allow adjustment of the optimal operating point), given by

$$\Delta\phi = \frac{2\pi}{\lambda} L \Delta N \qquad [8]$$

for the operating wavelength λ. The Mach–Zehnder interferometer translates this phase shift into an intensity change in the optical output intensity, I, by the well-known interferometer relationship

$$I = 2I_0 + 2\sqrt{I_0}\cos\Delta\phi \qquad [9]$$

where I_0 represents the intensity of the optical input.

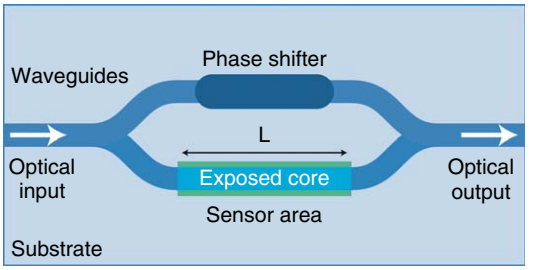

Figure 13 A waveguide-based Mach–Zehnder interferometer. In the sensor region, the waveguide core is exposed and variations in the external environment give rise to a phase shift with respect to the other arm, in which a phase shifter fixes the operating point.

A number of factors must be taken into account to optimize the performance of this optical sensor. A long sensor region of length L improves system sensitivity, usually given by a factor such as resolvable Δn per sensor length. The waveguide must be designed to have a large evanescent field strength outside the waveguide core such that the effective index N changes strongly with variations in external parameters; the resulting waveguide sensitivity is often given as

$$S = \frac{\partial N}{\partial n_{\text{ext}}} \quad \text{or} \quad S = \frac{\partial N}{\partial t} \qquad [10]$$

The phase shifter in the reference arm should be used to tune the operating point to the condition of highest sensitivity, which occurs when the reference and sensor arms have a phase offset of $\pi/4$. For most waveguide materials, changes in temperature will give rise to a change in N; the advantage of a compact integrated optical approach is that the temperature is generally uniform over the substrate and the two arms are typically separated by a few tens or hundreds of micrometers; thus the system is typically self-temperature compensating, an important advantage of microsystems approach.

Numerous implementations of this type of integrated optical interferometer have been fabricated. Using III–V technology (Chapter 1.02), a monolithically integrated system including a laser, a electro-optical phase shifter, and a photodetector has been fabricated (Maisenhölder *et al.* 1996, 1997a, b). The 5-mm-long chip had a sensor length of $L = 2$ mm and was combined with an external fluidic system to sensitively measure both external refractive index changes and selective adhesion of proteins onto the waveguide surface. A sensitivity of $\Delta n/L = 10^{-5}\text{mm}^{-1}$ was determined for the former and a concentration of $3\,\text{pg}\,\text{mm}^{-2}$ of surface analyte could be resolved.

Using silicon technology with an external light source, integrated Mach–Zehnder interferometer sensors with integrated microfluidics and CMOS-based evaluation electronics have been fabricated (Luff *et al.* 1998) and variations that use three mutually phase-shifted output waveguides (Sepúlveda *et al.* 2006) for enhanced phase shift resolution have also been shown. Significant recent progress in polymer-based waveguides suggests that hybrid microsystems that use separate substrates for light emission and detection, fluid handling, and sensing are feasible.

3.09.5.1.2 Young interferometer

The Mach–Zehnder interferometer translates a sensor phase shift into a single intensity change at the optical output. An alternative is to use a Young interferometer, as shown in **Figure 14**, which expands the output to a 1D line of interference maxima and minima, which can be imaged by, for example, an external CCD. As the sensor-based phase in one arm of the integrated optical Y-coupler shifts, the entire interference pattern shifts allowing a higher resolution of induced phase change. In addition, the ambiguity that results from the periodic nature of interference may be resolved such that a wider range of $\Delta\phi$ values can be measured.

Using dielectric-based (SiO_2 or Si_3N_4) waveguides on a silicon substrate, the Young interferometer has been demonstrated to be suitable for biosensing applications (Brandenburg *et al.* 2000). With a high sensitivity for external refractive index change ($\Delta n = 10^{-7}$) and for adhesion of surface analytes ($750\,\text{fg}\,\text{mm}^{-2}$) for a 1-mm-long sensor region, performance advantages over the Mach–Zehnder interferometer were noted. Miniaturization of this approach, perhaps using 1D photodetector arrays, is conceivable if not yet demonstrated.

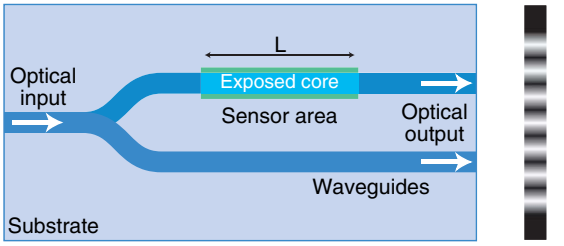

Figure 14 A waveguide-based Young interferometer in which the sensor region is found in one arm of a Y-coupler. The interference resulting from a phase shift in one arm results in a 1D interference pattern, which is imaged off-chip.

3.09.5.1.3 Directional couplers

Waveguide-based biosensor concepts need not be exclusively interferometric. An alternative concept, shown in **Figure 15**, uses an array of couplers to translate refractive index change into an intensity shift (Luff *et al.* 1996). In this structure, the optical input from the left is split into two waveguides using a Y-coupler, the lower of the two acting as a reference signal, unaffected by external index changes. The upper arm of the Y-coupler is fed into a directional coupler, formed by two waveguides in close proximity, in which part of the light is transferred to the uppermost waveguide (see e.g., Zappe 1995, Chap. 11.2.2).

The amount of light transferred into the output waveguide is a function of the spacing between the two waveguides, s, and the length of the overlap region, L, (both fixed) as well as the effective waveguide index; the latter parameter can be altered using an exposed waveguide core in the sensor region. Given an input power into a directional coupler I_{in} (in our example, the power delivered by the upper arm of the Y-coupler), the output power is given by the following equation:

$$I_{out} = I_{in} \frac{\sqrt{\sin^2(\kappa L)^2 + \left(\frac{\Delta\beta L}{2}\right)^2}}{1 + \left(\frac{\Delta\beta}{2\kappa}\right)^2} \quad [11]$$

in which

$$\Delta\beta = \frac{2\pi}{\lambda}\Delta N \quad [12]$$

where ΔN is the waveguide effective index and κ is the coupling coefficient between the two waveguides, determined from the waveguide dimensions and spacing. Thus, as in the interferometer structures, if external refractive index or surface layer changes occur, the resultant shift in ΔN leads to a change in the output intensity. The reference arm remains unchanged.

This type of coupler-based biosensor has been made using Ag^+ ion exchange waveguides (Luff *et al.* 1996). At an excitation wavelength of λ=633 nm, a waveguide spacing in the coupler $s = 7.2\,\mu m$ and an overlap length $L = 1$ mm, a refractive index resolution of $\Delta n = 5 \times 10^{-10}$ was achieved. Since an intensity comparison is required for a precise measurement, it is unlikely that this approach can reach the high resolutions achievable by interferometric techniques.

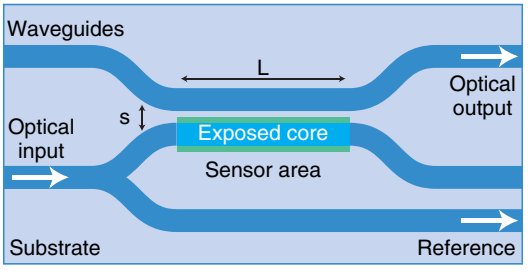

Figure 15 A combination of directional and Y-couplers used for biosensing. A change in the effective waveguide index in the sensor region leads to a change in coupling efficiency, and thus a measurable intensity shift at the optical output.

3.09.5.1.4 Waveguides as sensors

A surface-modified polymer waveguide biosensor using the waveguide itself as a sensor has been fabricated (Chang-Yen and Gale 2005, 2006). The waveguides were made from SU-8 photoresist and NOA61 optical adhesive. Both waveguides were surface modified with an oxygen-sensitive dye and the enzyme glucose oxidase, and were surrounded by a PDMS fluidic channel designed for restricting the diffusion process of the analyte into the enzyme in a single direction. The waveguide was coupled by optical fibers to an excitation LED operating at a wavelength of 450 nm and to a spectrometer for fluorescence detection. Except for the glass substrate, the biosensor itself consisted completely of soft and organic materials.

3.09.5.2 Surface Plasmon Resonance

Bulk optical systems do not use fibers or waveguides to guide light signals; instead, light is transmitted through free space and classical optical components (lenses, prisms, beam splitters, etc.) form the optical field.

Using this type of optical configuration, the SPR technique has become an established approach for high-resolution optical biosensing (Homola 2006). SPR relies on the excitation of surface plasmons (charge density oscillations) in thin metal films; this excitation occurs when the light field impinges on the surface at a precisely defined angle, which is in turn a function of the surface conditions. Thus adhesion of a biologically relevant substance onto the metal surface causes a shift in the excitation condition, which is then translated into a sensor signal.

A typical SPR measurement uses the Kretschmann configuration shown in **Figure 16**. Light is directed through a glass prism onto the thin metal layer, typically 40–50 nm of Au or Ag. At a particular incident

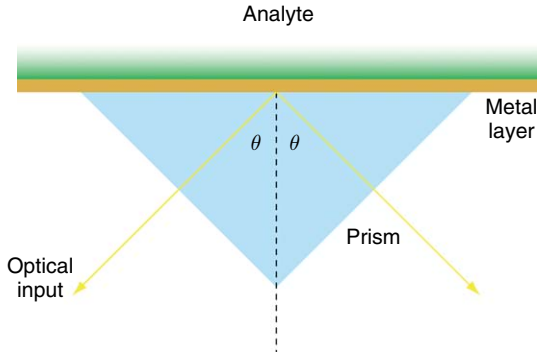

Figure 16 A surface plasmon resonance (SPR) measurement using the Kretschmann configuration. Surface plasmons are excited in the thin metal layer by an optical field incident at a precisely defined angle through the prism; this plasmon resonance leads to a dip in reflected intensity as a function of angle and is a sensitive function of surface conditions on the metal.

angle, known as the ATR angle, when the wavevectors of the excitation field and the plasmons overlap, resonance is achieved and the resultant transfer of energy to the plasmons results in a decrease in the reflection intensity. This angle is a sensitive function of the surface conditions on the metal such that external refractive index changes of a measurand or selective adhesion of an analyte results in a change in resonance angle. The SPR measurement works in TIR such that only an evanescent field exists in the metal and the analyte, similar to the waveguide-based approaches discussed in Section 3.09.5.1; the ATR angle is always larger than the critical angle for TIR (Section 3.09.2.4).

The SPR measurement is a spot measurement, which can be done in real time. Due to its high sensitivity and relatively simple optical setup, the approach has become a standard for high-resolution laboratory biosensing. Using variations in which optical heterodyning of two reflections was used (Kuo *et al.* 2003) or the excitation of two plasmon types was employed (Slavík *et al.* 2006), sensitivities to surface concentrations in the range of 5–250 ng l^{-1}, equivalent to 200 pM of analyte, were observed. A differential phase measurement (possible because SPR employs only the *p*-polarization) accomplished using an external Mach–Zehnder interferometer led to refractive index resolutions on the order of $\Delta n = 5 \times 10^{-10}$ (Wu *et al.* 2004).

Despite the high resolution and flexibility of the SPR approach, few attempts have been made to miniaturize it using microsystems technologies. MEMS-based micromirrors have been employed in highly parallel SPR systems, in which a single light source can be scanned over an array of sensor regions; microfluidics have been integrated onto the analyte side, allowing controlled flow in a miniaturized system. The need for coupling vertically onto a metal film with high angular accuracy and the need to vary this angle imply that a 3D structure is required so that complete microsystem integration requires further advances in micromachining capabilities.

3.09.5.3 Fabry–Perot Interferometer

Interferometric biophotonic measurements can be made using bulk free space optics in combination with MEMS-based structures, enabling increased integration. A Fabry–Perot interferometer, well-established in spectroscopy and the basis for the resonant cavity of most types of lasers, can be employed to sensitively measure changes in refractive index. For the structure shown in **Figure 17**, the ratio of output to input optical intensity is given by the well-known relation

$$\frac{I_{\text{out}}}{I_{\text{in}}} = \frac{1}{1 + \left(\frac{2F}{\pi}\right)^2 \sin^2\left(\frac{\phi}{2}\right)} \qquad [13]$$

for the case in which absorption in the mirrors is ignored. In eqn [13], for mirror reflectance R, the finesse F is given by

$$F = \frac{\pi\sqrt{R}}{1-R} \qquad [14]$$

the phase ϕ can be written as

$$\phi = \frac{4\pi nt}{\lambda_0} \qquad [15]$$

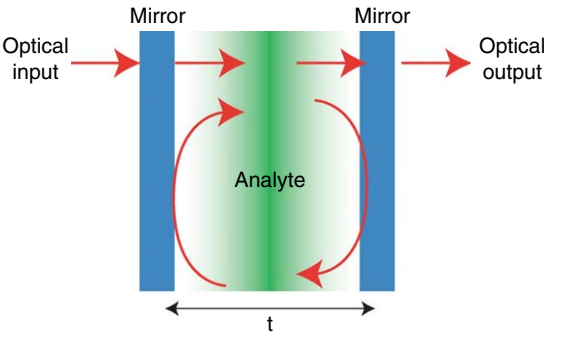

Figure 17 A Fabry–Perot resonant cavity consisting of two semitransparent mirrors with a spacing *t*. Changes in spacing or in analyte refractive index lead to a shift in the resonance wavelength.

where n is the refractive index in the cavity, λ_0 the free space (vacuum) wavelength, and t the cavity thickness.

From the above relationships, we see that the optical thickness (nt) can easily be varied to shift the resonance and thus the output intensity of the Fabry–Perot cavity; by allowing a change of n due to the presence of or variation in an analyte in the cavity, or possibly by changing the thickness t due to an external measurand, the output intensity I_{out} varies, thus providing a sensor signal.

The Fabry–Perot cavity can be fabricated using silicon micromachining technologies (Han 1999); the mirrors are formed using dielectric layers so that compact, intrinsically aligned high-finesse cavities can be manufactured in 2D arrays. The internal surfaces of the mirrors have been coated with chemically sensitive polymers, whose refractive index varies selectively as a function of the concentration of certain absorbed species. Interrogation can be done by using bulk optical, fiber-based or, in the future, micro-optical means allowing parallelization and miniaturization.

A deformable Fabry–Perot cavity has also been employed for blood pressure sensing (Haga and Esashi 2004, Katsumata *et al.* 2000, Tohyama *et al.* 1998). Using a silicon-based micromachined structure and a metal-coated SiO_2 membrane as a movable mirror, the resonant cavity with a diameter of 125 µm could be inserted into a blood vessel. Ambient pressure variations were sensed using light from an optical fiber, whereby pressure-induced movement of the diaphragm modulated the light reflected from the Fabry–Perot cavity; performance is as good or better than the established technologies (Reesink *et al.* 2002). Similar concepts using bendable micromachined cantilevers and white light interferometry or spectral modulation techniques for interrogation (Wolthuis *et al.* 1991) have also been employed for *in vivo* blood pressure sensing.

3.09.5.4 Promising Technologies

Numerous biosensing approaches have been developed, which show considerable promise for miniaturization and integration using the technologies of microsystems engineering; a few of these are discussed here. Of considerable interest for many is the availability of ultracompact, high-performance light sources, usually semiconductor-based diode lasers and LEDs (Zappe 2004), which have begun to replace many macroscopic laser systems. Optoelectronics technologies play a significant role in this area.

3.09.5.4.1 Laser diode technologies

For example, the integration of vertical cavity lasers (VCLs) with glass- or plastic-based microfluidics is reasonably well established; the 2D array capabilities coupled with the low power consumption of VCLs have made these attractive light sources for optical excitation and interrogation. Integration has been advanced further by including PIN photodiodes, microlenses, and filters, ultimately combining glass and GaAs substrates (Thrush *et al.* 2005); by employing an excitation wavelength of λ=773 nm, a detection limit of 40 nM (using dyes as a sample system) was reached using this complete optical biosensor microsystem. Silicon-based integrated microsystems, combining avalanche diodes as light emitters, PN photodiodes, and fiber mounting guides coupled with a microfluidic module, have been shown to have detection limits down to 20 fM using protein-based test systems (Misiakos *et al.* 2004); the concept uses ATR of waveguide modes in a silicon nitride-based fiber/waveguide.

A hybrid micro-optical sensor using the Doppler effect to continuously and noninvasively measure blood flow velocity *in vivo* has been developed using a distributed feedback (DFB) laser diode mounted along with a photodetector on a silicon-based substrate; as seen in **Figure 18**, the substrate incorporates a waveguide circuit and provides mechanical, thermal, and electric contact (Higurashi *et al.* 2002). The convex waveguide edge allowed horizontal focusing without the need for an external

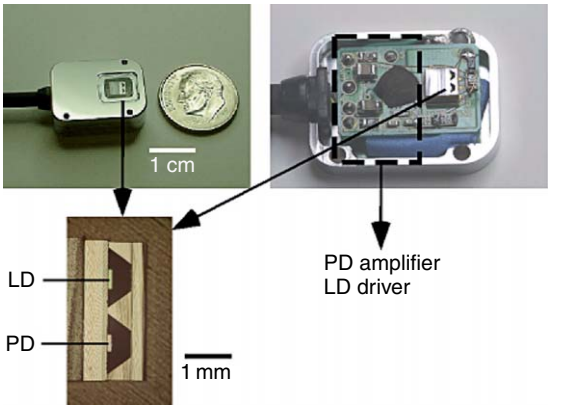

Figure 18 A micro-optical blood-flow sensor using the Doppler effect to sense flow velocity noninvasively. (Photo courtesy: Eiji Higurashi, University of Tokyo.)

lens, and the completely assembled optical sensor, with dimensions of 1.5 mm × 2 mm × 3 mm, was packaged together with a laser diode driver and photodiode amplifier. The performance of the sensor was sufficient to measure heartbeat and to determine the presence of occlusions, which lead to reduced blood flow; measurements could be accomplished by manually holding the sensor onto the skin.

3.09.5.4.2 Micro-optical technologies

The availability and manufacturability of microlenses (Chapter 3.02) together with microfluidic systems have led to numerous compact lab-on-a-chip concepts (Chapter 2.13) in which the optics is tightly integrated with the sensor system. In one example, PDMS-based microfluidics is combined with planar lens structures on a single, disposable substrate (Seo and Lee 2004); the optical excitation, an LED emitting at 466 nm, and the detection, a CCD camera or spectrometer, are part of a separate entity, which is passively aligned to the fluidic/optic chip. As a result, medically relevant fluorescence measurements can be made in which the orthogonal light paths of excitation and detection result in low cross talk and high signal-to-noise ratio. The concept allows fabrication of compound planar lenses, which improve measured fluorescence intensity markedly, in part due to reduced spherical aberration.

Microlenses have also been combined with microfluidic channels on a single chemical chip (Roulet *et al.* 2001); using cylindrical microlenses, separate light paths for excitation and fluorescence were generated, allowing, again using a dye test system, a resolution of 20 nM. The concept employed can be stacked to yield a highly parallel implementation capable of detecting a spectrum of compounds. Resonant microcavities (e.g., silica glass beads with a diameter of 300 μm) have been shown to have a resonance wavelength, which is a sensitive function of protein adhesion on the surface (Vollmer *et al.* 2002); these cavities have very high Q ($>10^6$), and using fiber input/output at $\lambda = 1340$ nm, molecular weights down to 50 g mol^{-1} can be detected, a limit below that of common SPR sensors.

Micro-optical sensing and interrogation concepts have been developed for continuous blood glucose monitoring, one of the most important routine medical diagnostic procedures. Whereas numerous transdermal measurement schemes, which use transmission of IR light through a section of skin, have been demonstrated, accuracy is insufficient to allow widespread application. An alternative is the measurement of glucose content in tear fluid, which has a concentration of about 10% of that in blood with a time lag of about 30 min. Using a soft contact lens doped with a boronic acid-based fluorescent probe, which binds glucose and as a result exhibits a shift in fluorescence intensity or wavelength, the user can monitor his or her blood glucose using a handheld micro-optical interrogation system (Badugu *et al.* 2004, Geddes and Lakowicz 2004). Excitation employs a white LED and the system including filters and detectors forms a hybridly assembled optical microsystem with which a sensitivity to glucose in the range of 50–500 μM is achieved. In the search for efficient, cheap, and adjustable light sources for fluorescence excitation in the blue and UV spectral ranges (where many proteins show intrinsic fluorescence such that fluorescence dyes are not required for their detection), microscopic discharge sources with a metal anode and a cathode cavity filled with an aqueous solution have been reported (Mitra *et al.* 2006).

Finally, a number of optical microdevices under development can provide technologies of importance for future biophotonic sensor systems. Of particular relevance may be atomic force microscope (AFM)-type cantilevers with optical readout, incorporating VCLs, photodiodes, electronics, and microfluidics in a compact system (Lechuga *et al.* 2006); the cantilevers themselves can be employed as waveguides and the efficiency of input or output coupling is a function of mass adhering to the surface. In addition, it is expected that further miniaturization, performance improvement, and integration of microspectrometers (Adams *et al.* 2003, Wolfenbuttel 2005) can provide a further micro-optical component integratable into compact biosensing systems.

3.09.5.4.3 Swelling polymers

Recently, swelling of polymer optical elements upon interaction of the polymer with organic compounds has been recognized as an effect, which allows the fabrication of tunable micro-optical components, and can be used as an optical sensing principle. Optical elements in which this effect was observed comprise Bragg mirrors and filters, and microlenses. It has been shown that the transmittance maximum of a Bragg mirror fabricated from cross-linked poly(methyl methacrylate)/poly(styrene) multilayers is shifted by 600 nm in a nitrogen atmosphere saturated with organic solvents (Mönch *et al.* 2006b). It was demonstrated using Bragg mirrors that polymer swelling with solvents is a robust and sensitive tuning principle for

such multilayer Bragg structures that can even be extended to 3D Bragg structures (Mönch *et al.* 2006a).

Microlenses have been fabricated from poly(*N*-isopropyl acrylamide) hydrogels and their tunability with pH and temperature of the surrounding aqueous solution has been demonstrated (Kim *et al.* 2004). Hydrogel particles have been functionalized with biotin molecules, and it was shown that microlenses fabricated from biotin-functionalized hydrogel respond specifically and reversibly to the target protein (Kim *et al.* 2005). This effect can be used for optical protein assays. Conversely, a tunable microlens system based on hydrogel response to various stimuli has been shown to be useful as a sensor for pH and temperature; sensitivity to light, electric field, or antigens was also shown (Dong *et al.* 2006).

3.09.6 Flow Cytometry

In this section, the focus is on microsystems that combine microfluidic elements such as microchannels with photonics technology and serve for detection and manipulation of biochemical or biological species. Since virtually all biological species are kept in liquid solution, MEMS technology-based optical manipulation strategies for liquids is also considered. Although flow cytometry in a narrow sense means measurement of cells in flowing liquids, here a wider view is adopted and also includes MEMS for optical detection of molecules in liquids in microfluidic channels.

3.09.6.1 Principles

Flow cytometry in its original sense means counting of cells or measuring their size while they flow past a detection point in a fluidic channel individually. For detection of the cells, a number of optical methods familiar from the field of biosensors can be applied, the most frequently used being fluorescence labeling and detection. In a wider sense, flow cytometry is a tool not only for measurement of cells in a liquid flow, but also for biochemical species such as molecular aggregates or colloidal particles. Colloidal particles tailored in their surface chemistry can be used for biochemical analysis at the surface of the particles. The measurement of cell size for subsequent mechanical, electrical, or optical sorting is indispensable for collecting cells with specific features.

3.09.6.2 Particle and Biochemical Detection

Flow cytometry microsystems require a microfluidic network and optical detection methods integrated on a chip. After briefly considering the materials required for the microfluidic part, different types of cytometry systems are discussed; these systems comprise fully integrated systems, systems fabricated in a hybrid approach, and microfluidic systems with external optical detection.

3.09.6.2.1 Materials

Many microfluidic channels and fluidic networks in optical microsystems have been fabricated from polymeric materials including not only those that can be processed by injection molding and hot embossing, including poly(methylmethacrylate), COC, and poly(carbonate), but also more specialized materials such as PDMS and SU-8 photoresist. Commercially available PDMS kits consist of liquid precursors (a base material and a curing agent), which are mixed and thermally cross-linked at moderately elevated temperature (≈60–100°C) to result in a nontoxic, optically transparent, and elastomeric material (Young's modulus ≈1 MPa).

PDMS is capable of being replicated using microstructures with nanometer precision and is frequently used as a mold material for different replication techniques. In an oxygen plasma, its surface is easily activated such that it adheres well to silicon dioxide surfaces. SU-8 photoresist is known for its exceptionally good adhesion to a variety of surfaces, its outstanding thermal and mechanical properties, and its capability of being processed into thick layers and structures (100–1000 μm) by conventional spin coating and photolithography. Both PDMS and SU-8 are compatible with silicon process technology.

3.09.6.2.2 The biodisk

One particular polymer-based low-cost microfluidic system for biological applications, such as colorimetric assays, is the so-called biodisk. The biodisk is a polymer (e.g., a cyclo-olefin copolymer) disc of the dimensions of a conventional compact disc with integrated microfluidic structures, including channels, reservoirs, and reaction chambers, depending on the particular application. Fluids in the microfluidic network are driven by capillary forces and, upon rotation of the disc, by the centrifugal and the Coriolis forces, leading to flow, mixing, and separation of the liquids, depending on the microfluidic structure and the

rotation speed and angular acceleration. After dispensing the liquids into the reservoirs of the biodisk, a rotation routine (including several steps of acceleration, shaking, and constant rotation) is run and the result is optically read out in a macroscopic device; the biodisk player may ultimately take the form shown in **Figure 19**.

Since it is fabricated from optical polymers, the biodisk allows an easy integration of optical structures by hot embossing or injection molding. The integration of two microprisms together with a detection channel into the biodisk, as shown in **Figure 20**, was recently demonstrated (Grumann *et al.* 2006, Steigert *et al.* 2005) using the example of a colorimetric glucose assay on whole blood. In these experiments, a light beam normally incident on the biodisk was totally reflected at the first 90° prism, propagated in the 10-mm detection path (within the plane of the biochip) containing the liquid under investigation, and was emitted out of the biodisk at the second prism. Compared to a beam directly transmitted through the biodisk, the interaction length was increased by a factor of 10 by this setup.

Figure 19 A biodisk installed in what a biodisk player might look like, in which the results of the microfluidic processes may be measured. The disk is of the size of a standard CD. (Photo courtesy: Jens Ducrée, University of Freiburg.)

3.09.6.2.3 *Flow cytometry systems*

Flow cytometry systems use integrated fluidics and optics to sort cells on a chip. As shown in **Figure 21**, the cells flow past an illumination and a detection system where the measured fluorescence is generally used as a criterion to sort a given cell into one of the several output fluidic channels.

A sandwiched multichip system consisting of microfluidic mixer chip on a silicon-based detector chip has been fabricated for quantitative measurement of the concentration of total protein in urine by spectrophotometry (Minas *et al.* 2006, Ribeiro *et al.* 2005). The microfluidic mixer consists of two fluid inlets, which are combined into a meandered mixing line, and a detection chamber followed by the outlet. The fluidic channels were 500 µm wide, and were defined by standard photolithography in a 600-µm-thick SU-8 layer on a glass substrate. A second glass substrate with drilled holes covered the fluidic channels. The bottom chip contained photodiodes and readout circuitry fabricated by a double-metal, single polysilicon, 1.6-µm *n*-well CMOS process. An optical Bragg filter consisting of nine layers (SiO_2 and TiO_2) is postprocessed onto the photodiode. The Bragg filter had a transmittance maximum at a wavelength

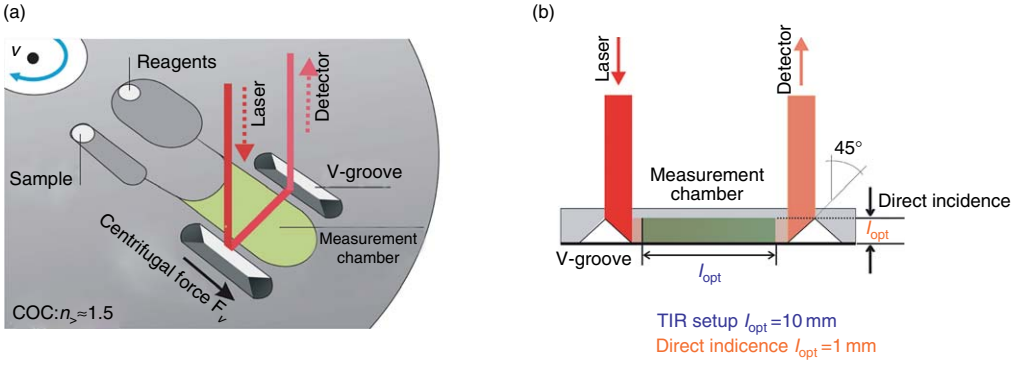

Figure 20 A biodisk with two integrated microprisms and an optical detection path length of 10 mm. (Source: Steigert J, Grumann M, Brenner T, Mittenbühler K, Nann T, Rühe J, Moser I, Haeberle S, Riegger L, Riegler J, Zengerle R, Ducrée J 2005 Integrated sample preparation, reaction, and detection on all high-frequency centrifugal microfluidic platform. *J. Assoc. Lab. Automat.* **10(5)**, 331–41.)

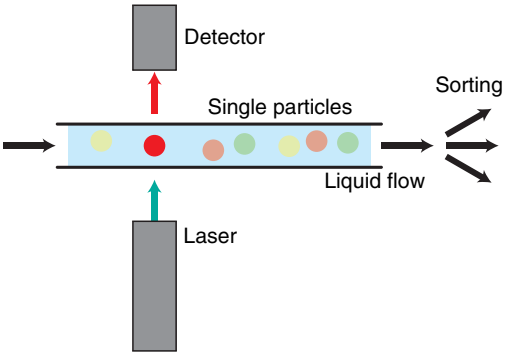

Figure 21 Flow cytometry: an illumination and a detection system use fluorescence of the cells, which flow past to sort these into one of several output fluidic channels.

of 600 nm and a passband FWHM of 10 nm. The fluidic chip is placed on top of the optoelectric chip, and a commercial passband optical filter is used for blocking IR and UV components of the excitation light spectrum. Excitation light was provided by an external tungsten halogen lamp and a monochromator.

It has also been shown that infrared particle image velocimetry may serve as a tool for measuring flow profiles in silicon-based MEMS without optical access through glass windows (Liu *et al.* 2005). This was demonstrated by Liu *et al.* (2005) by pumping a particle suspension thorough a fused silica capillary tube with a diameter of 255 µm; the optical absorption of a silicon microdevice was simulated in this work by placing a silicon wafer with a thickness of 500 µm in the optical path between the laser and the capillary tube. By that setup, the authors demonstrated that particle velocimetry in silicon-based microsystems is possible using infrared light.

A flow cytometry microsystem using mainly silicon technology was fabricated using a fluidic network in a deep-etched silicon wafer sealed at the top and the bottom by glass wafers (Baechi *et al.* 2002). The system was designed for manipulation of particles with a size ranging from a few hundred nanometers to a few microns (including cells and bacteria) and included photodiodes fabricated by ion implantation into the silicon and valves consisting of a thermopneumatically actuated silicone membrane with a thickness of 3 µm. The size of the valves was 300 µm × 300 µm and could be actuated at the rate of 10 Hz. In the experimental demonstrations, the system was illuminated with an external light source (a LED), and the integrated photodiodes were successfully used for particle detection.

3.09.6.3 Liquid Droplet Manipulation

Virtually all biological or biochemical species occur in a liquid solution. Consequently, manipulation and control of small volumes of liquids are major issues for all biochemical MEMS. Hence the electrowetting effect (Mugele and Baret 2005) has attracted renewed interest during the past decade. Apart from macroscopic optical traps and optical tweezers, several approaches for the manipulation of liquids on solid surfaces have been developed, including dielectrophoretic motion (Gunji and Washizu 2005, Jones *et al.* 2001) and digital microfluidic systems based on electrowetting with electrode arrays for creating, transporting, cutting, and merging of droplets (Cho *et al.* 2003). A review on integrated systems employing digital microfluidics is given by Fair and coworkers (Su *et al.* 2006).

Electrowetting has also been combined with photoconductive materials such as hydrogenated amorphous silicon to define active zones of the substrate (i.e., those zones of the substrate on which the electrowetting effect acts) by means of light (Chiou *et al.* 2003). By using such an additional photoconductive layer in the electrowetting substrate, the fixed arrangement of the electrodes limiting the applications of digital microfluidic devices is no longer needed. Instead, OEW allows the movement of liquids on a substrate in arbitrary paths by means of an SLM. The OEW effect was recently successfully applied for size sorting of microparticles (Chiou *et al.* 2005). Therefore, OEW has applications in light-directed cell sorting and highly parallel cell manipulation.

A photoconductive layer is also used in a recent experiment in which proteins in an electrolyte are moved by an electric field created between a photoconductive semiconductor electrode and a counter electrode (Hafeman *et al.* 2006). By applying a bias voltage between these electrodes, majority carriers in the semiconductor are depleted in the semiconductor–electrolyte interface such that no current flows across that interface. If the semiconductor is illuminated by a focused laser, carriers are generated and the depleted layer becomes conductive in the illuminated area. The resulting current leads to a high electric field over the illuminated area such that a trap is formed for the molecules. Molecules can therefore be moved by scanning the laser spot across the photoconductive layer. The authors call this method photoelectrophoretic localization and transport (PELT).

3.09.7 Microarrays

After the first experimental demonstration in the 1990s (Schena *et al.* 1995), microarray approaches to highly parallel biochemical analysis have become popular. Genomic and proteomic researches have profited enormously from the microarray approach, which allowed the detection of thousands of genes to the whole transcriptome of an organism. Consequently, microarray biochips are standard tools in genetic research today. The strong interest in fundamental genomics research and the need for fast and reliable biochemical analysis tools have triggered a considerable amount of research in microsystems technology in this field. In this section, an overview of optical microsystems devoted to particular steps in microarray biochip analysis is given and combined optical–fluidic microsystems for array-based biochemical analysis are presented.

3.09.7.1 Microarray Concepts

The first preparative steps in biochip analysis comprise amplification and fluorescence labeling of the analyte DNA. The biochip substrate consists of a glass or plastic (PMMA or COC) slide, which is coated with chemical coupling layers prior to spotting with probe DNA fragments. These coupling layers allow covalent linking of the probe DNA fragments to the surface of the biochip. Spotting is usually done using contact-free ink-jet or contact needle printing. A particular problem of microarray printing is that a standard format (pitch and spot size) of microarray biochips currently does not exist. While this fact impedes the conception of optical biochip excitation and readout laboratory equipment, it gives freedom to the microsystem engineer for designing integrated systems.

Current standard laboratory equipment for biochip fluorescence excitation and readout equipment are macroscopic systems, as shown in **Figure 22**. With regard to excitation, the simplest and most common method is flood illumination, but laser scanners (using Argon ion lasers) and several evanescent field approaches for excitation are also used (James *et al.* 2004, Lehr *et al.* 2003). For detection of the faint fluorescent light signals, most macroscopic biochip readers use photomultiplier tubes (PMTs). Photomultiplier tubes provide an excellent gain factor and linearity, but since typically only one PMT is used in a biochip reader, the chip must be read out sequentially. Consequently, only endpoint detection is possible, and the readout speed is low. Due to the availability of cooled (for increased signal-to-noise ratio) and/or electron multiplication CCD sensors, CCD cameras are becoming increasingly interesting for parallel and temporally resolved readout of whole arrays (Valentini and D'Andrea 2000).

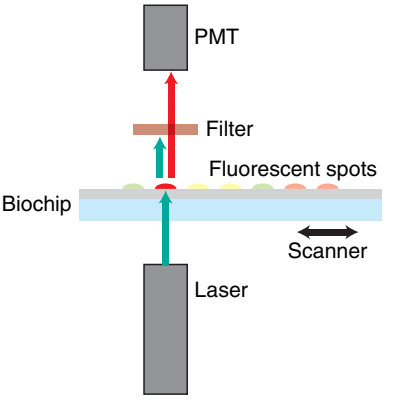

Figure 22 A typical setup of a biochip scanner. The fluorophores in a spot on the biochip are excited with a laser. The excitation light is filtered out in the optical path towards the detector (here a photomultiplier tube (PMT)). By mechanical scanning of the biochip, all spots are read out sequentially.

Current development in the field of biochip analysis instrumentation is driven by the need for fast and reliable point-of-care diagnostic tools for public and individual health care and for security. Though, until now, no fully integrated miniaturized DNA preparation device or biochip excitation/readout unit has been reported, many MEMS approaches have been realized for the preparation of the analyte or excitation or readout of biochips. Additionally, macroscopic biophotonics systems profit significantly from optical MEMS technology. In the following sections, an overview of biophotonic microsystems relying on an arrayed excitation or detection or for the generation of arrayed intensity patterns for use in macroscopic systems is given.

3.09.7.2 PCR Chips

Amplification of the analyte DNA fragment using polymerase chain reaction (PCR) is the first preparative step in genomic analysis. PCR is an enzyme-based method for synthesis of many copies of a given DNA molecule and requires careful temperature cycling. Macroscopic cyclers are standard equipment in biomolecular laboratories, but a

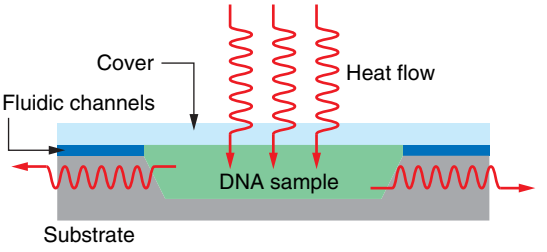

Figure 23 On-chip implementation of polymerase chain reaction (PCR), an enzyme-based method for synthesis of many copies of a given DNA molecule.

number of chip-based PCR approaches have been developed (Zhang *et al.* 2006a).

Several approaches for heating solutions in a micromachined chip, as shown schematically in **Figure 23**, have been developed; the promising approach is heating the analyte liquid in a volume of 5 nl by photon absorption (Slyadnev *et al.* 2001, Tanaka *et al.* 2000) using an external infrared laser diode (emission wavelength, 1472 nm; power, 150 mW). The liquid was in a simple, Y-shaped fluidic channel system in a chip and the system was operated under constant flow. Heating and cooling rates of 67 and 53°C s^{-1} were achieved; compared to conventional systems, this is faster by one order of magnitude.

Amplification of DNA by PCR in a silicon microreactor was also successfully demonstrated (Ke *et al.* 2004). Compared to a Peltier element-based temperature cycler, the amplification was achieved in a time reduced approximately by a factor of 2 (34 min instead of 62 min). A halogen lamp was used for noncontact heating of the liquid and a Pt100 resistor (a resistor with a very well defined temperature dependence of its resistance, hence a popular choice as a temperature sensor) for temperature monitoring and control.

Temperature control is an essential issue for successful PCR and many ultrasensitive biomolecular detection methods. It has been demonstrated that temperature can be measured in a cylindrical microchamber (8 µm diameter, 2.2 µm height) with an accuracy of 2°C (Arata *et al.* 2005). The proposed experimental method relies on the temperature dependence of the fluorescence intensity of a fluorescent dye, in this case Rhodamine B.

3.09.7.3 Integrated Photonic Detection

A further step toward system integration is a sandwiched silicon/pyrex PCR chip with pigtailed optical input and output fibers (Schabmueller *et al.* 2001). Two different systems have been developed: in the PCR chip, both fibers (one for fluorescence excitation, the other for detection of fluorescence light) were aligned perpendicularly. The other system employed only an input fiber, but instead of the output fiber an integrated photodiode was used at the bottom of the reaction chamber. The work demonstrates the feasibility of an integrated PCR system and fiber-based detection of fluorescence radiation.

A complete detection system for a pathogenic bacterium (*Listeria monocytogenes*) with external dimensions of 36 cm × 28 cm × 15 cm has been reported (Cady *et al.* 2005). The microfluidic system consisted of a connected DNA purification chamber and a second PCR amplification chamber, and was fabricated in a combination of silicon and PDMS using an SU-8 photoresist mold. However, the optical excitation and detection system was macroscopic and quite conventional, using a blue LED with an emission wavelength of 480 nm and 80 mW power for excitation and a PMT for detection of fluorescence signals at a wavelength of 520 nm. The excitation wavelength from the PMT was blocked by a notch filter.

Microfabrication techniques offer the advantage of the integration of a silicon photodetector and a blocking filter for the excitation light. Efficient blocking of the excitation light from the photodetector is indispensable in fluorescence experiments because of the low intensity of the fluorescence light, which is smaller by several orders of magnitude compared to the excitation intensity.

Such an integrated chip consisting of a glass chip with microfluidic channels which is bonded to a silicon-based chip with integrated photodiode and interference filter, has been fabricated (Namasivayam *et al.* 2004) and achieved a detection sensitivity of 0.9 ng μl^{-1}.

Finally, the development of arrayed single-photon detectors with a high temporal resolution (below 100 ps) for biophotonic applications is currently a hot topic in applied and industrial research (Pauchard and Rochas 2005).

3.09.7.4 Fluorescence Excitation

For excitation of an ordered array of fluorescence spots, the most straightforward approach (apart from flood illumination) is the arrangement of individual light sources, such as laser diodes, in an array with a pitch to match the spot pattern. However, this approach requires a completely new hardware design for every new spot array design. By several

microsystem-based approaches, this problem can be avoided in an economic and elegant manner.

Relying on the arrayed arrangement of the spots, several approaches use static or dynamic diffractive optical elements (DOEs) for providing an intensity distribution, which is matched against the spot pattern on the biochip. Diffractive optical elements have been used for multipoint holographic fluorescence excitation, and it has been demonstrated that this approach outperforms conventional methods with respect to excitation efficiency, signal-to-noise ratio and sample throughput (Blom *et al.* 2002, Mehta *et al.* 2001). For a new biochip design, only the DOE has to be exchanged on the hardware side.

Spatial light modulators, such as micromirror arrays and liquid crystal displays, can be used as dynamic diffractive optical elements, which allow flexible biochip excitation without exchanging hardware in the excitation unit. This was recently demonstrated using liquid crystal displays, as shown in **Figure 24** (Glasenapp *et al.* 2006). In this work, the holograms were calculated in advance to match the spot patterns and were loaded onto the liquid crystal display. The maximum hologram refresh rate using these displays was 100 Hz.

All holographic techniques for biochip fluorescence excitation require an accurately defined position of the spots on the chip. While accurate spotting of biochips is, in principle, not a problem in the current state of the art in microsystem technology, the reality is still different in many microbiological laboratories. Currently, coarse needle printers are frequently used for array spotting.

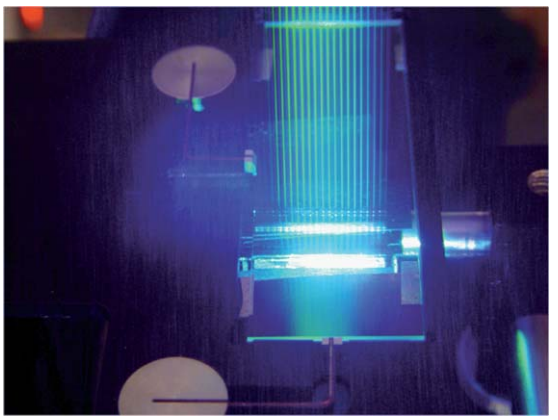

Figure 24 Photograph of fluorescence excitation using a holographically defined intensity pattern. The blue lines correspond to a linear array of excitation spots, which impinge on a biochip.

A completely different approach for multipoint excitation is the integration of low-cost dye microlasers into a microfluidic network (Kobayashi *et al.* 2005). The surface-emitting dye laser consisted of a dye-doped PMMA layer on a patterned glass substrate and was pumped optically by an external Nd:YAG-laser. Substrate emission occurs only over the patterned regions of the glass. By an appropriate choice of the periodicity of the pattern, the emission wavelength of the laser can also be selected. Therefore, emission at different wavelengths is possible within the same chip.

In biophotonics, providing an arrayed intensity distribution can be applied not only to fluorescence excitation of spot arrays on a biochip but also to parallel optical trapping and manipulation of biological specimens such as cells. As an example for this application, a liquid crystal display as a phase-only SLM has been used and the phase perturbation of the wavefront has been converted to an amplitude perturbation by means of a phase contrast filter (Mogensen and Glückstad 2000). A computing method for optimization of holographic optical traps and a for quantification of the performance of the holograms allowing them to be optimized in real time have been developed (Polin *et al.* 2005).

Acknowledgments

The authors are grateful to Khaled Aljasem, Jens Fiala, Christoph Friese, Carsten Glasenapp, David Kallweit, Nadja Katthagen, and Armin Werber of the Laboratory for Micro-optics in the Department of Microsystems Engineering for preparing some of the figures and tracking down some of the references; Jürgen Steigert, Jens Ducrée, Roland Zengerle of the Laboratory for MEMS applications in the same department for the pictures of the biodisk; Eiji Higurashi of the University of Tokyo for the photos of his blood flow sensor; and David Dickensheets of Montana State University for the diagram of his integrated confocal sensor head.

Biographies

Wolfgang Mönch was born in 1970 in Oettingen, Germany. He studied Physics at the University of Konstanz and graduated there in 1996. From 1996 to 1999, he worked with Prof. Herminghaus at the Max Planck Institute for Colloids and Interfaces in Berlin, Germany, on the dynamics of liquids on structured substrates and earned his doctorate in 1999. In 2000/2001, he investigated elastic instabilities of rubber films at the University of Ulm. Since July 2001, he has been a senior scientist in Professor Zappe's group at the Department of Microsystems Engineering, University of Freiburg, Germany. His current research interests are biophotonics and applications of soft matter in tunable optical microsystems and novel tuning mechanisms in micro-optics.

Hans Zappe was born in Paris and brought up in New York. He studied Electrical Engineering at the Massachusetts Institute of Technology (BSc and MSc, 1983) and at the University of California, Berkeley (PhD, 1989). He has worked on silicon VLSI at the IBM General Technology Division (Burlington, VT, USA), on GaAs electronics and high-speed lasers at the Fraunhofer Institute for Applied Solid State Physics (Freiburg, Germany), and on integrated optical microsystems and surface-emitting lasers at the Centre Suisse d'Electronique et de Microtechnique (CSEM, Zurich, Switzerland). Since 2000, Prof. Zappe has been Professor of Micro-optics in the Department of Microsystems Technology at the University of Freiburg, Germany. His current research specialties are in the areas of optical microsystems for medicine, tunable micro-optics, and the use of novel optical materials.

3.10 RF MEMS

3.10.1 RF MEMS Switches

Switches are an integral part of electronics. It is no surprise that there are countless types of switches, which can range from low-cost PIN diodes to high-power electromagnetic relays. Microelectromechanical systems (MEMS) switches are quickly becoming very popular with microwave engineers, and they have already been used in antennas, filters, phase shifters, oscillators, multiplexers, and other traditional (radio frequency) RF devices. Their popularity has grown because of their wider bandwidth, better isolation, lower loss at high frequencies, improved linearity, and lower power consumption compared with traditional switch devices (Goldsmith *et al.* 2001).

3.10.1.1 Introduction

MEMS switches as we know them today were conceptualized in the late 1980s and early 1990s. The first published articles were entirely conceptual and pointed out some of the design challenges and potential uses of MEMS devices (Koester *et al.* 1996). MEMS switches in particular were of great interest to RF engineers for their potential to reduce the total area, power consumption, and cost of their devices. A picture of an RF MEMS switch is shown in **Figure 1**.

MEMS were initially fabricated exclusively on silicon because integrated circuit (IC) fabrication at the time was on silicon. The material properties and fabrication processes for silicon were already well known.

MEMS devices quickly surpassed the RF performance of their solid-state equivalents. Even early MEMS switches had an insertion loss of 0.15 dB at 20 GHz, compared with an on-state insertion loss of approximately 1 dB for a typical GaAs-FET or PIN diode switch at the same frequency (Brown 1997).

For applications where the frequency of interest is less than 1 GHz, solid-state switches are still the switching element primarily used. They are cheap, have low loss, are easy to integrate, and are widely available. Above a few gigahertz, the losses begin to increase, and it becomes more difficult to integrate the switches. This is where the advantages of MEMS switches

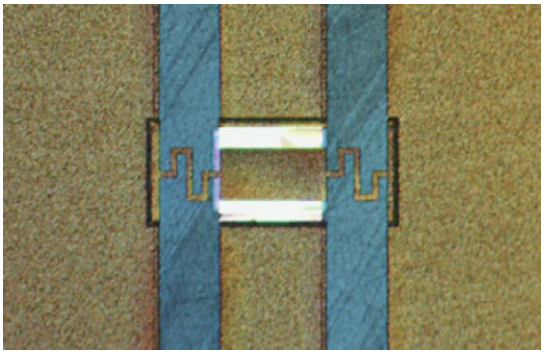

Figure 1 A single radio frequency microelectromechanical systems (RF MEMS) switch is shown in a coplanar waveguide structure. The metal pads on the *left* and the *right* side of the image serve as the DC and the RF ground. The center metal serves as the DC and RF carrier. A thin layer of silicon nitride prevents a direct connection between the layers during switch actuation. (Source: Thompson D, Kingsley N, Wang G, Papapolymerou J, Tentzeris M 2005 RF characteristics of thin-film liquid crystal polymer (LCP) packages for RF MEMS and MMIC integration. *IEEE MTT-S Int. Microwave Symp. Dig.,* © 2005; reproduced with permission from IEEE.)

become apparent. They are not as fast nor are they as robust as their solid-state cousins, but they can more than make up for that in electrical performance. A MEMS switch can easily have losses in tenths of a decibel up to 40 GHz. Switching times are typically measured in tens of microseconds for hundreds of billions of cycles. In recent years, MEMS switches that can handle multiwatt power levels have been reported (Que *et al.* 2004).

The holy grail for many MEMS designers is the cell phone market. The global wireless market generated $555 billion in 2005 and this number is expected to grow to $800 billion by 2010 (Reuters 2006). This presents a large funding source for any company that can integrate RF MEMS into a cell phone. Utilizing a bank of RF MEMS switches, capacitors, and inductors, a cell phone could offer fantastic reconfigurability. The cell phone could conceivably work at any frequency, on any channel, for any standard, and in any location. Dropped calls would be a thing of the past. Many performance limitations would arise when trying to do this with solid-state switches.

3.10.1.2 Operation

RF MEMS switches are one type of MEMS devices that utilize either a single-supported (cantilever) or a double-supported (air-bridge) beam suspended over a metal pad. Because a MEMS switch uses only a single moving part, it is one of the simplest MEMS in use today. By comparison, a sensor can have dozens of moving parts. Switches can come in various shapes, sizes, and materials. There are two main types of actuation for RF MEMS switches: thermal and electrostatic.

Most materials expand when heated and contract when cooled. This is the basic principle behind thermal switches. A resistive material is integrated on the switch membrane. Electrical current is passed through the switch, which heats the resistive material and causes it to expand. This expansion deflects the beam. When the current is reduced (or eliminated), the switch returns to the steady state. This switch topology is not widely used because it is much slower, has a lower bandwidth, consumes more power, and is more difficult to control than with electrostatic actuation; also, it results in higher losses. It can have a low actuation voltage, which could make it attractive for system-on-chip applications.

Electrostatic actuation relies on the principle that opposite charges attract. With one metal beam suspended above a metal pad, a voltage is applied to the beam while the pad is grounded or *vice versa* (as shown in **Figure 2**). A static charge will form from the voltage potential, and this creates an electrostatic

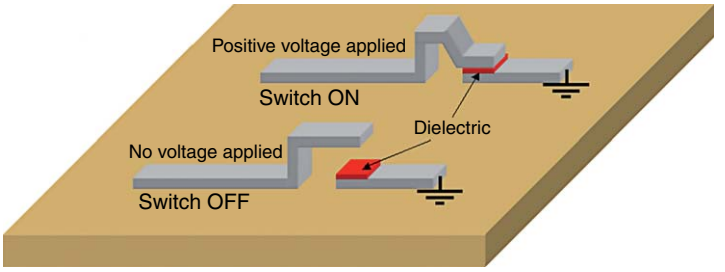

Figure 2 Basic operation of a single-supported, capacitive microelectromechanical systems (MEMS) switch. When no voltage is applied to the membrane, no actuation occurs. When a voltage is applied, the voltage potential creates an electrostatic force that pulls the membrane toward the grounded sign line beneath it. A thin layer of dielectric material prevents direct contact between the layers.

force between the layers. As the voltage potential is increased, the electrostatic force strengthens. When this force exceeds the beam's ability to resist deflection, the metal layers are pulled together. If the metal layers are allowed to make direct contact, this switch is ohmic and DC current is able to flow through the switch. If direct contact is prevented by a thin layer of dielectric (usually silicon nitride), then the switch is capacitive and no DC current is allowed to flow. Because a capacitor is the basis for this design, the frequency must be sufficiently high so that the RF energy can pass through. Switches of this type are typically used from 5 to 100 GHz. Varying the thickness of the dielectric layer is one way of tuning the resonant frequency of these switches. Filter designers are particularly fond of capacitive switches because there is no resistance and this gives a higher Q-factor.

MEMS switch designers have a number of variables at their disposal that can be optimized for a given application (Senturia 2001). There is a fundamental trade-off between isolation, switching speed, and actuation voltage. The best way of improving the isolation of a switch is to increase the vertical distance between the beam and the metal pad. This distance is typically 1–3 μm. As this distance is increased, the switching time and the actuation voltage also increase. Decreasing this distance will likewise decrease the switching time and the actuation voltage. The speed and voltage can also be improved by changing the beam material. Very pliable metals, such as aluminum, will switch more easily than stiffer metals, such as gold. The stiffness of a material is denoted by its Young's modulus (the higher the value, the stiffer the material).

Equations for predicting the bending of cantilever and double-supported beams have been around for decades. Unfortunately, trying to apply simplistic equations to complex MEMS devices can be cumbersome. One of the most important mechanical parameters of a MEMS switch is the pull-down voltage. This quantity can be estimated by treating the MEMS switch as a mechanical spring. In order to calculate the pull-down voltage, one must equate the electrostatic force pulling down on the beam

$$f_{\text{down}} = \frac{\varepsilon A V^2}{2g^2} \quad [1]$$

and the force pushing up from the spring (Hooke's law)

$$f_{\text{up}} = -k(g_0 - g) \quad [2]$$

For these equations, ϵ is the permittivity, A the area, V the voltage, k the spring constant, g_0 the initial gap, and g the evaluated gap. We can use these simple, spatially independent equations because we know the charge density (and therefore the force) is uniform across the capacitive region. It is well known that for parallel plate electrostatic actuation, when the gap reduces to two-thirds of the original gap, the beam becomes unstable and experiences a pull-in effect. That is, when the gap reaches a certain threshold, namely, two-thirds the original gap, the switch will snap down. Magnets experience the same effect. As two magnets of opposite polarity are brought closer together, the attractive force is barely noticeable until they reach a certain distance apart. At this point they snap together and the force between them is strong.

Equating eqns [1] and [2] where the gap (g) is two-thirds the original gap (g_0) and solving for the pull-down voltage gives

$$V_{\text{PD}} = \sqrt{\frac{8kg_0^3}{27\varepsilon A}} \quad [3]$$

In order to reduce the pull-down voltage, design engineers can reduce the spring constant, reduce the switch gap, or increase the area of the switch.

3.10.1.3 Comparison of Technologies: Electromechanical vs. Solid State

There are various switching elements available on the market today. In order to choose the right type of switch, one must consider the required performance specifications, such as frequency, bandwidth, linearity, power handling, power consumption, switching speed, signal level, and allowable losses. A comparison of electrical performance parameters for a typical RF MEMS, PIN diode, and FET switching element is summarized in **Table 1** (NASA 2003).

PIN diodes are useful switching elements because they are widely available commercially, have fast switching speeds, are of low cost, and are rugged. One of the main limitations of PIN diodes is the insertion loss. Above a few gigahertz, PIN diodes can start to have quite a bit of insertion loss. This becomes significant above X-band (8–10 GHz) when the skin effect causes an increase in the resistance of the switch. At any high frequency, diodes tend to have issues with linearity, bandwidth, and power consumption.

Like PIN diodes, FETs are widely used because of their availability, fast speed, low cost, and durability.

Table 1 Comparison of electrical performance for a typical RF MEMS, PIN diode, and FET switch

Parameter	*RF MEMS*	*PIN diode*	*Field-effect transistor*
Voltage (V)	20–80	±3–5	3–5
Current (mA)	0	0–20	0
Power consumption (mW)	<0.5	5–100	−0.5 to 0.1
Switching time	1–300 uS	1–100 ns	1–100 ns
Cup (series) (fF)	1–6	40–80	70–140
Rs (series) (Ω)	0.5–2	2–4	4–6
Capacitance ratio	40–500	10	N/A
Cutoff frequency (THz)	20–80	1–4	0.5–2
Isolation (1–10 GHz)	Very high	High	Medium
Isolation (10–40 GHz)	Very high	Medium	Low
Isolation (60–100 GHz)	High	Medium	None
Insertion loss (1–100 GHz) (dB)	0.05–0.2	0.3–1.2	0.4–2.5
Power handing (W)	<1	<10	<10
Third-order intercept (dBm)	+66–80	+27–45	+27–45

They consume much less power than PIN diodes, but they are not available for the same frequency range as diodes. That is, they have limited use in Ka-band (26–40 GHz) and are practically unusable above U-band (40–60 GHz) (NASA 2003).

MEMS switches are quickly becoming the preferred switching element for RF devices. They offer the lowest insertion loss, the highest isolation, an extremely high linearity, a negligible power consumption, and a small size. The switching time, power handling capability, and packaging requirements are the three main limitations in their use. The switching time for a MEMS device usually varies with isolation because of physical constraints (the better the isolation, the slower the switching time). However, for a microwave system that can tolerate a switching time in the micro- to millisecond range, MEMS are suitable. Switching times in the hundreds of nanoseconds have also been demonstrated (Mercier *et al.* 2005). Furthermore, if signal amplification in a wireless system can be done right before propagation (thereby eliminating the exposure of the switching elements to high power), then MEMS are also applicable. Packaging MEMS is not as straightforward as packaging solid-state devices. This topic is discussed in Section 3.10.4.

3.10.1.4 Limitations

One of the most difficult challenges for MEMS designers is overcoming dielectric charging. All electrostatic MEMS switches use some sort of dielectric to maintain the voltage potential. Over time this dielectric will store charge and the switch will remain in the actuated state. This charge naturally dissipates into the substrate, but it can take anywhere from milliseconds to hours for this to occur, depending on the actuation voltage, the substrate material, and the extent of the charging. Lower actuation voltages and materials with good charge mobility tend to dissipate charge faster. Cycle testing is a good metric for determining the lifetime of a switch, but it is not a good indicator of the reliability. Switch-cycle lifetimes in the hundreds of billions of cycles have been demonstrated (Radant MEMS 2006). A switch that can operate for a hundred billion cycles is sure to have a long lifetime, but if the switch becomes stuck after a minute in the actuated state, then it is not a very reliable switch. For a system that is not continuously being reconfigured, this is a big problem. Researchers are currently investigating better ways of removing this charge accumulation (Papaioannou *et al.* 2005). Many techniques that are being proposed involve the use of novel dielectric materials.

Another solution to the problem of long-duration actuation is to use a hybrid actuation technique, which uses electrostatic and thermal mechanisms. Electrostatic actuation is used first to quickly pull down the switch. The switch is then held down using thermal actuation and the electrostatics are turned off. This switch has the fast switching time of an electrostatic switch; however, the drawback is that there is a slight increase in the power consumed (by the resistive material). Because the static charge is only present for a very short time, this switch can be much more reliable.

Robustness is another big challenge for engineers. In order for a product to be successful, it needs to be able to survive a certain amount of abuse. Modern cell phones can survive years of abuse from keys,

pocket change, multiple falls, and sometimes even brief exposures to water. Could a MEMS switch survive the same? Many experts say that as their size is so small, they are almost unaffected by everyday vibrations. Other experts are more skeptical.

One last limitation worth mentioning is the power handling capability of MEMS. Typically, the geometry of a switch requires the RF signal to travel directly under the metal membrane. As the power level for the RF signal is increased, it can start to have an effect on the membrane. At some power level, the RF signal will become strong enough to self-actuate the switch. This is a fundamental limitation and is something that is also actively under investigation. At the moment, switches are typically rated in the tens or hundreds of milliwatts (Radant MEMS 2006) although power levels over a watt have been demonstrated (Que *et al.* 2004).

3.10.2 System-Level Approach to RF MEMS

Many commercial companies are investing top dollar to integrate RF MEMS into their products. Like many MEMS researchers, they have realized that in a device where low power consumption, low loss, low cost, and high performance are essential, there is no substitute for a MEMS switch. NASA, MIT Lincoln Labs, Intel, IBM, and Raytheon are just a select few who are trying to incorporate MEMS into their state-of-the-art systems. Radant MEMS and Memtronics (MEMtronics Corporation 2005) are two examples of commercial companies that have system-level switches available for purchase. This section will discuss several systems where RF MEMS switches have been successfully integrated.

3.10.2.1 MEMS on Organic Substrates

As consumers push for improved wireless systems, there is a related push from microwave design engineers for lightweight, low-loss, and low-cost substrate materials. Unfortunately, this creates an interesting problem. In a typical wireless system, one would find various active and passive devices. Most of the active devices require expensive substrate materials such as GaAs or InP. Making an entire wireless system with these materials would be impractical. Alternatively, active devices can be integrated onto a less expensive substrate with the passive devices. It is very difficult to find a substrate material that is of low cost, has low loss at high frequencies, and can easily package active devices.

Fortunately, liquid crystal polymer (LCP) is one such material. LCP is a thin-film, flexible, organic polymer composed of oxygen, hydrogen, and carbon atoms. The exact chemical formula is proprietary and varies with the manufacturer. LCP is commercially available from Rogers Corporation (R/flex® 3000), Solvay Advanced Polymers (XYDAR® LCP), RTP Company (RTP Compounds LCP), DuPont Engineering Polymers (Zenite® LCP), Ticona (Vectra® LCP), and several others.

LCP has been characterized up to 110 GHz as a low-loss, low-cost material (Thompson *et al.* 2004). The line loss for a microstrip structure is shown in **Figure 3**. Because LCP is strong and lightweight, with a permittivity of around 3, it is ideal for antenna arrays (surface wave propagation is usually less for substrates with low permittivity). Because LCP is flexible, systems on LCP can be kept flat or conformed to a curved surface (Kingsley and Papapolymerou 2006b).

As applications go higher in frequency, there is a distinct advantage to using MEMS as the switching element. One challenge with using LCP, or any polymer, as a substrate material is the difficulty in fabricating MEMS directly on the substrate. There is a good reason why MEMS engineers choose optically flat substrate materials, such as silicon or quartz, for their devices. Fabricating on a flexible, organic substrate is not as straightforward as using a smooth, flat substrate such as silicon. Being a flexible material, it is prone to curling. This effect becomes more pronounced throughout processing due to temperature fluctuations arising from the various baking, deposition, and etching steps. Because hard contact optical lithography with a 3- to 5-μm resolution cannot be performed on a curled substrate, it is necessary to mount the sample to a flat, clean room grade material before processing. Temporary mounting can be done using a spin-on or a roll-on adhesive. Permanent mounting can be done using a thermal bonding machine. Because the substrate is also a polymer, surface roughness is an issue. The surface roughness is usually on the order of 2–10 μm. Given that the MEMS switch is generally suspended 1–3 μm above the substrate, the surface roughness can be large enough to prevent the switch from deflecting. To solve this problem, each sample is mechanically polished using alumina or oxide slurry. After polishing, the sample will have a surface roughness between 10 and 50 nm, which is smooth enough for MEMS switch operation (Kingsley *et al.* 2005).

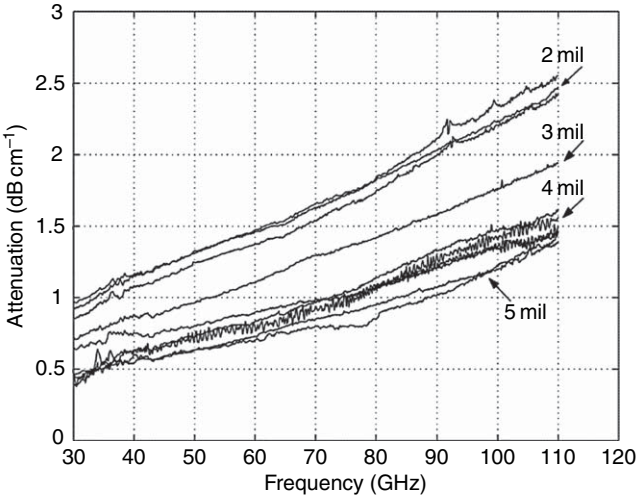

Figure 3 Measurement results of the attenuation of microstrip lines on various thicknesses of liquid crystal polymer (LCP). The loss increases as the substrate becomes thinner. (Source: Thompson D, Tantot O, Jallageas H, Ponchak G, Tentzeris M, Papapolymerou J 2004 Characterization of liquid crystal polymer (LCP) material and transmission lines on LCP substrates from 30 to 110 GHz. *IEEE Trans. Microwave Theory Tech.* **52**, 1343–52, © 2004; reproduced with permission from IEEE.)

3.10.2.2 Phased Antenna Arrays

Integrating switching elements into an antenna array is nothing new. However, using solid-state switches at the front-end of an antenna adds an element of noise. Furthermore, solid-state varactors have been used to tune antennas at the front-end, but this too adds a level of distortion that is often unacceptable in a communication system.

As the need for reduced bandwidths and beam steering increases, so does the use of planar antenna arrays. This type of antenna system allows for excellent control of the beam properties, especially when integrated with phase shifters and attenuators. All of these components require switching elements. As an array becomes larger, the number of components increases, and the required number of switches also increases. Using solid-state switches can add an enormous amount of loss to the array. This in turn will require active devices to compensate for this loss. These factors will increase the cost and create other problems such as heat dissipation and distortion. RF MEMS do not have these limitations. They do not consume power. They do not generate heat. They do not distort RF signals. They are an ideal component for planar antenna systems.

3.10.2.3 Multibit Phase Shifter

To date, there have been publications on multibit phase shifters on various materials, including silicon and GaAs (Rebeiz *et al.* 2002). In addition, various switching elements have been used, including FETs, PIN diodes, and in recent years MEMS. Given that phase shifters typically employ several switching elements, MEMS switches are a natural fit because they offer excellent isolation when in the off state and very low loss in the on state.

In a never-ending quest to lower the cost of devices, engineers often try to make devices on cheap substrates such as LCP. The first MEMS phase shifter on a flexible, organic substrate was presented at the 35th European Microwave Conference (Kingsley *et al.* 2005). That work was improved by greatly shrinking the size, lowering the loss, expanding to four bits, and integrating into an all-organic package. The improved geometry was 2.8 times smaller and 4 times shorter than a traditional switched-line phase shifter. In addition to the size reduction, the line length and the number of switches traversed compared with a traditional implementation were each reduced by a factor of 2. This resulted in half the line loss and half the switch loss by using this implementation (Kingsley and Papapolymerou 2006a). The size improvement over a traditional implementation is shown in **Figure 4**.

Works that claim small, reduced, or miniature size typically use high dielectric materials, such as silicon or GaAs, that have permittivities between 11 and 13. This is because the wavelength of a microstrip line is inversely related to the square root of the permittivity. Microstrip phase shifters on high-dielectric

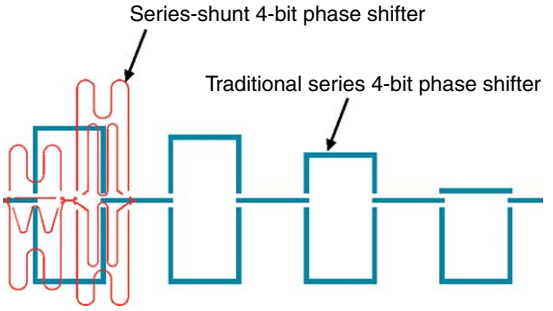

Figure 4 A series-shunt switched-line phase shifter (red) is compared to the traditional layout (blue). Not only are the overall dimensions considerably smaller but also the insertion loss is much less. Microelectromechanical systems (MEMS) serve as the switching elements, which further enhance the performance. The substrate material is liquid crystal polymer. (Source: Kingsley N, Papapolymerou J 2006a Organic ''wafer-scale'' packaged miniature four-bit RF MEMS phase shifter. *IEEE Trans. Microwave Theory Tech.* **54(3)**, © 2006; reproduced with permission from IEEE.)

materials will always be much smaller than those on low-dielectric materials. This approach attempts to level the playing field by introducing a design that is roughly the same size as a phase shifter on a high-permittivity material but is made on a substrate that is a fraction of the cost. The phase shifter fabricated on LCP is shown in **Figure 5**.

Because the phase shifter uses low-loss MEMS switches and is fabricated on a low-loss substrate, this device is capable of being very low-loss up to high frequencies. The phase shifter shown in **Figure 5** was designed for a 14-GHz center frequency. The measurement results are shown in **Figure 6**.

3.10.3 MEMS Packaging

There is an increased interest in moving toward system-on-package (SOP) RF front-end technologies. SOP offers design simplicity, lower cost, higher system function integration, better electrical performance, and various 3D packaging capabilities (Tummala 2004). Packaging is necessary for all devices, but it is particularly important for MEMS. On a hot humid day, many MEMS devices will fail in minutes if not protected. This is because at the micro level, changes in moisture and temperature can have a pronounced effect. MEMS are also sensitive to particulate matter and airflow. Dust particles can be less than a micron in diameter and invisible to the naked eye, but they can be like flying boulders to a sample of MEMS. For these reasons, MEMS must be packaged.

Electronic packaging can account for a good portion of the overall system area, mass, and cost. This is especially true for MEMS because they are ultrasensitive to environmental effects. The challenge for the package is to provide all crucial functions required by the component without limiting the performance of

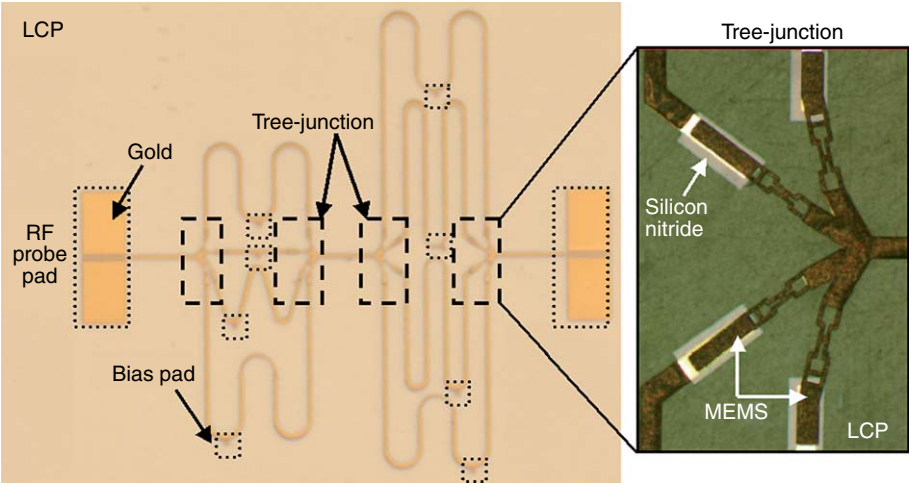

Figure 5 Four-bit microelectromechanical systems (MEMS) phase shifter fabricated on liquid crystal polymer (LCP). The switches used are a single-pole, four-throw implementation arranged into a tree-junction. Radio frequency (RF) probe pads allow for co-planar waveguide (CPW) probe measurements. DC bias pads are used to apply the DC actuation voltage. (Source: Kingsley N, Papapolymerou J 2006a Organic ''wafer-scale'' packaged miniature four-bit RF MEMS phase shifter. *IEEE Trans. Microwave Theory Tech.* **54(3)**, © 2006; reproduced with permission from IEEE.)

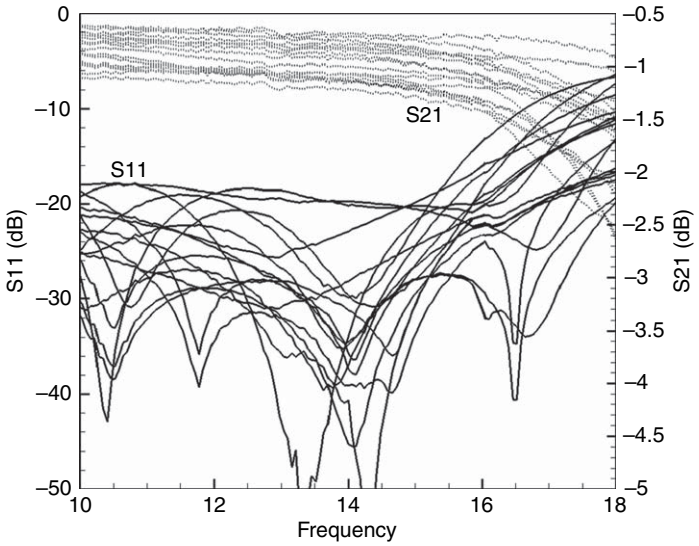

Figure 6 Measurement results for the four-bit microelectromechanical systems (MEMS) phase shifter shown in **Figure 5** (all 16 possible combinations are shown). The worst case S11 is −19.7 dB at the design frequency. The average insertion loss is 0.96 dB, which gives a per-bit loss of only 0.24 dB. (Source: Kingsley N, Papapolymerou J 2006a Organic ''wafer-scale'' packaged miniature four-bit RF MEMS phase shifter. *IEEE Trans. Microwave Theory Tech.* **54(3)**, © 2006; reproduced with permission from IEEE.)

the part. A slight crack in a seal, too much outgas from an epoxy, or too much exposure to heat can all damage a MEMS during bonding. Extreme care must be taken to isolate the device from the packaging technique, which is a difficult task because the smallest possible package is often preferred.

The semiconductor industry typically uses chip package standards. One package of a given size, shape, and number of leads can house any number of CMOS chips. The situation with MEMS is different. Some MEMS, such as pressure and chemical sensors, need to be able to sense the environment, but they also need to be protected from the elements. Other devices, such as switches, need to be completely sealed off from the environment. Some devices need to be packaged in air. Some need to be packaged under vacuum. For every application, there is a different set of package requirements. Packaging MEMS can be an expensive endeavor. Fortunately, there are several popular methods that are discussed here.

3.10.3.1 Silicon Packages

If MEMS are to be integrated directly on the wafer with CMOS or other silicon devices, then the ability to package with silicon can be useful. There are two main issues with using this method: impedance matching to the packaging layer and bonding the wafers together.

RF MEMS must be matched to the impedance of the system. This is usually not a problem because the dimensions can be tailored to match the system impedance. Therefore, cavities can be etched into a second silicon wafer and placed over the MEMS. However, when an air cavity is created around the MEMS switch, this creates a dielectric discontinuity. That is, before and after the switch, the RF signal propagates between two silicon layers. The impedance is known and constant throughout. While the signal propagates through the switch, it is sandwiched between a layer of air (permittivity of 1) and silicon (permittivity around 12). The impedance here is very different, and this will cause reflections in the system. These losses must be tolerated or a sophisticated matching network must be designed to minimize the effect.

Provided that the RF issues can be resolved, the wafers must be hermetically bonded. Bonding silicon to silicon is called fusion bonding, and it typically takes place at temperatures around 1000°C. Unfortunately, this temperature is much too high for RF MEMS switches, which can have problems with temperatures over 200°C. Instead, a different

bonding technique called eutectic bonding can be used. In this method, gold is deposited on both sides of the silicon wafers. Under pressure, gold and silicon will bond between 200°C and 300°C (eutectic bonding). This temperature is low enough for many MEMS devices, but with gold added to the processing, this will increase the cost and the complexity of production. Also, adding a great deal of metal to a wafer with RF devices can affect the devices themselves. This must be taken into account, which will also raise the design costs.

3.10.3.2 Ceramic and Metal Packages

Ceramic and metal packages are perfectly hermetic and robust, but they are costly. They are the preferred method for many high-volume applications because the ceramic cavity can be premolded and soldered or glued in place. Even though this process can be done quickly, it is not as efficient as wafer-scale techniques. To lower the production cost, chip-level packaging is becoming very popular where an entire device rather than just the MEMS is capped with ceramic (Tummala 2004).

Ceramic packaging is particularly useful for silicon devices because both materials expand and contract at nearly the same rate with temperature. Because they are mechanically durable and chemically resistant, they are useful for many applications that require a degree of robustness.

3.10.3.3 Organic Packages

Organic packaging eliminates many of the problems associated with silicon or ceramic packaging. In particular, cost can be reduced on both the design and the production side. Because polymers tend to have lower dielectric constants than semiconductors, there is less concern about impedance mismatches. Polymers are cheap and easy to work with, which will lower cost. One limitation of using organic packages is the moisture absorption. Unlike silicon, ceramic, and metal, polymers are only near-hermetic. This means that some small fraction of moisture may enter the package and cause problems for the devices. If the MEMS device is enclosed in a larger, hermetically sealed system-level package, then organic packaging is still suitable.

One popular material for organic packaging is LCP. Like in silicon, devices can be fabricated on and packaged in LCP for an all-organic system. With a permittivity near 3, dielectric discontinuities are minimal. Layers of LCP can be bonded using epoxy or heat via thermocompression bonding. LCP is ideal for thermocompression bonding because it can be manufactured to melt at either 315°C (high-melt LCP) or 290°C (low-melt LCP). Typically, the low-melt LCP is used as the bond ply and the high-melt LCP is used as the substrate and the superstrate layers. When the substrate (with MEMS), bond ply, and superstrate layers are sandwiched together and placed inside a thermocompression bonding machine at a temperature between 290°C and 315°C, the low-melt LCP bond ply will melt and adhere uniformly to the outer core layers. This creates the all-organic, near-hermetic package (Thompson *et al.* 2005). Other materials require high voltages, laser welders, or internal metal rings to adhere to the packaging layer.

LCP is an ideal material for SOP technologies. The water absorption rate for LCP is only 0.02–0.04% (Rogers 2005). Low water absorption is often necessary because absorbed water can alter the permittivity of the substrate material, which can drastically change the device performance. Like silicon packaging, it is very attractive because it allows for wafer-scale packaging. Organic materials show promise for biopackaging, which could be used inside of a human body. Because LCP is flexible, it is useful for bendable RF systems as demonstrated in **Figure 7**.

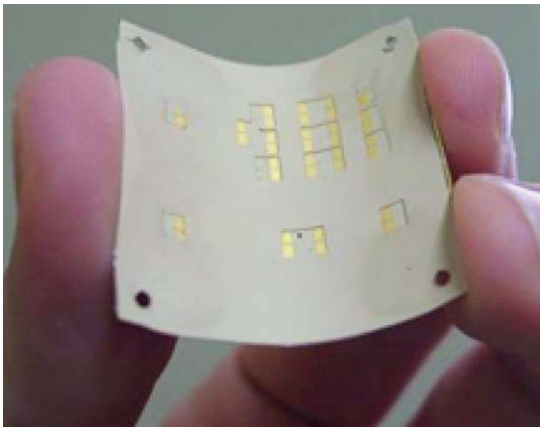

Figure 7 The phase shifter shown in **Figure 5** was packaged using liquid crystal polymer (LCP). The system can be flexed without damaging the phase shifter or switches. The presence of the packaging layer adds less than 0.045 dB of insertion loss and only 1.1 dB of return loss. This amount of loss is practically negligible.

Nickolas Kingsley received his BS (2002), MS (2004) and PhD (2007) degrees in electrical engineering from the Georgia Institute of Technology. He was a member of the Georgia Tech MiRCTECH Research Group and the Georgia Electronic Design Center (GEDC). He holds four invention disclosures for multilayer LCP technologies. He has authored or coauthored over a dozen publications in peer-reviewed journals and conferences. He is the recipient of the 2005 trainer-of-the-year award (honorary mention) from the Georgia Tech Microelectronic Research Center. He also received the 2002 President's Undergraduate Research Award from Georgia Tech and the 2001 Armada Award from Compaq Computer Corporation for engineering excellence. His research has won numerous accolades from Georgia Tech at the University, College of Engineering, and School of Electrical and Computer Engineering level. He is a student member of IEEE, IEEE APS, IEEE MTT-S, and Order of the Engineer.

Since June 2007, Dr. Kingsley has served as a principal engineer with Auriga Measurement Systems in Lowell, MA, USA.

John Papapolymerou received his BSEE degree from the National Technical University of Athens, Athens, Greece, in 1993, the MSEE and Ph.D. degrees from the University of Michigan, Ann Arbor, in 1994 and 1999, respectively. From 1999 to 2001 he was an assistant professor at the Department of Electrical and Computer Engineering at the University of Arizona, Tucson, and during the summers of 2000 and 2003 he was a visiting professor at the University of Limoges, France. From 2001 to 2005 he was an assistant professor at the School of Electrical and Computer Engineering of the Georgia Institute of Technology, where he is currently an associate professor. His research interests include the implementation of micromachining techniques and MEMS devices in microwave, millimeter-wave, and terahertz circuits and the development of both passive and active planar circuits on semiconductor (Si/SiGe, GaAs) and organic substrates (LCP, LTCC) for SOC/SOP RF front-ends.

Dr. Papapolymerou received the 2004 Army Research Office (ARO) Young Investigator Award, the 2002 National Science Foundation (NSF) CAREER award, the best paper award at the third IEEE International Conference on Microwave and Millimeter-Wave Technology (ICMMT2002), Beijing, China, and the 1997 Outstanding Graduate Student Instructional Assistant Award presented by the American Society for Engineering Education (ASEE), The University of Michigan Chapter. His student also received the best student paper award at the 2004 IEEE Topical Meeting on Silicon Monolithic Integrated Circuits in RF Systems, Atlanta, GA. He has authored or coauthored over 120 publications in peer-reviewed journals and conferences. He currently serves as the Vice-Chair for Commission D of the US National Committee of URSI and as an associate editor for *IEEE Microwave and Wireless Component Letters* and *IEEE Transactions on Antennas and Propagation*. During 2004 he was the Chair of the IEEE MTT/AP Atlanta Chapter.

3.11.1 Introduction and Definition

Ink-jet printing has perhaps been the most successful field of microsystems during the last 10 years. This is due to the breakthrough that drop-on-demand (DOD) ink-jet has achieved in the field of desktop printing. The increase in the rates of sales and revenue is considerable, and consumables like ink cartridges and special paper have an especially large share in it. Therefore, one must distinguish between microsystems and printer hardware plus consumables with respect to their share in this huge market.

3.11.1.1 The Market

According to the Nexus Market Analysis for microelectromechanical systems (MEMS), ink-jet printheads will rise from \$1.8 billion in 2004 to \$2.5 billion by 2009 (Nexus 2005). According to a different market study (McWilliams 2006), in 2004 microfluidic MEMS had a share of over 44% of the global MEMS market and MEMS ink-jet heads totaled \$1.8 billion or almost 40% of the global MEMS market in 2004. These figures obviously take into account only the MEMS themselves. If the complete printer hardware and consumables are taken into consideration, different figures are obtained.

In October 2002, Marc Boer, a consulting partner at IT Strategies, predicted an increase of worldwide revenues for ink-jet printers and inks from \$28.5 billion in 2001 to almost \$41 billion by 2006 (Boer 2002). In 2006 he predicted a growth from \$42.1 billion in 2004 to \$58 billion by 2009. The estimate for 2006 had been reached in 2004. This shows the development for wide- and narrow-format ink-jet hardware, media, and ink. For the ink, he predicted an increase from \$13.4 billion in 2002 to more than \$21.5 billion by 2006. In 2006 he predicted an increase from \$20 billion in 2004 to almost \$33 billion by 2009, and for media from \$7 billion to \$11 billion in the same period (Boer 2006). Not included in these estimates is the emerging industrial application of ink-jet technology, "perhaps the biggest opportunity" as Boer says.

3.11.1.2 Drop-on-Demand Systems

There are various systems of ink-jet printing. Only DOD systems, i.e., systems that eject single drops under electrical control, will be considered here. DOD systems use the vacuum method. This means that the ink in the printhead is under negative pressure. The printhead consists of a number of nozzles. Each of them communicates with a cavity filled with ink. Each of them is triggered by an actuator generating shock waves. The cavities are refilled from an ink cartridge by capillarity. Viscosity and surface tension of the ink are tuned in a way that the printheads can do without tight valves. Surface tension and vacuum at

the nozzle take care that the ink does not escape from the nozzle. Drops are only ejected when a shock wave coming from the cavity reaches the nozzle. Due to negative pressure, the surface tension forms a negative meniscus in the nozzle orifice.

This negative pressure can be created in several ways, either by the ink cartridge that is situated some centimeters below the nozzles (Heinzl *et al.* 1979), or by capillarity that keeps the ink (Hara 1985), or by a sponge that absorbs the ink (Baker *et al.* 1988) or by a valve (Nielson and Bolmgren, 1986) that holds the ink back in the cartridge until the vacuum reaches a threshold. The advantage of negative pressure is that many nozzles can be arranged side by side on one and the same nozzle plate without the ink on the nozzle plate disturbing the printing. As soon as the ink on the nozzle plate comes into fluid contact with the ink in a nozzle, it is sucked back by the negative pressure. Only this little trick makes it possible to arrange many nozzles close together.

These systems have made typewriters and needle printers obsolete and are just replacing classical paper prints in photography. Increasing reliability will allow more and more industrial applications, leading to quantum leaps in production strategies.

Apart from the above DOD systems, there are systems with tight-closing valves. They are used for large-scale applications like printing on tarpaulins, covers, or carpets. Also, there are continuous jets using high or low pressure. They produce a print using a continuous stream of droplets, which are selected and deflected (Le 1998). These systems will not be considered here.

Figure 1 shows the difference between nozzles used in high pressure, low pressure, and vacuum methods. High-pressure methods make the jet break into single droplets when leaving the nozzle. This is done either by the surface tension itself, with the droplets offering less surface than the jet (Rayleigh 1878), or by pressure waves of high frequency encouraging and synchronizing the breaking up of the jet. Pressures up to 3×10^6 Pa (300 m wc) create droplets of a volume of 2–10 pl with frequencies up to 1 MHz and reaching a speed of up to 40 ms^{-1} (Heinzl and Hertz 1985, p. 101ff).

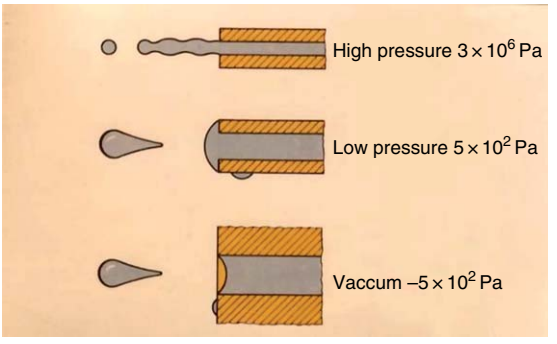

Figure 1 Nozzles at high pressure, low pressure, and vacuum method. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

Low-pressure methods use the positive meniscus of the ink in the nozzle. An electrical field draws out and deflects the ink. Here either the entire nozzle or at least its outer surface must be hydrophobic and remain so. Typical data are 5×10^2 Pa (5 cm wc) in the nozzle, droplet volumes of 20 pl, and frequencies of up to 5 kHz (Ascoli *et al.* 1975).

Vacuum methods use a nozzle that has at least a hydrophilic inner surface. So the negative meniscus remains in the nozzle in spite of the vacuum. Liquids on the surface of the nozzle plate are sucked back into the nozzles by the vacuum. Typical data are a vacuum of -3 to -5×10^2 Pa (-3 to -5 cm wc), a droplet size ranging from 1 to 200 pl, flying speeds from 4 to 12 m s^{-1}, and frequencies from 4 to 20 kHz. Usable frequencies of droplets up to 100 kHz are predicted for DOD systems.

3.11.1.3 Drops and Media

DOD systems are distinguished by the great variety of inks and recording media they allow. There are water-based inks, inks with solvents, ultraviolet (UV)-curable inks, wax inks, and solid inks. UV-curable inks are fixed after application by UV light. Wax and solid inks are melted before jetting. Soluble substances or pigments down to nanoparticles serve as colorants.

Meanwhile, medical drugs, glues, oils, organic substances, plastics, and even metals such as soft solder are jetted. This corresponds to a great variety of recording media from plain paper to coated paper, transparencies, films, corrugated cardboard, and thick card stock. There are applications on glass, ceramics, wood, metal, plastics, and different powders. Depending on the combination of ink and medium, there are differences in the ways by which the droplets hit the medium. **Figure 2** offers a schematic overview.

When water-based inks and plain paper are used, the droplets are deformed when they hit the paper. A meniscus with a flat wetting angle is formed. It defines the area in which the ink is absorbed by the paper, and it appears as the dot. A long tail and satellites of the droplet hit the meniscus and unite. If the printing speed approaches that of the flying droplets, tails and satellites can be distinguished on

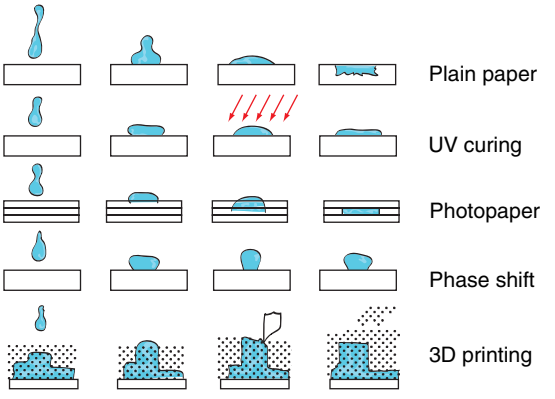

Figure 2 Drops and media. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

the paper. If a neighboring droplet hits the meniscus before the latter is absorbed, the two droplets coagulate, the second drop enlarging the first and shifting it slightly aside. The drops are absorbed in fractions of milliseconds. Drying takes considerably longer.

UV inks can be directly applied to nonabsorbing surfaces. Their viscosity is higher. Therefore it is heated for jetting. When they hit the medium, they cool down quickly and are fixed by UV radiation.

For printing on films or transparencies, at least a gelatin coat is necessary, as long as water-based or solvent inks are used. Without such a coat the ink would take hours to dry, and a major part of the droplets would coagulate. Special photo papers consist of several layers, one of them holds the color.

It takes a temperature of more than 300°C to shoot soft solder on copper or gold conductors. At this temperature, viscosity and surface tension of the soft solder closely resemble those of water ink at room temperature. The drops freeze on the conductor without wetting it, and thus become uniform bumps.

Three-dimensional printing requires the spreading of single layers of granular material. Either the granular material is coated with a hardener, or the hardener is applied to each single layer. A binder is jetted, thus creating layer by layer the structure of the 3D body. The loose granular material serves as support. Normally, the newly created surface is smoothed before the next layer is spread.

3.11.2 Products on the Soho Market

Available ink-jet products range from small printing calculators and a variety of desktop printers, photo printers to all-in-one devices, and large-format printers. The companies Hewlett-Packard (HP), Lexmark, Canon, and Epson dominate this market. The printheads of these devices contain either small heating elements creating vapor bubbles or piezoelements.

3.11.2.1 Desktop Printers

When you buy a desktop printer you do not usually know which technology is hidden in it. The packaging only says ink-jet. It does not give any indication whether a thermal printer, a bubble jet, or a piezojet is inside. Obviously, the term ink-jet is the decisive advertising argument. Canon uses bubble jet technology. HP and Lexmark call the same technology thermal ink-jet.

Only Epson offers printers in piezotechnology. They look almost alike. **Figure 3** shows typical printers from HP, Lexmark, Canon, and Epson: HP deskjet 990c (**Figure 3(a)**), Lexmark Z735 (**Figure 3(b)**), Canon Pixma iP 1600 (**Figure 3(c)**), and Epson Stylus C64 (**Figure 3(d)**). On almost every packaging, you find data such as 4800 dpi (dots per inch), up to 22 ppm (pages per minute), and the number of colors and cartridges.

You can find such printers for prices below €30. Thus, the complete device is hardly more expensive than a new set of cartridges. In order to avoid the customer buying a new printer instead of new cartridges, some companies provide their printers with only partly filled cartridges. Without the sale of replacement cartridges, the sale of the printers would not be economical. The ink, which consists mainly of water, can be sold in the cartridges for a price higher than that of expensive perfumes. That is why a lot of companies try to have a share in the sale of cartridges, even if they themselves do not offer printers. The companies Epson and Canon are especially affected by these substitutes. They do hold a number of patents to protect the technology of their cartridges. These patents are the object of numerous nullity and infringement suits. Many of these patents have already expired.

The cartridges of HP and Lexmark are less affected by substitutes because apart from the ink they contain the complete printhead (Buck *et al.* 1985). Only for heavy-duty printers ink cartridges without printhead are provided by HP (**Figure 4**).

Figure 3 (a) Hewlett-Packard (HP) deskjet 990c, (b) Lexmark Z735, (c) Canon Pixma iP 1600, and (d) Epson Stylus C64. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

Figure 5 The Epson Picture mate 500. (Source: Epson Deutschland GmbH or SEIKO EPSON Corporation.)

3.11.2.2 Photo Printers

Especially for the direct printing of photos, a special printer type has been developed. Small, handy printers for the formats 10 cm × 15 cm and 10 cm × 30 cm, partly also for 13 cm × 18 cm are for sale. Epson's picture make 500 offers a resolution of 5760 × 1440 dpi. Figure 5 shows this printer. A 10 × 15 photo print takes 77 s. HP printers such as the Photo Smart 385 or P 475 have a resolution of 4800 × 1200 dpi. The higher figure describes the resolution along the raster lines, whereas the lower

figure is the resolution between the lines. The special photo papers offered for these printers contain a special layering providing a cover layer, a layer that absorbs the colors, a layer for the solvents, and a support layer. According to what is printed on some packages, the specially pigmented inks will not fade in the next hundred years.

In this field, ink-jet printing is competing with thermal transfer. The latter uses color foils in addition to photo paper and provides waterproof prints. It must be said that traditional photo prints on paper are not waterproof either.

3.11.2.3 All-in-One

By combining a scanner and a printer, numerous functions can all be realized in the same device: printing black-and-white, color printing, photo printing, scanning, copying and color copying, and faxing. In this field HP is the market leader. The devices differ in the number of interfaces, especially for memory cards, the number of paper cartridges, the size of the stack for originals, the printing speed, the number of ink cartridges, the scanning resolution, and the transmission speed for faxes. The Photosmart 3110 of HP, with six ink cartridges, 32 ppm, 4800×4800 dpi scanning resolution and 33.6 kbps. Such devices are available for less than €300 in the marketplace. **Figure 6** shows the Brother MFC-820 CW.

3.11.2.4 Large Format Printers

Meanwhile, a great variety of devices for the printing of posters is available. Rolls of special paper are printed on, their breadth ranging from A1 to 60″. The performance of HP printers is $52.8\,m^2\,h^{-1}$ on plain paper and $13.7\,m^2\,h^{-1}$ on special paper, using four colors with 1200×600 dpi. **Figure 7** shows the HP large format printer Designjet. Canon's best device is the PROGRAF 9000 using 30 720 nozzles, a 12-color pigment inking system, 60″ paper breadth, 4-pl drop size, a resolution of 2400×1200 dpi with an enlarged color gamut and a strongly reduced granularity. Most of the devices are equipped with a cutter and a stationary ink refill station. In this field, ink-jet printing is unequaled. Laser printing is not suitable for large formats.

3.11.3 Actuators and design of Printheads

In order to eject a droplet from a nozzle and to produce a dot, you need a shock wave containing a certain amount of energy. This energy is necessary to accelerate the fluid against the vacuum and to overcome the viscosity of the fluid in the nozzle, in the ink cavity and in the feeder, and to build a new fluid surface. A drop of water of 30-pl size that flies at $8\,m\,s^{-1}$ has 9.6×10^{-10} J kinetic energy and 3.1×10^{-10} J surface energy. The power loss caused by the viscosity is far less. Depending on the type of actuator and the design of cavity and nozzle, you have to apply 10^{-8}–10^{-6} J of energy to the actuator in order to eject a drop. In wire matrix printing,

Figure 6 Brother MFC-820 CW. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

Figure 7 Hewlett-Packard (HP) large-format printer DesignJet. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

the mechanical energy is transmitted from an electromagnetic transducer to the tip of a print needle by the motion of the needle. The electrical energy required to print a dot is about 10^{-2} J. Approximately, one-tenth of this energy is dissipated at the tip of the needle and on striking the ribbon. The needle has to be accelerated and has to squeeze the much thicker ink out of the ribbon and to knead it into the paper. The remainder is transformed into heat together with a tiny but especially annoying part that is transformed into noise. In comparison to that, ink-jet printing is nearly soundless. What can be heard in the office is only the movement of the printing carriage and the paper.

3.11.3.1 Efficiency and Power Density

Various actuators are suitable for miniaturization and thereby for the use in a high resolving printhead. There have been experiments with electrostatic, electrodynamic, electromagnetic, piezoelectric, and thermoelectric actuators. There are two kinds of thermoelectric actuators: one uses a phase-change medium and produces bubbles, the other uses a solid-state body and produces thermal dilatation bending like a bimetal.

Obviously, the thermoelectric actuators with bubbles are best suited for miniaturization. The ink, however, must be resistant to boiling, which distinctly restricts the choice of inks. Piezoelectric actuators need more space, but they are more universally applicable. Electrostatic actuators in air have too low a power density. Electrodynamic actuators can only be produced reasonably when there are few windings. They also need strong currents and very low voltages. For this purpose, there is no applicable circuit technique (Berdelle-Hilge 1990). Electromagnetic actuators have the same problem. They have a low efficiency of not more than a few percent. In comparison, piezoceramic offers efficiencies up to 25% and a high power density. An even higher power density can be found in thermoelectric transducers when they produce bubbles.

Figure 8 shows an experiment for measuring the efficiency of piezoelectric actuators. A piezoblade or a piezostack is fixed on one side. At its free end, there is a sphere that hangs on a thread. While the piezoceramic is charged, current and voltage are measured, and thus the energy input is calculated. The sphere is flung off during charging. The kinetic energy that is imparted to the sphere is determined by means of the deflection, i.e., the ascent height of the swing. The mass of the sphere can be varied until the optimal ratio between mechanical work and electric energy is reached. In this way, by using a large signal, an efficiency of 25% was observed (Heider 1975).

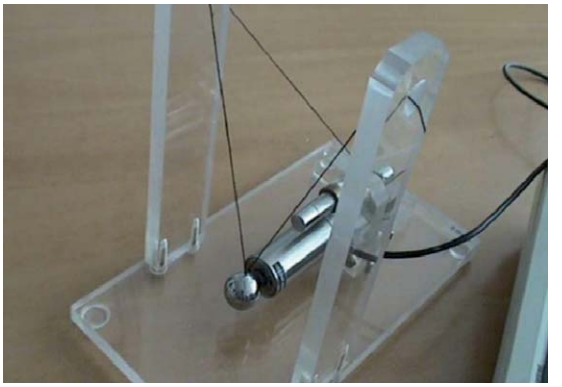

Figure 8 Efficiency experiment with piezoactuators. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

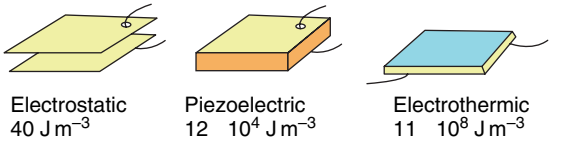

Figure 9 Comparison of power density. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

Figure 9 shows a comparison of power density among electrostatic, piezoelectric, and thermoelectric actuators. The forces applied to the plates of a parallel plate capacitor are calculated up to the insulating strength of air. Where piezoceramic is concerned, power density is calculated from the change of length and Young's modulus. For the vapor bubbles, the increase of volume during vaporization and the heat of evaporation are taken into account. While expanding to atmospheric pressure, the vapor film increases its volume by the factor 1700. It is assumed that the evaporating fluid film and the heating element have roughly the same thickness. The power densities of electrostatic, piezoelectric, and thermoelectric transducers with evaporation differ from one another by a factor of 3^{10} or 4^{10}.

3.11.3.2 Thermoelectric Actuators

In 1979, Endo and Hara of Canon (Endo *et al.* 1977) invented the DOD method with droplets ejected

from a nozzle by growth and collapse of a vapor bubble generated by a small heater element located near the nozzle. They called it bubble jet technology. At the same time HP developed a similar technology (Vaught *et al.* 1984). They called it thermal ink-jet.

Thin resistor layers serve as heater elements. Layer t+hickness typically is about 100 nm. The heater of the first printheads of HP measured about 100 µm × 100 µm. Today's printheads need only 1% of this area. Tantalum aluminum and hafnium boride are typical materials chosen for heaters. Water- or solvent-based color solutions or pigmented versions are used as inks. The heaters reach temperatures greater than 300°C (Runge 1993). While the ink is heated, no residues should remain on the heater, as they might burn or coagulate. In some products, the heater is covered with a protective layer of quartz. The surface is highly stressed, not only thermally, but also mechanically. When the bubbles collapse, cavitation occurs, which cleans the heaters, but may also damage them.

Three types of arrangements can be distinguished: the edgeshooter, the sideshooter, and the backshooter. The edgeshooter ejects droplets tangent to the heater surface. The sideshooter contains a nozzle plate arranged in parallel to the heaters and the droplets are ejected normal to the heater surface. The backshooter contains the heating elements on the nozzle plate. The drops are ejected normal to the heater surface, but the vapor bubbles emerge on the opposite side of the nozzle plate. **Figure 10** shows the three types.

Once again, the advantage of the thermoelectric heaters is that they are small and can be arranged in close proximity to the nozzles. Their drawback is that there is a great demand on the ink and the heater. Sometimes sideshooters are also called roofshooters. Edgeshooters and sideshooters are also used for piezoprintheads if the heaters are replaced by piezomembranes.

3.11.3.3 Printheads with Thermoelectric Actuation

The process of evaporation could be observed particularly well with the first printheads. **Figure 11** shows the top view of the HP Thinkjet heater. It is a sideshooter with heating areas of 100 µm × 100 µm. Its nozzle plate has been removed. The heating elements enhance their electronic conductivity a little when the temperature rises. The coefficient is enough to make the heater serve as a sensor at the same time. After starting the pulse, the curve of the current rises slowly with increasing temperature. After 5 µs the nuclei of the bubbles multiply and after 6 µs they form a hermetic film above the heater. The vapor barrier now interrupts the heat transfer to the ink, and accordingly, the temperature of the heater increases rapidly. Therefore, the current curve bends sharply and continues more steeply (Pöppel 1990). After about 20 µs, the bubble collapses and cavitation jets starting from the corners can be detected. After about 200 µs, the initial state is reached again. Frequently, single nuclei remain, which disappear very slowly or not at all.

Figure 12 shows the design of an early Canon bubble jet printhead. Conductive patterns and heaters are applied to the silicon substrate in thin-film deposition technique. The channels and nozzles are made of photoresist. The channels are closed on top by a glass lid fixed with adhesive film. The preparing of the front edge of the nozzles was challenging. Silicon, glass, and photoresist had to be cut, ground, and lapped. Nevertheless, this head was built in great numbers.

Figure 13 shows the design of a backshooter, which was developed to the stage of a prototype. On the substrate, two series parallel converters and the end transistors were integrated on top of the nozzle plate. Therefore, only six contacts were necessary for 128 nozzles. The heaters were arranged on both sides of the nozzles. The cavity was structured by anisotropic etching. The nozzles were made by dry etching (Heinzl *et al.* 1990, Wehl 1995, Zollner 1995).

Figure 14 shows a HP ink cartridge with its contacts and the nozzle plate. It is a consumable. The number of contacts is reduced by a matrix of diodes. **Figure 15** shows a section of the nozzle plate with two rows of nozzles. The long slits in between serve to separate inks of different colors. Behind the slits, there are felt pads that absorb the mobile ink. **Figure 16** shows some nozzles more

closely. The single nozzles are slightly staggered so that the pulses can be given at different moments and nevertheless form a vertical line. The nozzle plate is electroplated. One can recognize the starting electrode, upon which the nickel has grown uniformly. The nozzles have a sharp outer edge; toward the cavity they expand donut-shaped.

Figure 17 shows the structure beneath the nozzle plate. Two rows of cavities and heaters can be seen. Behind a structure that resembles a rake, there are two tributaries to the proper ink cavity

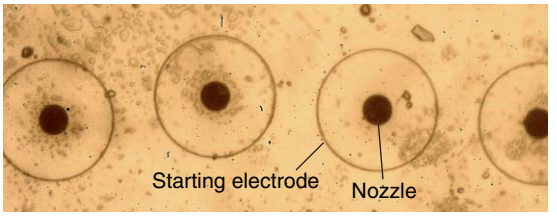

Figure 16 The nozzles. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

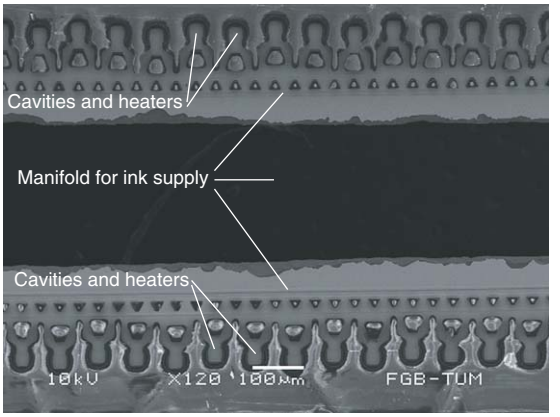

Figure 17 Heating elements and channel structure. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

with the heater. Between the two rows, one can recognize the through hole where the ink comes in.

Figure 18 shows a schematic of the new Canon PIXMA MP800 nozzle element. It is also a sideshooter. The 6000 nozzles are arranged in an area of 20 mm × 16 mm. The bubble cleans the nozzle. **Figure 19** shows the corresponding channel structure designed for the production of 1- and 5-pl drops. Canon has developed a new manufacturing technology for it. First the heater and circuit pattern are formed on a silicon wafer, after that two different photoresists are applied, exposed to light, and developed. While the first photoresist is fully leached out, the complete structure of cavities and nozzles appears on the wafer. The distance between neighboring nozzles is 85 µm.

Sideshooters are predominant in the design of printheads with bubbles because the increasing number of nozzles can be arranged in several rows close together. As we have seen, the production technology can vary. There are electroplated nozzle plates glued

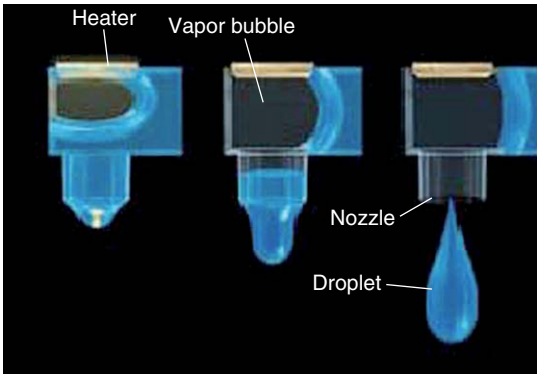

Figure 18 Canon nozzle element. (Source: Canon Deutschland, Europark Fichtenhain A10.)

to a silicon structure (HP). There are nozzle plates built with polyimide foil in which the nozzles and the cavities are formed by laser ablation in various layers. They are mounted on the structures with the heaters (Kahlert 2001). Finally, there are nozzles and cavities of photoresist, which are applied on the wafer in a batch process (Canon).

Literature describes printheads that make use of the bimetal effect. With adequate miniaturization and by using ink as coolant, the electrically actuated bimetal can react with high frequencies. Short pulses can heat it on one side and thus deflect it.

3.11.3.4 Piezoelectric Actuators

A large number of materials show piezoelectric effects. This means that mechanical stress evokes an electric charge on the surface and *vice versa* an electric charge on the surface creates a mechanical stress inside the material (Curie and Curie 1880). Seignette salt, quartz, ice, and turmaline are well known. Apart from that, there are ceramics that show excellent piezoelectric characteristics after sintering and polarizing (Ikeda 1990).

3.11.3.5 Piezoceramics

PZT (lead zirconium titanate) has a high efficiency as discussed in Section 3.11.2.1. In the following, piezoelectricity, polarization, and Curie temperature will be discussed taking PZT as an example. As long as its temperature is higher than the Curie temperature, its elementary cell consists of eight lead atoms that are situated at the corners of a cube. In the center of each of the six faces of the cube, there is an oxygen atom,

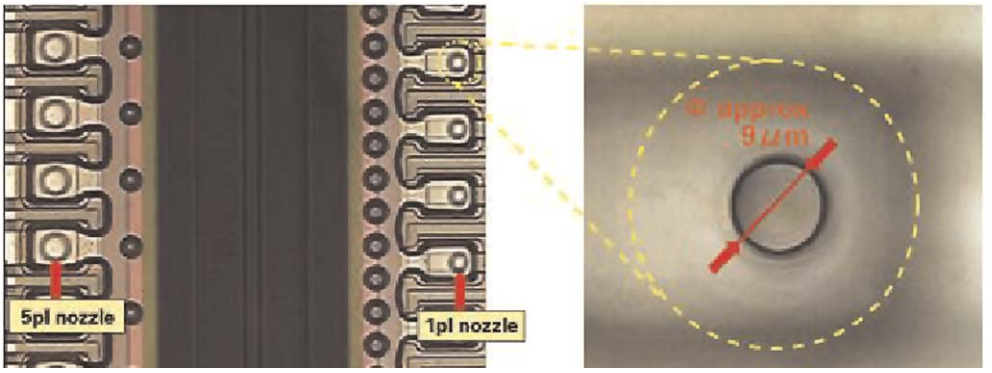

Figure 19 Canon's channel structure and heating elements. (Source: Canon Deutschland, Europark Fichtenhain A10.)

and in the center of the cube there is a titanium or a zirconium atom. In **Figure 20** this elementary cell is shown. Only one lead atom, one oxygen atom, and one titanium or zirconium atom belong to the elementary cell. The other atoms are part of the neighboring cells.

As the ceramic slowly cools down, the atoms move closer together. On reaching the Curie temperature, the central atom instantaneously fits in between the oxygen atoms. The Curie temperature depends on the mixing proportions. For PZT it is between 240°C and 370°C. The length of the cell edge is about 0.4 nm at the Curie temperature. Above the Curie temperature the elementary cell is only electrostrictive. In an electric field, the lead atoms and the central atom move relative to the oxygen atoms. The cube shape is not deformed. Below the Curie temperature, the central atom has to shift one of the oxygen atoms in order to gain space. The other oxygen atoms move closer together, and the cube is deformed into a cubic. An electric field in the direction of the shift intensifies this tendency, making the cubic even longer.

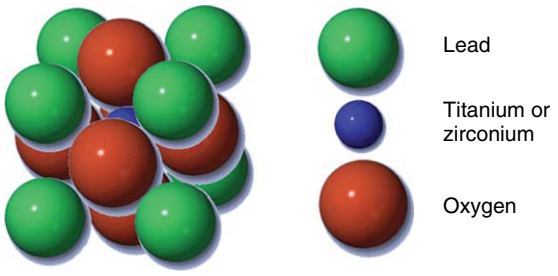

Figure 20 PZT (lead zirconate titanate) elementary cell. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

As ceramics are not monocrystallic, it consists of numerous domains. Within a domain, the elementary cells show the same orientation, but the central atoms can shift in different directions while falling below the Curie temperature. One of the six oxygen atoms must give way, so there are six different directions that can be chosen. When an electric field is applied, the distortions will compensate each other on average, and therefore there is no piezoelectric effect. Only when the distortions are oriented roughly in the same direction, the piezoelectric properties appear. This is achieved by applying a strong electric field at temperatures near the Curie temperature. Then the oxygen atom that lies closest to the direction of the field has to give way while cooling down. This process is called polarization. Electrodes are fixed to the ceramic in order to apply the voltage. The positive direction of the electric field is called direction of polarization. To avoid flashovers, the ceramic can be dipped into a transformer or silicon oil. The polarization moves the central atom to that of the six directions, which is closest to the direction of polarization. Deviations up to 54.7° can occur. If we could succeed in growing a monocrystal and in getting polarization into line with it, the effect would be far stronger. There is as well a difference between small signal and large signal reaction of the ceramic (Reiländer 2003, Wolters 2004).

To describe the directions of PZT, it has become customary to use a rectangular coordinate system with axes 1 and 2 parallel to the electrodes, and axis 3 in the direction of polarization.

3.11.3.6 Longitudinal, Diagonal, and Shear Effects

If voltage is applied in the direction of polarization, the ceramic is lengthened in this direction and thins out crosswise. These effects always occur simultaneously. They are called longitudinal and diagonal effects. If the voltage is applied in the normal direction, the ceramic will shear. A cubic is transformed into a parallelepiped. This effect is called shear effect. To achieve it, though, the electrodes for polarization must be replaced and new electrodes normal to the former electrodes must be put in place. **Figure 21** shows the middle plane of the elementary cell before (**Figure 21(a)**) and after polarization (**Figure 21(b)**) as well as the deformation in the direction of polarization (**Figure 21(c)**) and normal to it (**Figure 21(d)**), both excessively magnified. In reality, the effects are very small.

Flashover in air limits the longitudinal effect to 0.2% in the direction of polarization and the diagonal effect to 0.1% (**Figure 21(f)**) compared to the unloaded dimension (**Figure 21(e)**). In the opposite direction, only a third of these effects is usable. If it exceeds, there is a risk for partial depolarization. Shear effect can be used up to 0.2% in both directions (**Figure 21(g)**).

Piezoceramic can be used in many different ways as an actuator, as shown in **Figure 22**. The red arrows indicate the direction of motion. The longitudinal or the diagonal or the shear effects can be applied. The piezotube (**Figure 22(a)**) with its electrodes on the inner and outer circumferential surface uses both the longitudinal and the diagonal effects (Heinzl and Kattner 1975). An electric field applied in the direction of polarization can make the wall thicker and the circumference as well as the length shorter. The

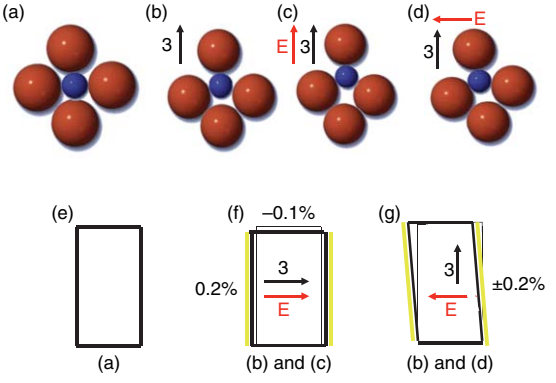

Figure 21 Middle plane of the elementary cell. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

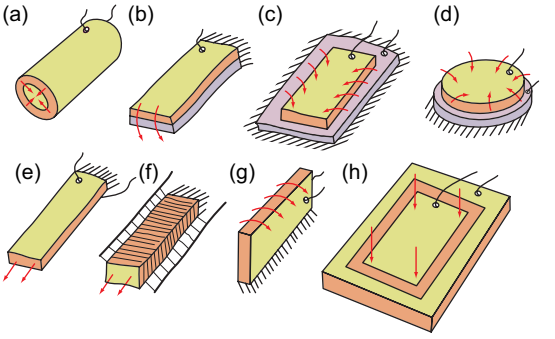

Figure 22 Piezoelements and their deformation. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

dimension can be determined in such a way that the outer diameter remains constant while the inner diameter and the length change (Heinzl 1977).

A structure of two layers of which at least one is a piezoceramic is called a bimorph. If an electric field is applied using the diagonal effect, the ceramic layer and the bimorph bend (Kyser 1981). A small strip fixed on one end acts as a cantilever beam (**Figure 22(b)**). When fixed on all sides, it acts as a membrane. This membrane can form a square, a rectangle (**Figure 22(c)**) or a circle (**Figure 22(d)**), or even a diamond. If there is a distinct distance between the ceramic and the fixation line, the uncovered part of the second layer acts as a solid-state hinge.

If you use it like a ram, either the diagonal or the longitudinal effect can be applied. To have a great dilatation and at same time low voltage, a long, narrow, and very thin cubic is selected. The large lateral surfaces can be used as electrodes and the diagonal effect can be made use of (**Figure 22(e)**). You can also make use of the greater longitudinal effect by stacking many layers upon each other, putting electrodes in between (**Figure 22(f)**). The electrodes can be contacted in such a way that the direction of the field changes from layer to layer. Such multilayer stacks are available with layers as thin as 20 µm. The art in producing these stacks consists in making the electrodes withstand sintering. This can only be achieved by using palladium and silver.

Because the electrodes for operating and polarizing are the same, polarization can be renewed if the longitudinal or diagonal effect is used. In contrast, it is not possible to renew polarization if the shear effect is used. Application of very strong voltages to the operating electrodes is likely to make the shear effect

disappear. To obtain the shear effect, there are two typical arrangements of electrodes. The first is to put electrodes on two opposite sides of a polarized ceramic wall normal to the direction of polarization. In this case, the field lines run across the ceramic, normal to the direction of polarization, thus producing the shear effect (**Figure 22(g)**). The second especially elegant arrangement is to use a thin layer of polarized ceramic, to remove only one of the electrodes completely, and to partition the other electrode. In the gap between two partitions, a great part of the field lines run normal to polarization if different potentials are applied to the different parts of the electrode (Fischbeck 1986). Then the ceramic shears all along the gap (**Figure 22(h)**). These arrangements can be operated as monomorphs.

3.11.3.7 Shock Waves and Drop Generation

As soon as a voltage is applied to the electrodes, the mechanical tension in the ceramic rises without delay. This tension tries to deform the ceramic. The inertial forces in the ceramic must be overcome. This leads to a finite speed of structure-borne sound. Besides, elasticity and inertial forces of the mechanical structures attached to the ceramic must also be overcome. And the ink must be compressed or moved. This can happen in different ways, depending on the mechanical impedances of the materials and structures involved.

If the ceramic is oversized, the ink must be considered as compressible. This was the case with the piezotubes (Wehl 1984). For the greater part, the propagation of pressure is done acoustically. Inside the tube, the pressure is imparted to the ink, and it runs through the cavity at the speed causing a sound. Every change of diameter and/or elasticity of the cavity results in a splitting: One part runs on, the other part is reflected. If the cavity opens to the manifold, the pressure wave is reflected with reversed sign. The running waves are superimposed by the reflections.

As long as the ink in the nozzle is in static condition, it reflects like a closed end. When the ink begins to move in the narrow nozzle, the impedance changes together with the increasing speed. At the beginning of a drop ejection, the cavity acts like a covered organ pipe and then changes into an open one. Drops can be formed by harmonizing the pulses with the waves running to and fro and the pressure history at the nozzle (Heinzl and Hertz 1985, pp. 113–31).

Less energy for drop ejection is needed, if the mechanical impedance of the ceramic is well adapted to the impedance of the filled cavity. The shorter the distance between the actuator and the nozzle and the fewer the changes in cross section, the less is the influence of the acoustics. The actuator then simply forces away the liquid. The actuator can then be regarded as a piston in a leaky cylinder. A change of the electrical field on the actuator results in a new balance of the piston. This balance, however, is not achieved at once. Not before the ink is forced through the nozzle and back through the manifold, can the actuator follow the balance.

Under these conditions, the mass of the piston can be neglected, and the ink can be seen as incompressible. A restrictor is placed between the manifold and the ink cavity with the actuator. It is of the dimension of the nozzle. It has to constrain the flow back to the manifold during the ejection of a drop and it has to allow the refill of the cavity in time. The restrictor can also be a sintered metal forming the cavity between actuator and nozzle (Karlinski 1999). The movement is monitored almost exclusively by forces of inertia and the viscosity of the ink. A small contribution is added by the surface energy needed to build the drop and to remove it.

The drops are formed almost exclusively by the speed that is imparted to the ink at the exit of the nozzle. The ink can only be accelerated or slowed down as long as it is inside the nozzle. As soon as it leaves the nozzle, it can only be shaped further by surface tension, which is counteracted by inertia and viscosity. If the ink that leaves the nozzle is slowly accelerated, the first and slow parts of the drop are overtaken by the faster parts. The slow parts do not move forward and so form a long tail. When the ejection speed finally slows down, the end of the drop becomes longer and thinner and is detached if that results in smaller surfaces.

Better drops can be formed if the ink is first pulled back deep into the nozzle. Inside the nozzle, the ink can be accelerated so that even the first parts of the drop reach the required flying speed. The greater part of the drop should be ejected at that constant speed. In order to separate the drop quickly, the speed of the ink in the nozzle should be reversed as fast as possible. Then the share of the ink that forms a tail is particularly small and can be attracted to the droplet by surface forces. Accordingly, the sequence of pressures applied to the nozzle should start with a short phase of negative pressure followed by a wave of positive pressure, whose duration is proportional

to the size of the droplet, and finally again a short phase of negative pressure to remove the droplet (Heinzl *et al.* 1982). This ideal pressure history can only be approached roughly for the following reasons: mostly the pulses are only monopolar, and the pressure history at the nozzle is not similar to the driving pulse. It depends on the kind of pressure propagation and the part acoustics plays in it.

3.11.3.8 Design of the Printheads with Piezoelectric Actuators

The different kinds of piezoelectric actuators mentioned above have all been used in printheads. In industrial applications, a trend toward shear actuators can be seen. Zoltan (1974) had suggested tubes, Kyser and Sears (1976) used membranes, Nilsson tried a comb with cantilever beams (Bolmgren and Nilsson 1982), Larsson (1983) used push pistons, Bartky (1989) introduced shear walls (Michaelis *et al.* 1989), and Fischbeck (1986) introduced shearing monomorphs.

Figure 23 shows design principles with tubes (**Figure 23(a)**), rectangular bimorphs (**Figure 23(b)**), round bimorphs (**Figure 23(c)**), cantilever beams (**Figure 23(d)**), push pistons (**Figure 23(e)**), shear walls (**Figure 23(f)**), monomorphs (**Figure 23(g)**), and with refill through sintered metal (Karlinski 1999) (**Figure 23(h)**).

The first ink-jet printer that entered the market in considerable numbers was the Siemens Printer Terminal PT80. It was the first to use vacuum and it contained piezotubes (Heinzl and Rosenstock 1977). **Figure 24** shows the printhead in cross section. The tubes surround cylindrical cavities that taper toward the nozzles. The tubes have a 2-mm diameter, a length of 10 mm, and a wall thickness of 0.5 mm. Thus the volume of PZT is 12 mm^3. The power that a contraction of one tube might yield is 1.5×10^{-3} J. To eject a drop, an electric pulse of only 10^{-6} J was necessary while the flying droplet contained an energy of 10^{-8} J. The tubes were extremely oversized. The vacuum was established by positioning the ink cartridge 3 cm below the nozzles. The acoustics of the long cavity were tuned by the position of the tube.

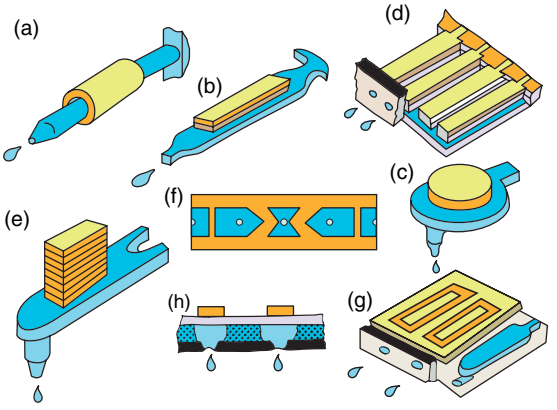

Figure 23 Different configurations of piezoelements and ink systems. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

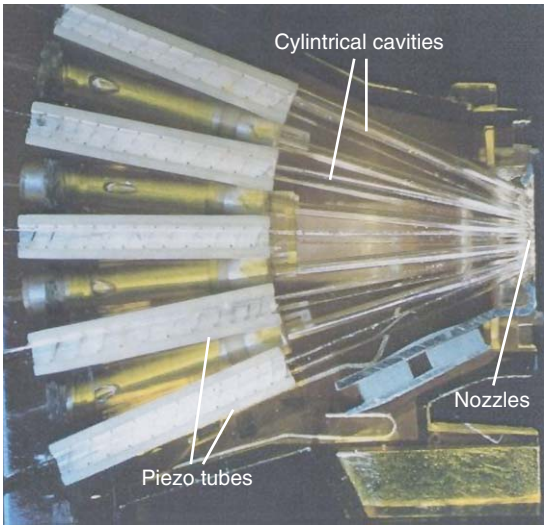

Figure 24 Cross section of the PT80 printhead. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

The bimorph membrane used by Kyser and Sears was long and narrow. The Ink Jet Technology (IJT) printhead shown in **Figure 25** has developed from it, which is an edgeshooter. The cavity structure consists of glass ceramic. To the covering above the cavities, single strips of piezoceramic are glued. Early Epson printheads are similarly designed. **Figure 26** shows two of them, the bodies formed of glass with square or round bimorph actuators. Their ink channels are differently bent to achieve an equal acoustic length. Modern Epson printheads again use lengthy bimorphs. They have succeeded in building the cavities from zirconium oxide, which can be sintered together with the piezoceramic that is formed in thick-film technology. **Figure 27** shows the printhead of the Epson Stylus 64. **Figure 28**

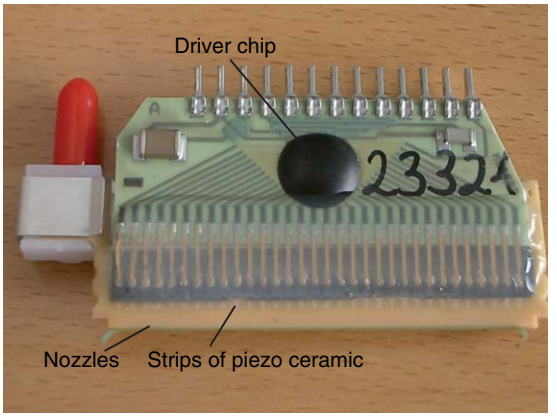

Figure 25 Ink Jet Technology (IJT) printhead. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

shows the actuators after the contacts have been removed. One end of the channel beneath the piezoceramic leads to the manifold, the other is connected to the nozzle through the substrate. **Figure 29** shows a scanning electron microscope (SEM) shot of an opened ink cavity. The PZT layer on top has a thickness of up to 10 µm. The PZT is about 2.2 mm long, and up to 100 µm wide. Altogether the volume of the PZT is 0.003 mm^3. This is less than 0.1% of the PZT of the PT80 tube. This design is realized in the present Epson desktop printers. It is not exchanged together with the disposable ink cartridge (Zhang 2005).

A whole series of printheads uses piezocombs whose teeth are fixed to the membranes covering the cavities and which are acting as push pistons. For this purpose, Epson used 20-µm multilayer ceramic produced by Philips, the Netherlands, in earlier printheads. **Figure 30** shows the design. The cavity structure is built of silicon and covered with plastic material on which the tips of the teeth are glued (Kitahara 1997, Usui *et al.* 1991). Some of these printheads are still in use for large-format printers. Instead of the longitudinal effect used by the multilayer, the diagonal effect can be used, with electrodes arranged along the teeth.

First experiments with printheads containing cantilever beams were made by Kenth Nilsson at Siemens Elema, Sweden. The tips of the teeth of a comb sawn out of a bimorph were placed directly opposite the nozzles and were bent toward them. As the electrodes were in contact with the ink, insulating inks were used. Crosstalk was a problem as well. Recently, this principle has been taken up by Tally (Beurer *et al.* 2003), and small partition walls between the cantilever beams or the teeth of the comb were introduced in MEMS technology. **Figure 31** shows an SEM picture of the inside of a prototype. The advantage of this design is the short distance between actuator and nozzle, which makes the system indifferent toward air bubbles in the ink. Nevertheless, this system did not make it to the market.

A piezoceramic cavity structure can be obtained by sawing bulk material. XAAR has developed a technology that joins two such structures. Bulk material is polarized before sawing. After sawing, the electrodes used for polarization are removed, and the straight walls of the cavities are provided with new electrodes and are contacted. In this way, the walls can be tilted by the shear effect, thus altering the volume in the channel. Nozzles are formed by laser ablation in a plastic strip that is fixed to the ends of the channels. Because narrowing one channel means widening its two neighbors, every third nozzle can only be triggered simultaneously. The others are triggered with time delay. **Figure 32** shows this design.

The monomorph with electrodes only on one side makes a somewhat different use of the shear effect, as described in Section 3.11.2.5. Spectra uses this principle in its printheads. The piezolayer covers the ink

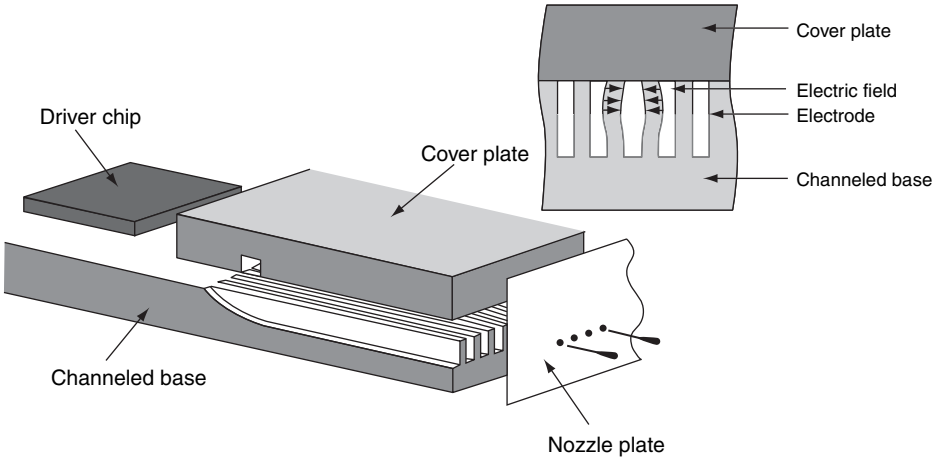

Figure 32 Design of the Xaar printheads. (Source: Xaar plc.)

channels. Above the single channels, the electrodes are separated from the surrounding electrodes by a gap. Only this rim is exposed to the shearing effect and deforms the monomorph thereby ejecting ink. Spectra attaches two rows of channels back to back, interlacing them in order to form a single row of nozzles. Spectra's most recent printheads are produced in MEMS technology offering improved resolution.

Recently Brother has announced a printhead with diamond-shaped cavities and arranged in a honeycomb pattern (Katayama 2004). The cavities are covered with a so-called monomode piezoceramic consisting of a number of layers where only the electrodes are structured.

3.11.4 Print Quality, Colors, and Halftoning

The first ink-jet printers had a pattern structure like that of needle printers. Only 9–12 nozzles composed the letters and the graphs. The distance between the nozzles was 250 µm. Along the lines, the pattern could be refined by introducing quarter steps, whereas the distance between the two neighboring dots is at least one full step. Nowadays it represents 400 × 100 dpi. Thus the slanting lines in particular could be improved substantially. The dot size was suited to the paper in a way that a black field without gaps was created when all positions of the pattern were printed. Since then, ink-jet printing has reached photo quality by increasing the resolution, by the use of three, four, or even six different colors and by applying new halftone strategies.

3.11.4.1 Resolution and Throughput

The resolutions in SOHO printers today range up to 4800 × 1200 dpi or even 5760 × 1440 dpi. The high resolution between the pattern lines is achieved by multipass printing. The printhead crosses the paper several times, each time filling more of the remaining gaps in the writing. Here it makes sense to differentiate between dpi or possible dot positions per inch on the paper (dpi) and nozzles per inch (npi) on the printhead. So a printhead with 300 npi and two rows of nozzles produces 1200 dpi between the raster lines and admitting quarter steps in line direction reaches 4800 dpi when passing the paper four times. Neighboring droplets in the same raster line are not printed at the same pass, thereby coagulation can be avoided. So the resolution in line direction at a single pass is 600 dpi. Hence, in the above example, the basic resolution is 600 × 600 dpi.

The throughput results from the number of nozzles per color multiplied by the maximum drop frequency, divided by the basic resolution, and the number of passes. So a printhead with 300 nozzles per color, a maximum frequency of 8 kHz, and 600 × 600 basic raster doing four passes can print $2''^2\ s^{-1}$ or $12.9\,cm^2\ s^{-1}$. As the printer carriage travels to and fro and needs time for changing direction, this throughput does not come to bear fully. By multipassing, the printhead can print on both ways, forward and back. The position of a dot on the paper depends on the distance from the printhead

to the paper, on the flying speed of the drops, and on the direction in which the carriage moves. Therefore, dots in the same raster line are always printed with the carriage traveling in one direction.

If a nozzle prints with a resolution of 600 dpi along the raster line and with a drop frequency of 8 kHz, it travels at a speed of 0.34 ms^{-1}. The drops fly at a speed of 6–8 ms^{-1}. Because of that the droplet and its long tail do not influence the printing quality. All parts of the droplet meet again in the same dot on the paper.

3.11.4.2 Halftones and Color

Sharp contours and clear letters are obtained by the use of quarter steps. Round and slanty contours are distinctly rendered. The difference between the possible dot positions along the lines and between the lines cannot be perceived with the naked eye, even if flat arcs follow the raster line. As for the contours, photo quality has been obtained. Halftones are more difficult to obtain in photo quality.

There are a number of ways to render halftones in a raster. You can repeatedly trigger small droplets in rapid sequence, vary the size of the drops, use inks of different degrees of saturation, and use halftoning with a fixed drop size using clusters or raster cells (Wild 1990). You can alter the distances between the droplets using error diffusion. Part of these strategies can be interpreted as amplitude modulation (AM) and others as frequency modulation (FM).

It would be ideal to produce droplets in various sizes in order to get a linear gray scale of 16 or 32 steps. Unfortunately, the variation in drop size is difficult to bring about. No more than three different drop sizes have been achieved so far. It is much easier to put together different dot sizes by superimposing varying numbers of small drops. Up to eight microdrops are in use.

If you use only one drop size, you can produce half tones by clustering, and by laying down which dots of the cluster are to be printed in every step of the gray scale. Typical strategies are Digital Halftone and Ordered Dither. Digital Halftone uses neighboring dots in the cluster, and this leads to a greater granularity. Ordered Dither separates the dots within the cluster as far as possible. The transitions in the highlights are especially critical with Ordered Dither.

Error Diffusion does without predetermined clusters. The desired levels of gray are added up along the line. When a threshold is crossed, the next dot is printed and the addition restarts. If in this strategy you only calculate along one raster line, wavy lines may cross the raster lines. Therefore you have to calculate several raster lines at a time and to distribute the dots in such a way that they are staggered in neighboring raster lines.

Normally white paper is used for ink-jet printing. The application of colored inks leads to subtractive color mixing. The colors cyan, magenta, and yellow (CMY) are used. As far as possible, dots of different colors should aggregrate on the paper without overlap. With dark colors this is only possible to a certain extent. The three basic colors can render a big part of the color gamut (Petschik 1994). However, the superimposing of the three colors does not lead to a satisfactory black, but to a brownish gray. Therefore, black has to be used as a fourth ink (cyan magenta yellow black (CMYK)). Because black is used most frequently in the printing of texts, many printers usually provide more nozzles for black than for the other three colors.

There is a major difference between color printing with ink-jet on the one hand and offset printing and laser printing on the other. This concerns registering, which is how the prints of the different colors fit together. Ink-jet printheads carry all the colors and print them in one run of the paper. Offset and laser print the colors in successive runs, thus registering is much more difficult. To avoid moiré, the color screens are slightly twisted, this leads to circular patterns and rosettes for laser printing, especially in light areas.

The difference can be seen clearly in **Figure 33**. The sample on the left side is printed with the HP Laserprinter Color LaserJet 4600, the sample in the middle is printed with the ink-jet printer HP

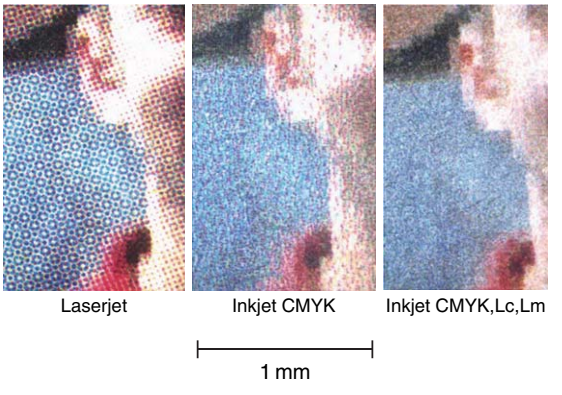

Figure 33 Enlarged samples printed by laser and four or six color ink-jet. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

Officejet 6210. Both samples used the same data. The magnification shows the effect of the different raster strategies. Error diffusion was used in the ink-jet sample and avoids the artifacts that can be seen in the laser print. A further improvement can be achieved by two additional colors. With light cyan (Lc), light magenta (Lm), and CMYK, the granularity and the roughness can be reduced. The sample on the right-hand side is printed with the same ink-jet printer, but using six colors (Allen 1997, 1998). Increasing the number of nozzles by 25% brings on smooth color transitions and low image grain.

Even on plain paper acceptable color prints can be achieved. For photo quality, special coated papers are necessary. They are available on the market in formats from 10 cm × 15 cm up to A4 and for large format as rolls with a breadth up to 60″ or 1524 mm.

3.11.5 Inspection of the Piezoceramic

In this section some instruments and methods are described that can be used to test the function of piezoactuators. The measuring of impedance, the laser Doppler vibrometer, and the SEM are useful in developing an actuator application. The registration of step responses is a powerful tool for quality control.

3.11.5.1 Impedance Measuring

Mechanical stress within the piezoceramic forms instantaneously the moment the field is applied. The transient reaction that relieves the mechanical stress starts after that. Unless hindered, it proceeds at the speed of sound. Depending on the type of ceramic, this sound speed ranges between 3500 and 5000 ms^{-1}. Therefore, the eigenfrequencies of the oscillating ceramic can be predicted easily and measured. The ceramic then acts as a $\lambda/2$ or $\lambda/4$ oscillator. The setup for measuring the electrical impedance applies a sinusoidal alternating voltage to the electrodes of the polarized ceramic and shifts through the frequency range in question. Thus, the ceramic acts as a capacitor. As soon as it enters an eigenfrequency, the amplitude response deviates, even more so does the phase response, because energy is oscillating in the ceramic.

These responses are typical for the magnitude of efficiency and damping. **Figure 34** shows the setup that can measure up to 50 MHz with low-level signal and the resonance peek on the display.

Figure 34 Setup for measuring impedance. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

A tube fixed in the middle will show two eigenfrequencies, lengthwise it is a $\lambda/2$ oscillator, within the wall it is a $\lambda/4$ oscillator. Eigenvalues of 200 kHz and 2 MHz correspond to the length of 10 mm and the wall thickness of 0.5 mm at a sound speed of 4000 ms^{-1}.

Even after the ceramic has been fitted into the printhead, eigenvalues can be measured. Of course, the eigenvalues of a bimorph cannot be calculated easily as the ceramic is fixed to a second layer. This layer, the ceramic, and the glues in between form the oscillating system. The viscosity and the thickness of the glue are difficult to predict. Although the setup measures with low-level signals, a difference can be seen between a full and an empty ink cavity. It is difficult to make these measurements on the actuators of a ready-made printhead since in most cases a serial-to-parallel converter is integrated and whose contacts would have to be uncovered first.

3.11.5.2 The Laser Doppler Vibrometer

The displacement and the motion of the ceramic can be determined by means of the laser Doppler vibrometer. **Figure 35** shows the setup. Fiber optics is coupled into the microscope. Typical deviations of a bimorph range from 10 to 40 nm. The vibrometer resolves motions as small as 2 nm of the piezoelements in one dimension.

3.11.5.3 Measurements Using the SEM

Especially with multilayer ceramic, it is of importance to test whether all electrodes are in contact or if

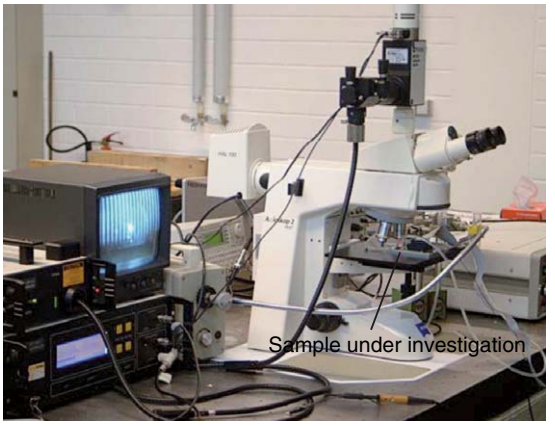

Figure 35 Laser Doppler vibrometer. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich)

electrodes between the ceramic layers are interrupted or broken. Anyone working with the SEM knows about the frustrating phenomenon of insulating materials getting charged and flaring the picture. You can profit from this phenomenon if you provide contacts to control from outside the electrodes in the SEM. **Figure 36** shows the electric field applied to the multilayer ceramic from outside the SEM. By this method, misfunctions of the electrodes can be detected.

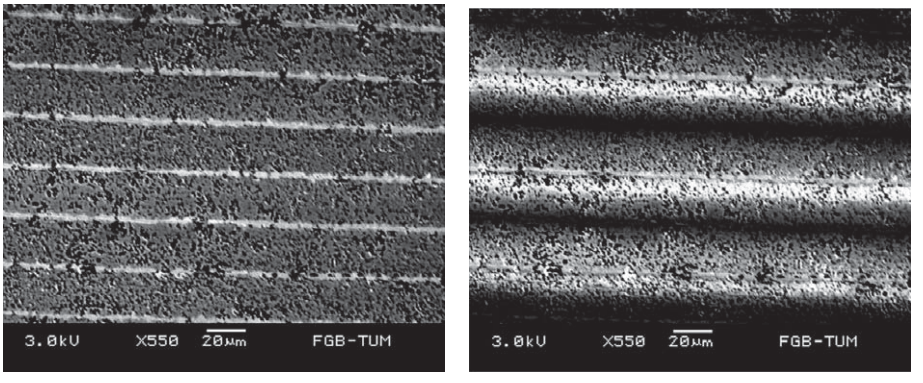
3.11.5.4 Registration of the Step Responses

The first piezotube printheads had to be provided with a potentiometer for each actuator in order to compensate the efficiency. Such an individual adjustment is no longer necessary in today's printheads. The quality of the ceramic and its processing lead to a fairly uniform function of the actuators. At most, an attenuation of the driving pulses of the entire printhead is provided. For quality control, the examination of every single actuator is recommended. This should happen before the serial-to-parallel converter is connected and before ink is filled in. For this purpose, the piezoelectric actuator can be used as a sensor. The actuator is charged slowly. After a sudden discharge, a step response can be seen at the contacts if the electrodes are disconnected from the control. The actuator oscillates and the step response shows its eigenvalues, its efficiency, and its degree of damping. Within some seconds, hundreds of actuators can be tested and their step responses can be registered (Schindler 2005). **Figure 37** shows the printout of such a protocol.

3.11.6 Examination of the Drop Formation

For the ultimate examination, a printhead prints test patterns after being installed in the printer. The patterns that are used show very quickly whether each nozzle prints as required. Helpful test patterns are also installed for the user and can be invoked on the printer. So misfire or missing nozzles can be detected easily.

To examine the formation and the flight of the drops more closely an observation setup like that in **Figure 38** is recommended. The printhead is



Ungeladen Geladen

Figure 36 Charges made visible in the scanning electron microscope (SEM). (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

fixed adjustably and single nozzles are observed. This is done with two telescopic microscopes in stroboscopic light. One of these microscopes looks at the drops in profile, the other looks at the nozzle orifice sideways. Both pictures can be seen on the monitor and can be stored.

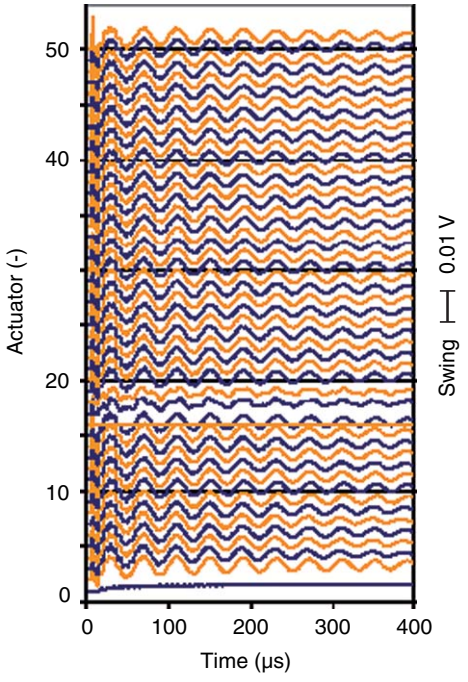


Figure 37 Step responses. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

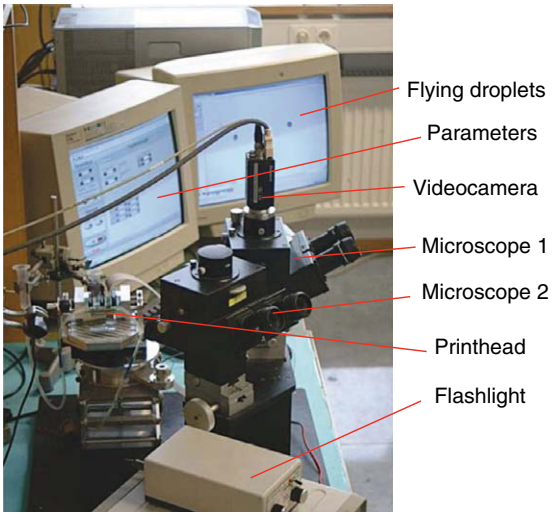

Figure 38 Setup for drop observation. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

3.11.6.1 Flight of the Drop

The profile shows the formation and the disintegration of the drops. If the frequency of the stroboscopic flash is set lower than that of the drops, one observes the drops emerge from the nozzle, disconnect, and fly on. Mostly, drops draw a long tail that disintegrates into small droplets flying at different speeds. Figure 39 shows a typical droplet on the flight. From these pictures you can conclude what the dots will look like on paper if you take into account the distance to the paper and the printing speed. Very high speeds can be achieved by arranging several printheads in series. This is interesting in applications where the printheads are stationary and only the paper moves. The more the printing speed approaches the flying speed of the drops, the more distinctly the drops with the ensuing tails show on the paper. These applications call for high-speed drops that draw in their tails on the flight.

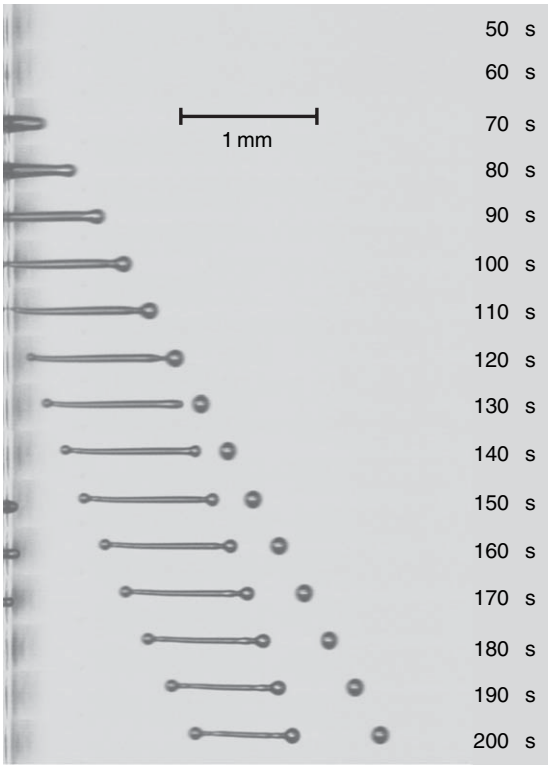

Figure 39 Flying drops. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

3.11.6.2 Formation of the Drop

The second microscope of the setup observes the nozzle. If drops that deviate from their path or slow down are detected, this second microscope starts functioning. It shows whether the flow separation is concentric to the nozzle or whether it starts at the rim. You can detect dust particles or uneven wetting. If the drop is ejected irregularly or at a low speed, air or gas bubbles inside the nozzle can be the reason. You can also check how far the meniscus is pulled back into the nozzle before ejecting the drop and how long it takes to refill the nozzle. Should the meniscus be pulled back too far, air can enter the nozzle.

3.11.6.3 Frequency Response

If you synchronize the stroboscope with the drop frequency, you get a standing picture of the drop. If you shift the time delay, you can choose in which position you want to view the drop. You can, for example, select the position in which the drop would hit the paper. If you change the frequency of the drop sequence, you see how the drops change their shape and speed in relation to the frequency of their ejection. As long as the frequency is low, the influence of the frequency can hardly be detected. The meniscus in the nozzle comes back to its starting position after every drop ejection, and its vibration dies away long before the next drop is triggered. If the sequence of the drops is increased, this steady-state position can no longer be reached completely. The vibration of the meniscus influences the following drop. The drops are faster or slower, depending on the phase of the fading vibration in which they start. If you increase the frequency further, these changes in speed increase. Eventually the drop generation breaks down, the nozzle can no longer be supplied with ink, and air enters the nozzle. If you skip these frequencies, you can find higher-frequency ranges in which drop generation works again.

For printing, a continuous frequency band is not needed, and because the drops are normally printed in a defined pattern, only discrete frequencies are needed. To make use of the full speed, you can select the required frequencies from the frequency response.

3.11.6.4 The First Drop of a Sequence and Crosstalk

In order to examine the usable frequencies in more detail, special patterns of drive pulses can be used. Most instructive are periodic patterns. In a sequence of eight drops, for example, you eject five drops in sequence and then leave a gap. You synchronize the stroboscope to the second drop and, with this pattern of five out of eight, you run through the frequency range. The distances between the second and the following drops behave as expected. Only the first drop moves to and fro, and these deviations cannot be detected from the simple frequency response, because at every frequency the meniscus has reached another stable position when the next drop comes along. The short interval within the above pattern takes it back to its stable rest position or at least near to it. Therefore, the speed of the first drop deviates from the speed of the following. In addition, it must be said that small drops are influenced by air resistance. The following drops fly in the wake of the first, so to say.

Depending on the design of the cavities and the actuators, neighboring channels can interact (McDonald and Zhou 1999). In systems with cantilever beams, this crosstalk is especially strong if the cavities are not completely separate and pressure waves can spread to the neighboring cavities. In order to examine the effect, the drop formation of a single nozzle is observed, while the neighboring nozzles are activated synchronously or with time shift throughout the frequency range.

3.11.6.5 Simulation of Drop Generation

Modern software tools allow the simulation of drop generation. For example, with FLOW 3D the motion of the actuator and the motion of the fluid can be calculated. Even the formation of drops and their flight as well as crosstalk can be included into the simulation. Seitz used a combination of two different software tools (Seitz 2003). With a fast laptop it took him more than 24 h to simulate the 250 μs from the start of the driving pulse up to the separation of a drop and the refill of the nozzle. That is about 4×10^8 times real time. He did it for the prototype of a Tally printhead (Seitz 2002, Yu and Sakai 2003).

Scheicher used SIMULINK for the simulation of the same printhead. He had to introduce some simplifications. He took into account the size and the stiffness of the actuator, mass acceleration, and the viscosity of the ink in the nozzle in the restrictors and the newly created surface. The speed and volume of the ejected drops were calculated in this manner. He found that 10 min were required for one shot. This is

in the range of 10^6 times real time (Scheicher 2004, Voigt 2002).

A version of this program was written in VisualBasic (Irlinger 2007). As a result, it took only 50 ms to simulate the 250 µs, i.e., 2×10^2 times real time. Even in this simple model, 18 parameters are involved: length and cross section of the nozzle, of the restrictor, and of the connections to the neighbors; viscosity, density, and surface tension of the ink; size and stiffness of the actuator; voltage, rise time, and length of a first driving pulse, and in some cases of a second. Such a simple model can be easily adapted to the experimental data. Speed and volume of a single drop are known to depend on voltage and length of the driving pulse by measuring as well as through crosstalk. Some of the parameters are known exactly, others approximately, and the rest is fitted to the data of a single drop known from the experiments.

The advantage of the short runs is that one can simulate not only a single shot, but also the frequency response and one can identify the sensitivity of the system from every single parameter. The calculated frequency response shows how far the system behavior agrees to the measured data. This shows that the simplifications are justified. After fixing a set of nominal values, one can vary every single parameter while all the others are kept. **Figure 40** shows a set of results. Every parameter is varied from half the nominal value to twice the value. The blue line represents the speed of the drop and the red one the volume. The scales on the *y*-axis always remain the same.

For the understanding of the behavior and for the optimization of the design in combination with the measuring of prototypes, a fast and simple model is much more helpful than the simulation in commercial fluid dynamic computer software.

3.11.7 Industrial Applications

Wherever data for production are represented in hardware – master plates, masks, molds, printing plates, negatives, etc. – to be used in the production process, sooner or later there will be a direct digital procedure without intermediate storage in hardware. Reliability, speed, and quality of the digital transformation process are decisive here. In this connection, DOD procedures play an important part. This development has only started as yet. Compared to the classical printing technologies like offset, the speed is not high enough so far. Up to now, it has been easier to replace screen printing and dosing technology. And with 3D printing, completely new production technologies arise.

3.11.7.1 Printheads for Industrial Application

Printheads are pivotal in industrial applications. Reliability and lifetime are of vital importance here (Schwartz 2002). So far thermal ink-jets have a limited lifetime and have severe restrictions as to ink. In almost every industrial application, piezoprintheads are gaining ground. Two technologies using the shear effect are to the fore, the printheads of Xaar and of Spectra, i.e., Dimatix. These printheads are available on the market and both companies support OEM applications. Besides, there are printheads from IJT, Trident, Ricoh, PicoJet, PixDro, and many others. To obtain high speed and high throughput on an industrial scale, printheads moving to and fro will be replaced by stationary printheads covering the full printing width, so that only the workpiece has to be moved. Such printheads should contain an enormous number of nozzles (Allen 1996). Obviously, a great number of companies are developing such print beams or line heads in piezotechnology (Zhou 2000, Zhou and Rensch 2001). Time and time again, there are announcements and presentations of such beams in fairs. In 2003 Panasonic announced a 600 dpi line head with 400 nozzles using a 3-µm sputtering process with a lifetime of 10 billion or more drops per nozzle. Recently, Brother has presented a line head that will be discussed later. Of course, such beams of many single printheads can be composed.

Xaar offers a whole series of printheads, which all make use of shear technology on thin walls (Beurer and Kretschmer 1997). The company's OmniDot760 in **Figure 41**, for example, uses 764 nozzles in 360 npi and distinguishes between binary mode and gray-scale mode. Its maximum drop frequency is 7.8 kHz with a maximum drop size of 40 pl and six shades of gray. In the binary mode, the drop size is 8 pl at up to 40 kHz.

The IJT head 64 ID2 in **Figure 25** contains 64 nozzles at 40 npi and it reaches 6 kHz. The piezo-actuators are glued to the layer that covers the channels. Three such printheads, slanting, can be combined for a resolution of 187 dpi and a width of 24.9 mm. In 2003 IJT Inc. was sold to DGI (Digital Graphic Incorporation), Seoul, Korea.

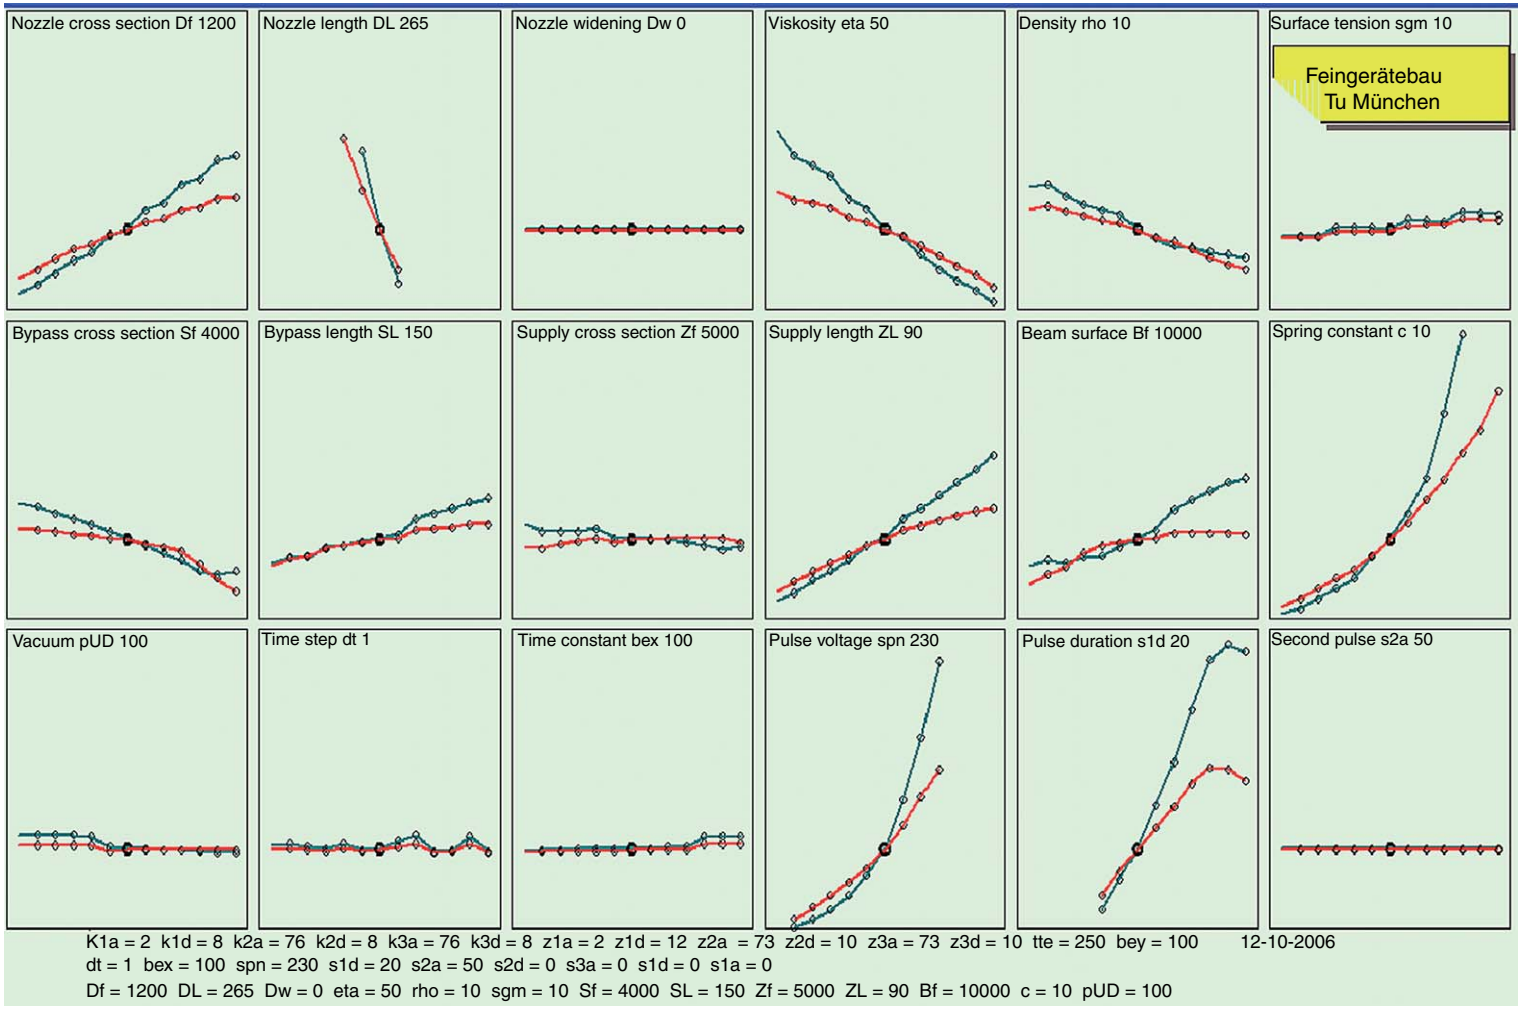

Figure 40 Simulation of sensitivity. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

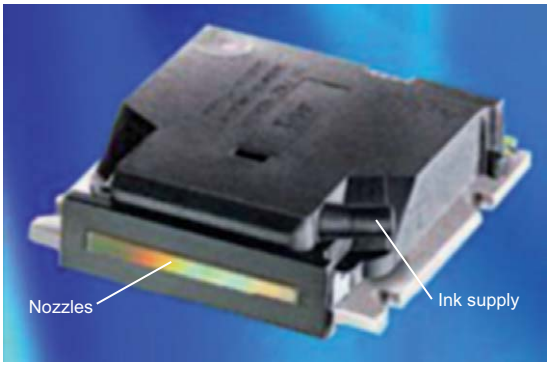

Figure 41 Xaar's OmniDot760 printhead. (Source: Xaar plc.)

Trident offers a particularly robust printhead, the dismountable 768Jet™, as shown in **Figure 42**. It contains 768 nozzles in 256 controllable channels on a length of 100.8 mm. The nozzle plate is built from stainless steel, and push pistons are used as actuators (Chen 2005, 2006, Zhou 2004).

Spectra's printheads use the shear effect. Spectra is a division of Dimatix. The piezolayer covers the ink cavities as a monomorph (Zhou 1997). **Figure 43** shows the SL-128AA with 128 nozzles at 450 npi. Drops of 80 pl fly 8 ms^{-1} at 30 kHz (Duby 2001). There are variants with 50 and 30 pl. Inks with organic solvents and UV-curable inks are used at temperatures of up to 90°C. Systems for water-based inks are also available.

Dimatix has developed monolithic printheads in MEMS technology, the so-called M-Class (Creagh 2005b, Menzel *et al.* 2004, Torrey 2005). The new M-300/10 with 304 nozzles at 180 npi creates 10-pl drops and has a gray-scale mode using multiple

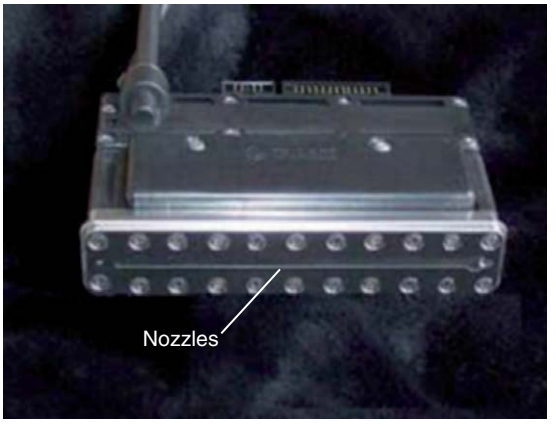

Figure 42 Trident's 768Jet™Printhead. (Source: Trident.)

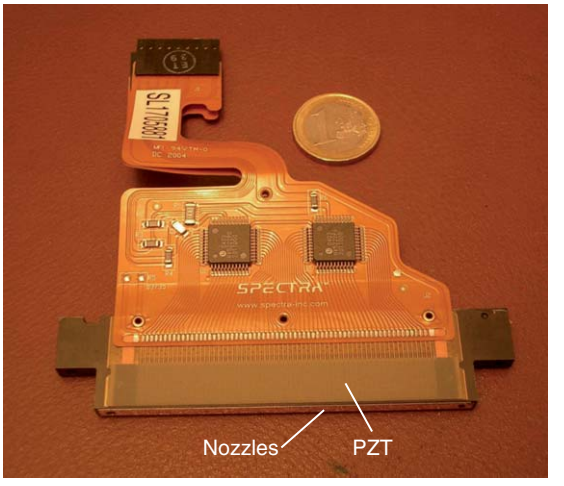

Figure 43 Spectra's SL-128AA printhead. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

pulses. **Figure 44** shows the restrictor at the end of the channel (**Figure 44(a)**), the entrances to the nozzles (**Figure 44(b)**), and a nozzle etched in silicon (**Figure 44(c)**). Dimatix offers this printhead with a complete dosing system Dimatix Material Printer DMP-2800. The printhead can be rotated to adapt to the printing pattern. DMP-2800 is shown in **Figure 45**.

PixDro's printhead PL 128 is also built using MEMS technology (PixDro 2006). As it consists mainly of silicon and glass, even corrosive fluids can be handled. The printhead contains two rows of 64 nozzles each and is piezoactuated. Drops of 6–30 pl fly at a speed of 5–10 ms^{-1} at 25 kHz. Complete systems are working for flat panel display (FPD) manufacturing, plastic electronics, glass and metal etching, etc.

PicoJet offers printheads with 256 nozzles and 300 dpi (Le 2005). The sideshooter contains 16 rows of 60 nozzles each, and is made of layers that are welded together by ultrasonics. The piezoceramic is applied from outside and does not come into contact with the ink.

Brother has presented a novel line head, the Piezo Inkjet Line Head (Hirota and Ishikura 2005, Katayama 2004, Sakaida *et al.* 2003). It was developed in cooperation with Kyocera Corp. On a length of 108 mm, 2656 nozzles are arranged. It is also built from layers of stainless steel and is welded together. The ink cavities are diamond shaped and arranged in trapezoid fields like honeycombs. The sideshooter has dimensions of

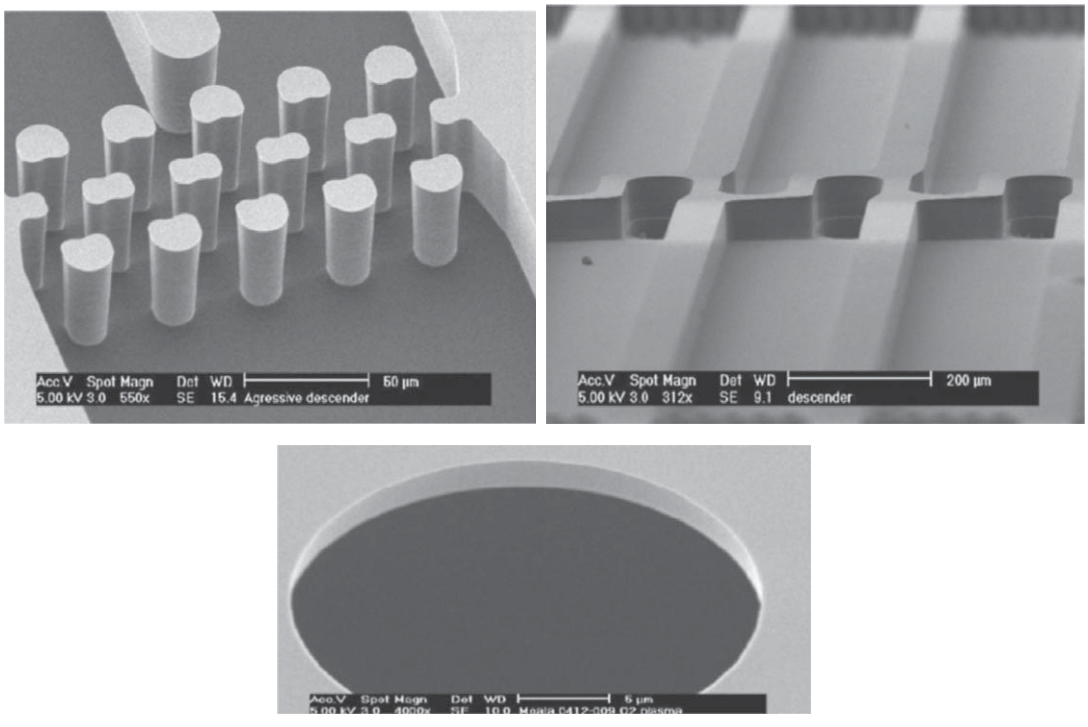

Figure 44 Scanning electron microscope (SEM) shot of the restrictor and the nozzle of M-class. (Photo courtesy: Fujifilm Dimatix.)

Figure 45 Dimatix Material Printer DMP-2800. (Photo courtesy: Fujifilm Dimatix.)

152 mm × 22 mm × 1 mm. Characteristics of 20 kHz, four different drop sizes, and a lifetime of 100 billion drops are predicted. A print speed of 0.847 ms^{-1} at 600 dpi is assumed to be possible.

3.11.7.2 Two-Dimensional Printing

With high production runs, nonimpact printing (NIP) has so far not had a chance. Conventional printing technologies like gravure printing, relief printing, and offset cannot be ignored with respect to cost and speed. Things are different for low runs and personalized printouts. Besides laser printing, color ink-jet printing is especially on the rise. At the beginning of the 1990s, the distribution according to the value of the printed matter was 15% gravure printing, 25% relief printing and flexo, and 40% offset. Following international estimates, a growing percentage passes over from offset to NIP (Kipphan 2000, p. 1019). In absolute numbers, all sectors are growing since the demand of printed matter is increasing steadily.

If ink-jet line heads can be introduced successfully, they will reach a speed of about 1.5 ms^{-1}, compared to sheet offset with 4 ms^{-1} and roll offset with up to 15 ms^{-1}. Even at present, sheet offset is competitive only for batches of 400 or more, and roll offset for batches of 4000 or more as compared to NIP. According to Kipphan (2000, p. 0108) this is true for double-sided four-color prints on A3.

But ink-jet is catching up. The Agfa Dotrix is a modular print system based around ink-jet arrays. It prints 300 dpi with gray scale in CMYK with UV-curable inks. The web width is 0.65 m and the linear

speed ranges from 5 to 24 m min^{-1} (van Daele 2005, Willis 2006). For 2007 Olympus has announced the Wep Printer OP-1 for duplex printing with 12.5″ width and 40 m min^{-1}. Fixed print head arrays print on a drum. A real-time misfire detection will be integrated (Masakawa 2006). Konica Minolta has presented a road map for a single pass printing machine for the years 2006–2008 (Corrall 2006).

Glunz and Jensen have presented an interesting application of ink-jet in offset printing. The PlateWriter™4200 produces press-ready aluminum plates for offset without the use of chemical processing. The patterns are written on the plate with special ink by an ink-jet printhead, the liquid dots are dried and bonded to the plate, and protected with a gum layer in a finishing unit. This technology can make sheet offset profitable for small runs (Beals 2004).

3.11.7.3 Wide-Format Flatbed Printers

In the wide-format market, an increasing number of ink-jet printers is offered even for printing on corrugated cardboard or other materials. On the US market, the number of newly introduced flatbed machines has doubled yearly since 2001, and you can now find more than 50 systems offered by different companies. These machines print at speeds of 40–200 m^2 h^{-1} with resolutions between 300 and 720 dpi. **Figure 46** shows a selection of European devices.

Most of the industrial wide-format printers use UV-curable inks which can produce gloss if desired. Some of them can print white inks to apply the right colors even on colored or metallic substrates. **Figure 47** shows prints on glossy golden paper with (**Figure 47(a)**) and without (**Figure 47(b)**) white underlay.

The machines print on paper, cardboard, corrugated cardboard, wood, vinyl, foam-core board, plastics, acrylic sheets, Plexiglas, glass, metal, canvas, cotton, and T-shirts. In **Figure 48** a 5-mm aluminum panel is printed on. For textile printing, a lot of new inks (Hees *et al.* 2003) and special printheads (Le 2005) are under development, and there are ideas to integrate the weaving and the printing processes (George *et al.* 2005).

In 2005 HP took over Scitex, the leading expert in large format printing. HP Scitex now offers extremely fast printing systems. The HP Scitex TJ8300 in **Figure 49**, for example, offers a multihead, DOD piezoelectric ink-jet printing with six colors (CMYK, Lc, Lm), formats up to 163 cm × 360 cm and a printing speed of 400 m^2 h^{-1} at up to 336 dpi or 100 m^2 h^{-1} at 600 dpi. The printhead Aprion MAGIC (multiple array graphic ink-jet color) is the heart piece of the machines. It is a printhead with ink supply through porous medium (Karlinski 1999, 2000). It is said to achieve 150 kHz in the laboratory.

These printheads have been used in the DReAM textile printer that was introduced in 2002 in Bergamo, Italy, in cooperation with Reggiani Macchine S.p.A., Aprion Digital, and Ciba (Nespaca 2004). Forty-two Aprion Magic PIJ printheads have been used each having 512 nozzles, with each jetting up to 35 kHz. There are 21 504 nozzles or 7.5×10^8

total drops per second (TDPS). On a breath of 1.6 m, the machine prints up to 150 m h^{-1} at 600 dpi using special inks developed by Ciba (Cahill and Ujiie 2004).

3.11.7.4 Packaging

Printing on corrugated cardboard opens a lot of possibilities to produce single pieces and small series of cartons and packages, especially in combination with cutting by laser. The speed of ink-jet printing is still far away from the speed of flexoprint, which is 4 m s^{-1}. When printing comparable widths, the fastest flatbed printers reach a mere 12 mm s^{-1} with their printheads running to and fro. This can change as soon as line heads are installed. Up to now UV inks are still much more expensive than flexoprint colors. Nevertheless, DOD promises a lot of advantages over flexoprint machines: smart and small machines, economical productions of small batch sizes, no resetting while patterns are changed, personalization and customization, thereby improved security, the length of prints independent of the size of the cylinder, no flexible printing plates, no waste of board and color, and less environmental pollution (Heinzl 2005, Springford 2004).

For a breadth of 25 mm, Jetrion offers print systems that can be used to print at a speed of 5 m s^{-1} and a resolution of 100 dpi on packaging. They are used for addressing and consist of a staggered arrangement of Spectra printheads in connection with special UV and solvent-based inks.

In 2007 Sun Chemical Digital will launch a digital printing machine Fastjet for corrugated packaging. It contains 480 Spectra printheads with 128 nozzles each. About 1 m^2 can be printed in 0.8 s and will use full-color CMYK plus varnish for UV curing (Gross 2006).

3.11.7.5 Printed Electronics

Nanotechnology allows a lot of applications in plastic electronics. Inks with nanoparticles are used to print conductor paths, to build passive components, diodes, and semiconductors (Bentley 2005, Creagh 2005a, Creagh and Schoeppler 2005, Grooten 2006, Schöppler 2006). There are many areas for applications with integrated circuits (ICs), antennas, radio frequency identification devices (RFIDs), in photovoltaics, and with batteries. In the production of FPDs with organic light-emitting diodes (OLEDs) DOD is already in use (Dirksman *et al.* 2005,

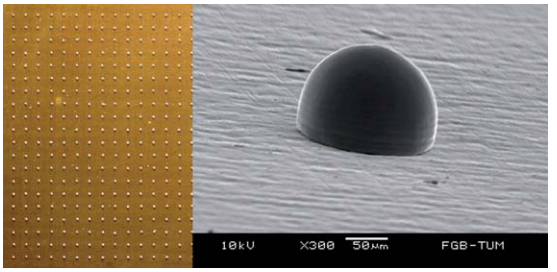

Figure 50 Printed solder bumps. (Source: Lehrstuhl für Mikrotechnik und Medizingerätetechnik, Institut für Mechatronik, Technische Universität Munich.)

McDonald 2003). One can even think of flexible displays and electronic papers (Derbyshine 2004).

Printed electronics will not compete with conventional electronics in the productions of large series. For rapid prototyping and small series, it is advantageous if there is no need for masks or stencil. This is also true for the contacts and the soldering. For single boards the solder bumps can be applied by ink-jet. Lemmermeyer and Wehl have developed a printhead for solder (Lemmermeyer 2006). There is a heater for temperatures higher than 300°C and for piezopush pistons. The tip of the ceramic is not polarized. It pushes against the membrane and separates the polarized ceramic from the hot cavity. Nozzles and contacts are under protective gas. **Figure 50** shows the printed samples.

3.11.7.6 Dosage

Wherever contact-free dosage is needed, DOD systems fit best. That applies for biotechnology and microbiology as well as for medicine, and for analytic as well as for production engineering (Sumerel 2005). The application of DOD in these fields is starting slowly. The Dimatix Material Printer DMP-200 is a good example for a universal device that can be used for applications like rapid prototyping, glass and metal etching, photoresist application, and many more.

3.11.7.7 Three-Dimensional Printing

As in 2D printing, there is a competition in 3D modeling between laser- and drop-based systems. Rapid prototyping, the possibility to produce exemplary embodiments, is developing faster toward rapid manufacturing. Besides stereolithography and laser sintering, 3D printing is gaining ground. In all these technologies the 3D body is built from horizontal layers that are stacked one upon the other and structured by laser beam or drops. In general, drop-based methods are cheaper and more versatile than laser-based ones. They are faster, less restricted as to size, and can print parts in different colors. Apart from fragile embodiments that show the geometry of envisaged construction elements and that serve as models, functional parts in the original materials and with the necessary strength are produced and used (Wohlers 2006). Three-dimensional printing even allows the printing of molds to cast metal and bone substitutes.

Z Corporation offers 3D printers for the printing of design concepts. Spectrum Z™510 offers a building volume of 254 mm × 356 mm × 203 mm with adjustable layers between 0.1 and 0.2 mm. It takes 30 s to print one layer with 1216 nozzles in four printheads. Depending on the powder used, either stiff or elastic structures are obtained (Reid 2005). The colored inks that serve as binders can be mixed and are printed at a resolution of 600 × 540 dpi (Tremblay 2005). **Figures 51–53** show the printer and print samples.

Prometal RCT offers machines that produce cast molds for metals of a size up to 1500 mm × 750 mm × 700 mm. The molding sand is mixed with a curing agent and is brought out layer by layer. The binder is printed after the layer is flattened. After finishing the last layer, the loose sand is sucked off. Then the mold can be mounted and cast. This method can produce far more complex castings than conventional methods, and time, above all, can be saved. The interval between providing CAD data for the mold and the cast is shortened – typically from 20 to 5 days

(Koewius 2005). **Figures 54–56** show the machine and cast examples.

Voxeljet Technology (Ederer 2005) offers a machine that produces plastic parts made from polymethymethacrylate (PMMA). The digital production plant VX 800 prints volumes up to 850 mm × 450 mm × 500 mm. It prints layers of 150 µm at a speed of 36 mm h^{-1}. Modified acrylic glass is infiltrated with epoxy or wax and solvents are used as binders. According to the company's indications, the resistivity is 18 MPa, strain at break is 2.9%, and Young's modulus is 1700 MPa. **Figures 57 and 58** show the machine and a digitally formed plastic part.

Figure 56 Cast mold after sucking off the loose sand. (Source: from Voxeljet Technology GmbH.)

Experiments at the Technische Universität Munich (TUM) have shown that porous bone structures made from hydroxyapatite can be printed as a green pellet with an organic binder (Pelzer 2005). The organic components are burnt out during the sintering. Living cells grow into the structure using it as a scaffold (Zeilhofer 1998). It is envisaged that patients can get personalized implants settled with their own cells and thus can be healed quickly. **Figure 59** shows a scaffold for a lower jaw.

3.11.8 Summary

DOD ink-jet technology holds an increasingly big market share in SOHO printers. In addition to that, especially piezo-driven printheads offer a great number of further applications. The great variety of designs shows that this technology continues to develop and has not yet come to an end. The mode of functioning of the different actuators and the creation of drops are discussed. Measuring methods and quality checks are described. The chapter gives an overview over the printheads available on the market and of their applications.

Biography

Born in 1940, Joachim Heinzl received his diploma in mechanical engineering in 1965 and his doctoral degree in 1970 from the Technische Universität Munich, Germany. In 1968 he joined the Central Laboratory of Siemens AG. Among other projects he conceived ink-jet printing in vacuum technology driven by piezotubes and developed it right to its line production as Printer Terminal PT 80. He held the Chair for Feingerätebau und Mikrotechnik (Precision-Engineering and Micro Technology) from 1978 until 2005. He focused on the fields of research of aerostatic bearings and ultra-precision technology, microactuators, dispensing technologies, rapid prototyping for microsystems, laser metrology, and laser processing. From 1995 to 2002 he was the First Vice President of the TUM, and at present is President of the Bayerische Forschungsstiftung (Bavarian Research Foundation). Professor Heinzl has published more than 50 papers as an author or coauthor. He has filed 90 patents at the German Patent Office as an inventor or coinventor, 44 of them have been filed internationally. In 2003 he was awarded the Aachener and Münchener Prize in recognition of his pioneering research and inventions that have led to the introduction of ink-jet printing worldwide. In 2004 he became member of Acatech (the Convent of Engineering Sciences at the union of German Academies of Sciences). In 2006 he received a honorary doctorate by the Universität Hannover in recognition of his achievements in national and international cooperations. In 2007 he was appointed Foreign Associate of the National Academy of Engineering, Washington, DC, for contributions to the worldwide introduction and the use of DOD ink-jet printers.

3.12 Automotive Applications

Nobuaki Kawahara, Research Laboratories, Denso Corporation, Aichi, Japan

3.12.1 Automotive Control Systems

3.12.1.1 Introduction to Automotive Control Systems

The basic function of automobiles is to transport passengers and objects; however, they are now expected to satisfy various additional demands. Besides meeting such demands that include ever-diversifying user needs, improvements in safety features, and environmental friendliness, automobiles are required to improve their basic functions, such as driving, stopping, and turning, to be more convenient, to have enhanced safety characteristics in the case of accidents, to preclude traffic accidents, to help relieve traffic congestion, to be more energy-efficient, and to realize clean gas emissions. To satisfy these demands, automobiles are equipped with various newly developed control systems. These automotive control systems are classified into four categories:

(1) Powertrain control systems
(2) Vehicle-body control systems
(3) Vehicle control systems (for driving and safety)
(4) Information and telecommunications control systems

Conventionally control systems were mechanical; however, with the recent advances in electronic

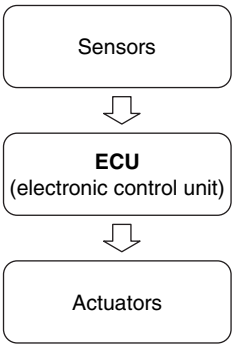

Figure 1 Structure of control systems.

technologies, the performance of these systems has been improving, providing innovative functions. Today, a control system basically consists of sensors, an electronic control unit (ECU), and actuators, as shown in Figure 1. The sensors detect many conditions and send information to the ECU. On the basis of the delivered information, the ECU performs computation to place the function into the best condition and controls the actuators. In the figure, the arrows show the direction of flow of information.

Microsystem technology has contributed to improved performance, reliability, and a lower cost for sensors. Future goals of the automobile industry must be the development of environmentally friendly cars that are capable of obtaining higher gas mileage and are safer and more comfortable. Also, these cars should be capable of receiving and transmitting the necessary information. The automotive industry is currently focusing its R&D on ultralow emission vehicles and intelligent transport systems (ITS). Microsystem technology is expected to play an extremely important role in future R&D in the automotive field, particularly in achieving higher levels of safety. The integration of microsystem technology in various devices is essential so that the system maintains a high level of reliability and mass productivity. This section discusses how microsystem technologies are used in current vehicles and will be used in future vehicles.

3.12.1.2 Microsystem Technology for Automotive Control Systems

Microsystem technology has made major progress in the past few years because of the advancement in miniature machining techniques, drastic improvement in performance due to miniaturization, and realization of new functions that could be attained only by miniaturization. With progress in electronics, microelectromechanical systems (MEMS) sensors have replaced mechanical sensors in many applications. MEMS sensors have the following advantages:

(1) Deterioration-free and durable for a long period
(2) Low cost (suitable for mass production)
(3) Small in size and easy for installation
(4) Good dynamic characteristics (high response and sensitivity)
(5) Superior impact resistance
(6) Low power consumption
(7) Self-diagnosis function

Due to these overwhelming merits, use of MEMS sensors has been naturally increasing in scale. These sensors permit sophisticated control, contributing to the improvement in the basic performance of various kinds of equipment. MEMS sensors are commonly made from silicon, which is better than mechanical sensors, due not only to the superior physical properties of semiconductor silicon but also to their compactness and light weight (essential requirements for automotive parts); in addition they have high environmental resistance and reliability.

Table 1 compares the physical properties of iron and silicon as the substrate material for MEMS sensors. Silicon is equivalent to steel in its physical properties, is precisely machined into the desired shape by semiconductor processes, has various effects for converting change in physical properties to electrical signals (piezoresistance effect, photoelectric effect, Hall effect, etc.), and enables integration in electrical circuits.

3.12.1.3 Automotive Sensors Used in Current Vehicles

The survey by the Japan Electronics and Information Technology Industries Association reveals that approximately 310 million automotive sensors were

Table 1 Physical properties of silicon and iron

	Si	*Fe*
Density ($g\,cm^{-3}$)	2.33	7.86
Young's modulus (GPa)	190(111), 130(100)	210
Melt point (°C)	1412	1534
Specific heat ($J\,g^{-1}\,K^{-1}$)	0.76	0.64
Thermal expansion coefficient ($\times 10^{-6}\,K^{-1}$)	2.6	11.8
Heat conduction ($W\,m^{-1}\,K^{-1}$)	168	48

produced in Japan during 2002, and approximately 10.26 million motor vehicles in the same year. This means that on an average about 30 sensors are installed in each vehicle. It is difficult to obtain accurate figures since the specific number of sensors installed per vehicle differs depending on the vehicle model, e.g., a recent luxury car contains approximately 100 sensors of about 70 types (Fujikawa 2004).

Table 2 lists typical automotive sensors used in current vehicles. As for the basic control functions of drive, stop, and turn, they are the largest in number, of which many are of the semiconductor/MEMS type. The detection parameters are temperature, pressure, acceleration, position/angle, rotation, flow, liquid level, vibration, and gas. The number of MEMS sensors is increasing due to the advantages mentioned in the table. In the table, the bold-faced type is a MEMS sensor.

Table 3 compares the specification for sensors used in different applications. Automotive sensors are used under severe environmental conditions: a wide temperature range, bumpy conditions, an unstable power supply, and a strong electromagnetic field.

3.12.1.4 Engine Control Systems for Automobiles

This section describes how the above-mentioned sensors are used in actual automobiles and their functions. The engine control system controls the engine power, gas emissions, energy efficiency, and other engine conditions to enable optimal operation conditions. Electronic engine control emerged in the 1970s and became common in fuel injection systems (Betta *et al.* 2004, Hirooka *et al.* 2004, Kishi *et al.* 1998, Nishida *et al.* 2005, Nishizawa *et al.* 1997, Shimoda *et al.* 2006). Recently, electronic engine control has evolved to include control of the fuel ignition system and subsystems, such as the ignition system and electronic throttle control system, sharing sensors for a single ECU.

A gasoline engine control system consists of a fuel injection system, an ignition system, and a diagnostic

Table 2 Automotive Sensors

	Application		
	Drive, stop, and turn	*Safety, conformity, and environment*	*Information/communication*
Measurement Temperature	Water temperature sensor, intake air temperature sensor exhaust temperature sensor	Oil temperature sensor, room temperature sensor, air temperature sensor, refrigerant temperature sensor	
Pressure	**Intake air pressure**, **fuel tank pressure**, **atmospheric pressure**, **combustion pressure**	**Air-conditioner coolant**, **pressure sensor**, **brake pressure sensor**

Electromagnetic environment	Bad	Good	Good	Good
Price	$1~10	$1~10	$10~100	$10~100

monitoring system as major functions, complete with subordinate functions including an electronic throttle control system, a variable cam timing system, and a knock control system (KCS). In actual operation, a gasoline engine control system measures the amount of air intake into the engine using an air flow sensor and the crank angle using a rotation angle sensor, determines whether the engine is free from knocking via a knock sensor, and examines exhaust gas conditions using an O_2 sensor, controlling the rate of fuel injection, timing of injection, timing of ignition, and timing of valve opening and closing, as shown in Figure 2. The controlled functions are thus adjusted to maintain engine power, emissions, and noise under optimal conditions. Today, fuel-efficient direct injection gasoline engines are mass-produced. For use with these engines, systems that control the direct fuel injection into cylinders are emerging. Figure 3 shows sensors used in a gasoline engine control system.

3.12.1.4.1 Fuel injection system

A gasoline engine supplies a mixture of air and fuel (gasoline) into cylinders, produces combustion, and obtains power from the thermal energy generated by combustion. The fuel injection system measures the amount of air intake into the engine and supplies the amount of fuel required for combustion. The fuel injection rate is controlled by an ECU, which calculates the amount of fuel to be injected based on the signals from the sensor that detects the amount of air intake and controls the length of time to keep the fuel injection valves (injectors) open.

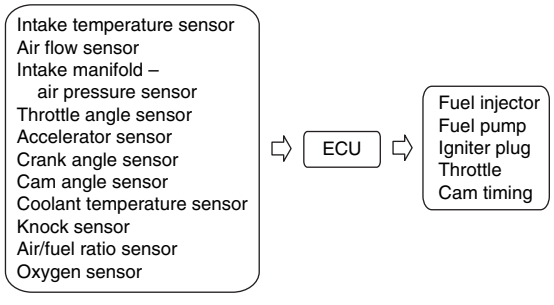

Figure 2 Structure of engine control.

There are two representative methods for detecting the amount of air intake: the mass flow method and the calculation method. The mass flow method directly measures the amount of air intake into the engine by means of an air flow meter. The thermal air flow meter, which is a typical sensor that uses the mass flow method, is able to measure the mass of air accurately even when the amount of air intake varies due to changes in air pressure and/or temperature or due to exhaust gas recirculation (EGR). The calculation method estimates the amount of air intake based on the speed of engine rotation, air temperature, and the pressure detected at the air intake pipe by the intake air pressure sensor, i.e., the manifold absolute pressure sensor (MAPS). Nevertheless, this method can measure the amount of air intake into the engine with superior response characteristics even during a period of transition, because the intake air pressure sensor is placed downstream from the throttle.

3.12.1.4.2 Air–fuel ratio feedback control

The ideal ratio by mass of air to fuel for complete combustion is 14.7:1. The lambda (λ) value (an alternative way to represent air–fuel (A/F) ratio) is 1, which is known as stoichiometric ratio. When $\lambda > 1$, i.e., when air is excessive, NO_x gases increase. When $\lambda < 1$, i.e., when air is insufficient, engine gases HC and CO, which are hazardous substances, increase in the exhaust gas. To reduce the hazardous substances (HC, CO, and NO_x), emissions are cleaned by a posttreatment process using a catalyst. Among the various catalysts that are available for this process, three-way catalysts are the most common today. A three-way catalyst simultaneously performs the oxidation reaction of CO and HC and the reduction reaction of NO_x, converting these substances into harmless substances (CO_2, H_2O,

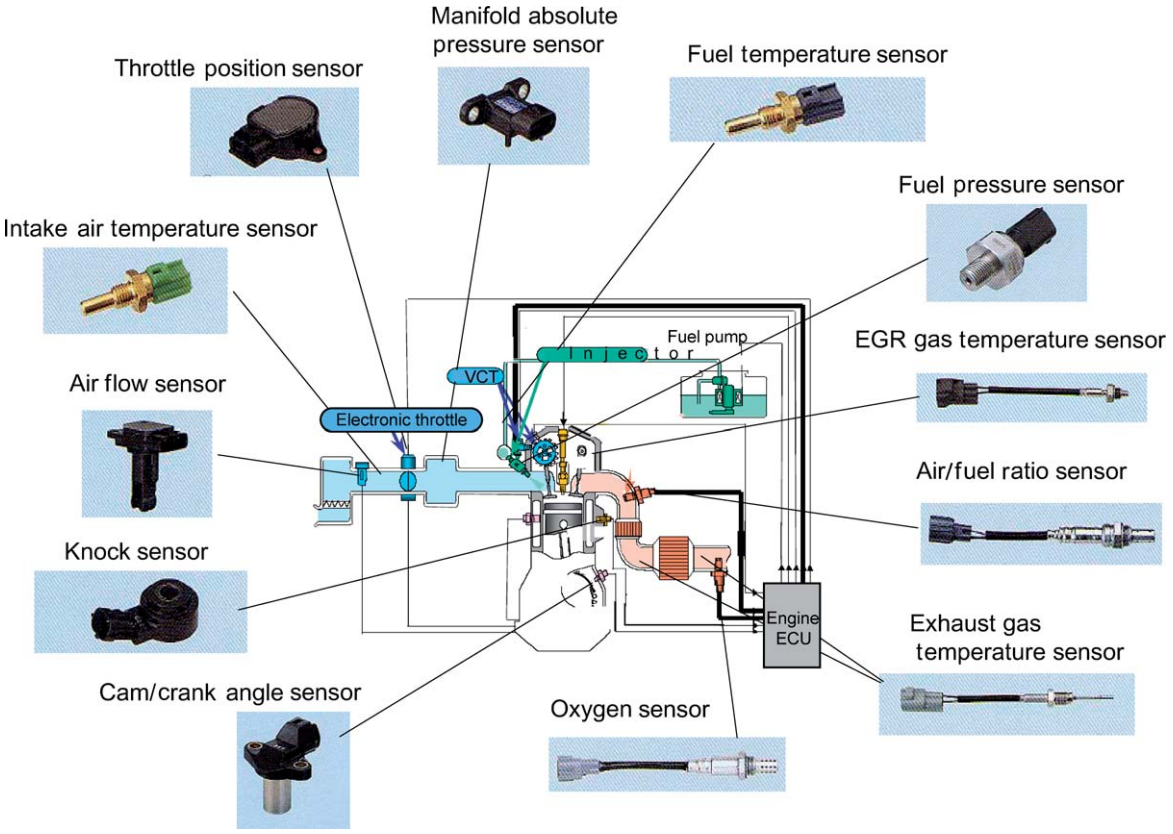

Figure 3 Sensors for engine control.

and N_2). A three-way catalyst achieves an extremely high cleaning rate when λ is controlled within a narrow range of the stoichiometric ratio. To retain the A/F ratio at $\lambda = 1$ under varying driving conditions, the A/F ratio feedback control is used. This control obtains A/F ratio information from an O_2 sensor installed at the exhaust pipe of the engine and corrects the fuel injection rate based on the signals received from the sensor.

3.12.1.4.3 Electronic spark advance system

The electronic spark advance (ESA) system calculates duration for keeping the electric power on and the timing of ignition, and outputs an ignition signal depending on the crank angle. The ESA system detects the angular position of each cylinder based on the signal of the crank angle sensor. The ECU calculates the optimal ignition timing depending on the driving conditions and sends an ignition signal to the igniter. The igniter produces high-voltage electricity in response to the ignition signal, applies it to the electrode of the spark plug, produces a spark, and burns the A/F mixture in the cylinder.

3.12.1.4.4 Knock control system

The KCS has a knock sensor installed at the cylinder block to detect engine knocking, which represents anomaly burning, as mechanical vibration. When the sensor detects vibration, it outputs electric signals. The output signal passes through a filter, is converted into voltage by an analog–digital converter, and is detected in the form of voltage. The KCS determines whether the engine is knocking or not based on the difference in the voltage level between when the engine is knocking and when it is not. Accordingly, the KCS delays or advances the timing of ignition. Because a single knock sensor is used to check multiple cylinders for knocking, the sensor is positioned at an optimal location.

3.12.1.4.5 Electronic throttle control system

The electronic throttle control system determines the throttle opening by means of the engine control computer (i.e., ECU) based on the degree to which the driver depresses the accelerator pedal (i.e., according to the accelerator opening) and

controls the throttle valve to the determined opening. The control system determines the amount of air intake into the engine by controlling the throttle opening. The throttle valve is operated by means of a motor based on the signals from the ECU, and the data of throttle opening are fed back to the ECU by the throttle sensor. The electronic throttle control system can directly control engine output (the amount of air intake) by controlling the throttle opening. The system takes advantage of this feature, and, accordingly, has many functions, such as engine power control based on accelerator opening (determining the throttle opening by considering acceleration based on the accelerator opening specified by the driver), idling speed control (control of throttle valve opening to realize the ideal idling speed, which is determined in advance based on the engine's driving conditions, such as warm-up conditions and accessories' load-carrying conditions), control of torque produced at the time of automatic transmission gear change (engine power control to reduce shock or an abrupt change of torque at the time of gear change), maximum speed limit control (controlling vehicle speed increase beyond a previously set speed by closing the throttle valve to lower engine power), cruise control (controlling engine power to enable the vehicle to continue at a constant speed after the release of the accelerator pedal), traction control (engine power reduction for preventing the slipping of driving wheels), and vehicle stability control (VSC) (engine power reduction for preventing the slipping of driving wheels).

3.12.1.4.6 Diagnosis system

Vehicles are expected to have increasingly sophisticated failure resistance and safety performance; therefore accurate diagnosis is becoming increasingly important. The purpose of the diagnosis is to ensure vehicle safety and to prevent the emission of gas whose quality has deteriorated because of a failure. A diagnosis system detects a fuel leak to preclude a vehicle fire and indicates a deteriorated catalyst, thus preventing aggravated gas emissions. The diagnosis system has a computer (ECU) on the vehicle that self-diagnoses the vehicle in real time. The system checks that the catalyst has not deteriorated in cleaning performance; how frequently an ignition failure occurs, such as the firing failure of the A/F mixture; in what cylinder or cylinders such an ignition failure occurs; that the O_2 sensor has not deteriorated or is functionally abnormal; that the feedback of the A/F ratio is not hindered for any reason including low fuel pressure; that other sensors and actuators are normal; and that any circuit is not disconnected or short-circuited.

3.12.1.5 Air-Conditioning System

There are various onboard heating, ventilating, and air-conditioning (HVAC) systems, such as heater, cooler, manual air conditioner, and automatic air conditioner. This section focuses on the automatic air conditioner, which enables the most advanced control. Today's automatic air conditioner uses a microcomputer, and a passenger can obtain a more comfortable environment by a simple operation, while the conditioner actually performs all highly complicated adjustments (Kataoka *et al.* 2005, Sugi and Yamanaka 2005).

The basic functions of the automatic air conditioner are cabin temperature control (output air temperature control), fan speed control, air distribution control, fresh or recirculated air control, and humidity control (dehumidifies the air for demist). To realize these functions, a number of sensors are used to provide input to the ECU, as shown in **Figure 4**.

3.12.1.5.1 Sensors in air-conditioning system

The temperature sensors include an ambient temperature sensor, a cabin temperature sensor, an evaporator temperature sensor, and a water temperature sensor. They are usually thermistor devices. The

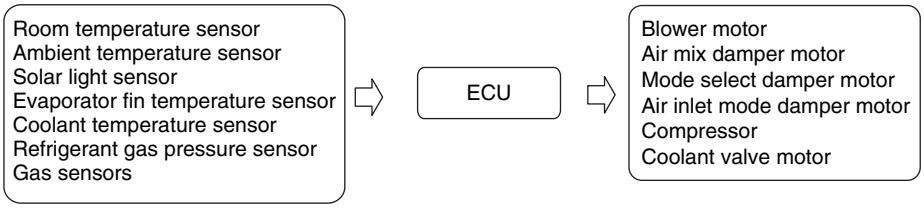

Figure 4 Structure of air-conditioner system.

cabin temperature sensor is used for detecting the average air temperature in the cabin and for allowing an accurate reading; a small fan is used to lead sample air to the sensor. The evaporator sensor is used for detecting the cooling capacity. The water temperature sensor is installed at the engine cooling water outlet for detecting the maximum heating capacity. It is also used for warm-up control to prevent the output of cold air when the engine cooling water, which is used as the heat source at the time of starting up the engine in winter, is not sufficiently warm. The intake air is cooled by means of an evaporator. The blower then adjusts the air volume, and the air mix damper adjusts the ratio of the air that is allowed through the heater core and the air that is not to control air temperature. The heater–cooler switch damper controls the air output opening. To raise the temperature in the cabin area, the air is output from the opening at the passenger foot level; to lower the temperature, the air is output from the opening at the passenger face level. In addition, the differential switch damper uses the air conditioner to ensure clear vision.

A solar light sensor that consists of a segmented photodiode and a window is located on a dashboard and detects the direction and strength of sunlight. When the sunlight shines directly on the driver, the ECU tries to increase the cooling capacity on the driver's side, i.e., tries to increase the air to the driver's face vents and to lower the temperature of the wind. This requires independent controls for the driver's side and for the passenger's side. Control systems that allow the temperature of the air conditioner to be set separately between the driver's seat and the passenger's seat are becoming common.

Gas sensors detecting CO and HC are located outside of the cabin. When these gases are detected and fresh air is introduced into the cabin, the ECU switches fresh/recirculation damper. An air quality sensor that detects diesel exhaust fumes emitted from trucks and the like is installed at the outside air intake of the air conditioner, and when exhaust fumes are detected, the fresh/recirculation switching damper is activated, shifting the fresh air mode to the recirculation mode (Honda *et al.* 2001). New systems that control humidity besides controlling temperature are also emerging. They improve the thermal comfort in the cabin while improving energy efficiency.

The refrigeration cycle of a vehicle air conditioner consists of a compressor, a condenser, an expansion valve, and an evaporator. Refrigerant is circulated in this sealed circuit (cooling cycle), thus transferring heat from the low-heat source (air in the cabin) to the high-heat source (outside air). This mechanism is called vapor compression refrigeration system, which is the most common refrigeration system used in many applications, such as room air conditioners and compact refrigerators. As part of compressor control, this system has the function of detecting excessively high or low pressure by means of the refrigerant pressure sensor and by turning off the compressor. To ensure comfort, the compressor of an automatic air conditioner is always on. Some automatic air conditioners automatically turn off the compressor when the cooling function is not in use, realizing energy saving and economical compressor control.

3.12.1.6 Air Bag System

Besides seat belts, air bags are the most common passenger protection equipment. Air bags are stored in the steering wheel and in the instrument panel. They instantaneously inflate at the time of a frontal collision, offering additional protection for passengers in combination with seat belts.

An air bag consists of a sensor that detects a frontal collision, an ECU that decides whether to deploy the air bag or not based on the signal from the sensor, an inflator that produces gas, as shown in **Figure 5**, and a bag that inflates to protect the passenger and the driver. When the vehicle decelerates due to a collision, the sensor detects the deceleration. This sensor is an electronic accelerometer. The ECU decides whether to inflate the air bag or not based on the waveform obtained at the time of the collision. A sensor may detect vehicle acceleration whose

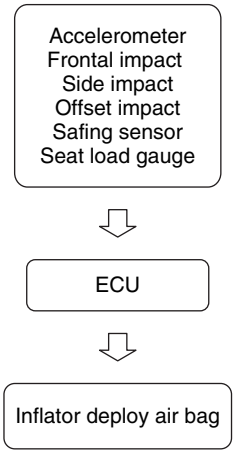

Figure 5 Structure of air bag system.

impact compares to that of a collision, such as when the vehicle collides against a curb, when the vehicle is trapped by a hole on the road, or when the vehicle is hit by a hammer in a service shop. To prevent erroneous air bag inflation in these cases, whether to inflate the bag or not is decided based on the waveform of the signal instead of the threshold value of a sensor signal. It prevents the erroneous inflation of the air bag because this may block the driver's vision and induce panic, possibly causing an accident. The waveform used to make this decision at the time of a collision is determined individually for different vehicle models, because the waveform is influenced by body strength and equipment.

When the ECU decides that an air bag should be inflated, ignition current is supplied to the inflator, the igniter ignites the gas generator material, and the generated nitrogen gas inflates the bag. This process from collision to bag inflation should be completed in tens of milliseconds before the driver's upper body hits the steering wheel. After the air bag has been inflated fully, gas is slightly removed to reduce surface pressure to absorb the shock that the driver and the passenger receives. In case the ECU is not supplied with power by the battery due to the disconnection resulting from the collision, the ECU is provided with a backup capacitor.

Safety features are increasingly in high demand in the market nowadays, and to satisfy such demands, various air bags have been developed in addition to the air bags for frontal collisions (Kamiji 2003). For side collisions, side air bags and curtain air bags are available. A side air bag protects the chest of the passenger, while the curtain air bag protects the head. The side air bag is inflated from the side of the seat, and the curtain air bag is inflated between the side window and the head of the passenger in the front seat (Summers *et al.* 2005). Curtain air bags for rear seats are also in practical use. Knee air bags, which inflate from below the instrument panel to protect the passenger's legs, are also available.

As for accidents involving children seated in the front passenger seat, the child may become injured due to bag inflation pressure when the child is not restrained by a seat belt, when the child's seat is not correctly installed, or in other situations. In some cases the air bag has blown away the child and the child's seat. As an improvement measure to prevent such accidents, some air bags are designed to inflate more slowly when a collision occurs while the vehicle is being driven at a low or medium speed. As another measure, the air bag is designed not to inflate when a child or a child's seat is detected. Among the various methods that have been publicized to detect a child or a child's seat, the method of providing the seats with a load meter and measuring the weight to distinguish a child from an adult is the most common. It is expected that the cabin will be provided with a camera or another sensor in the future, to enable more delicate control.

3.12.1.7 Antilock Brake System

The antilock brake system (ABS) ensures the vehicle's steering control, shortens the braking distance, and prevents abnormal tire wear by preventing the wheels from locking during braking (Hou and Zhuoping 2003). When the brakes are applied while the vehicle is in motion, the tire's rotation speed (wheel speed) decreases, decelerating the vehicle. Normally there is no difference between the vehicle speed and the wheel speed, but on a slippery road surface, a difference may be generated. This phenomenon is called a slip, and the value that represents the size of the slip is called slip ratio, which is calculated by dividing the difference between the vehicle speed and the wheel speed by the vehicle speed, namely ((vehicle speed – wheel speed)/vehicle speed). The ABS controls the brakes to maximize the friction coefficient using the slip ratio.

An ABS consists of wheel speed sensors provided for individual wheels, an ECU that obtains the slip ratio and calculates the signals that will adjust the slip ratio to an adequate value, and an actuator that sets the brake pressure based on the signals from the ECU, as shown in **Figure 6**. Wheel speed sensors are normally magnetic sensors. A sensor with a built-in magnet is placed in opposition to the teeth of the rotor of the axle, detecting the projections and depressions of the rotor teeth. Rotation speed can be obtained depending on the numbers of the

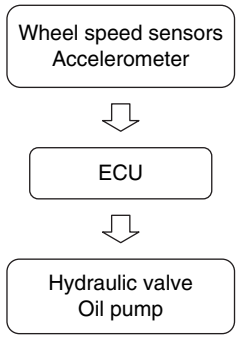

Figure 6 Structure of ABS.

projections and depressions detected during a unit period of time. The ECU calculates a virtual vehicle speed, namely, an ideal deceleration pattern, based on the signals received from wheel speed sensors. Because the simultaneous locking of all four wheels should be prevented, some systems have an accelerometer to correct vehicle speed by measuring deceleration. Because each wheel is provided with a wheel speed sensor, the slip ratio of each wheel can be obtained separately. The ECU sends signals to the actuators to realize the slip ratio that will maximize the friction coefficient. More specifically, if the slip ratio is large, the ECU sends signals to reduce the hydraulic pressure of the brakes, lowering the slip ratio of wheels. If the slip ratio does not lower sufficiently because of the residual hydraulic pressure of the brakes, the ECU sends rapid deceleration signals. When the wheel speed has lowered almost equal to the vehicle speed and the slip ratio has also sufficiently lowered, then the ECU sends pressure-increasing signals. Simply speaking, the ABS performs pumping braking at high speed in the place of the driver. The actuator consists of a valve controlling hydraulic pressure, a reservoir, a pump, and accessories. The ABS is becoming common, as an increasing number of people are becoming conscious about safety (Lu and Chan 2004). An ABS is provided in almost 100% of vehicles and is widely recognized as a common safety feature.

3.12.1.8 Stability Control

In addition to the ABS, which ensures stability when the vehicle is under braking, a traction control system (TRC) is the system that is used mainly to ensure stability when the vehicle is under acceleration after the accelerator has been applied. These are VSC systems in the longitudinal direction. These days, there is a stability control system that ensures vehicle stability while it is cornering via the steering operation (Aga 2004). Normally, a vehicle makes a turn stably at a curve as the driver steers the wheel, but when the road surface is slippery, when the vehicle speed is extremely high, or when the vehicle is making a sharp turn, the front wheels or the rear wheels may skid. In such a case, the stability control automatically controls the engine power and brakes, relieving the skid and ensuring stability. Unlike the ABS, the stability control system does not have a single designation, and can be called a VSC system, a vehicle dynamics control (VDC), or an electronic stability program (ESP) (Liebermann 2004). These systems are developed into a more sophisticated system, which controls complicated vehicle dynamics and realizes safer driving.

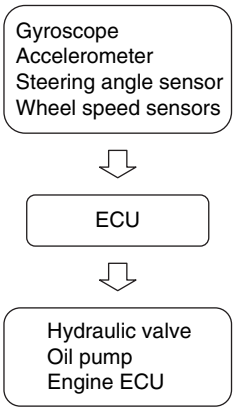

Figure 7 Structure of VSC.

The VSC system consists of a gyroscope, an accelerometer, a steering angle sensor, a wheel speed sensor, an ECU, and a brake actuator as shown in Figure 7. The vehicles skid on a curve in two modes: vehicle spin and drift. The ECU determines whether the skid occurs based on the signals from the sensors in either mode. The ECU initially calculates the angular velocity of the vehicle under no-skid conditions and the lateral acceleration generated by a centrifugal force and applied to the vehicle, based on the signals received from the wheel speed sensor and steering angle sensors. The ECU then determines whether spinning and/or drifting occurs or not, receiving the signals of the vehicle's actual angular velocity from the gyroscope and the signals of the centrifugal force the vehicle is actually exposed to via the accelerometer. When the vehicle has a strong tendency to spin, the system applies the brakes to the front and rear wheels running on the outside of the corner, producing yaw moment toward the outside of the vehicle, thus depressing spinning. When the vehicle drifts, the system limits engine power and applies the brakes to the front and rear wheels to slow down the vehicle, restoring grip to the front wheels. The construction of the brake actuator is almost the same as that of the ABS. The VSC changes the balance of the braking force between the right-hand side and left-hand side. According to some literature, the VSC is highly effective in reducing the number of serious accidents. Apart from air bags and ABSs, VSCs are expected to become a standard safety component in all vehicles.

3.12.1.9 Adaptive Cruise Control System

The cruise control is a system that maintains vehicle speed at a given level. The adaptive cruise control (ACC) system enables the vehicle to maintain a certain distance from the vehicle directly in front. This system is a representative system that will realize the automatic operation of vehicles in the future.

The ACC consists of a radar sensor that measures the distance between the ACC-built vehicle and the vehicle in front, the wheel speed sensor that determines the speed of the ACC-built vehicle, and the ECU. The ACC controls the engine, transmission, and brakes, but the ACC does not have its own actuator and so it controls them indirectly, sending signals to the ECUs of each component as shown in **Figure 8**. The radar sensor of the ACC can be a laser or a microwave radar (Furui *et al.* 1998, Tokoro *et al.* 2003). The measurement principle of laser radar is that the radar emits a laser beam from the front of the vehicle, and the optical reflection from the object in front is received by a photodiode. The time of flight (TOF) of the laser beam is measured to determine the distance between vehicles. The laser beam has a wavelength in the near-infrared region and is invisible to the human eye. An exclusive integrated circuit is provided to measure the extremely short period of time in the nanosecond range between beam emission and reception. The laser beam scans it both horizontally and vertically. The scan angles and periods are calculated to detect any vehicle in front, the position of the vehicle (in the same lane or adjacent lane), the distance up to the vehicle, and the relative speed. The principle of the microwave radar is basically the same as that of the laser radar. The wavelength of microwaves is about 77 GHz, and the target object that is to be detected by the microwaves is the body of the vehicle in front. In the case of the microwave radar, the emitted microwaves do not scan the object; they are emitted at a wide angle and a phased-array antenna functions as the receiver of the reflection, thus realizing angular resolution. Microwave radars are superior in bad weather conditions like fog or rains and laser radars are more economical.

The current ACC is for cruise driving, but a new radar-based system has been developed to follow vehicles in a traffic jam. In addition, the radar-based precrash safety (PCS) system has been developed to reduce damage resulting from a collision. A system equipped with both a radar and a camera has been publicized recently, enabling sensing of integrated image information and distance information. These new systems are expected to significantly improve the convenience and the safety of automobiles.

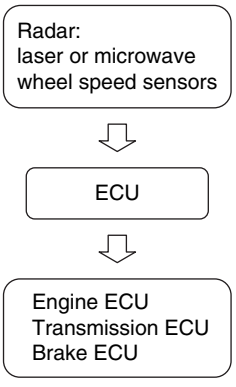

Figure 8 Structure of ACC.

3.12.2 Automotive Sensors

There were no electronic sensors in vehicles in the 1950s. All the components were mechanically controlled. MEMS sensors are very useful for satisfying automobile requirements, which realize new functions such as high-speed operation, fast response, self-diagnosis, compact and lightweight devices, low power consumption, long life, and cost efficiency. Hence, MEMS sensors were first used on vehicles in the 1980s, and have since become common. This section describes typical automotive sensors, such as the accelerometer, pressure sensor, gyroscope, and air flow sensor, as well as the most recent air quality sensor and laser radar.

3.12.2.1 Accelerometer

An accelerometer detects the impact to which the vehicle is exposed and the inclination of the vehicle as it accelerates. More specifically, an accelerometer is used with many control systems such as air bag systems, ABSs, stability control systems, navigation systems, and security systems. Concerning air bag systems, the acceleration at the time of a collision differs between a frontal and a side collision, and depends on the rigidity of the vehicle body. Therefore a sensor is required to sense gravitational acceleration (g) in the range of tens to hundreds of g ($1\,g = 9.8\,\mathrm{m\,s^{-2}}$). As for navigation systems and security systems, the inclination of the vehicle is

identified as changes in gravity, so that the sensor is required to be able to detect a range below 1 *g*. Accelerometers are now becoming common with the dramatic spread of air bag systems.

There are two typical detection methods for MEMS accelerometers: the piezogauge method and the capacitance method. Accelerometers using the piezogauge method started to be used on automobiles in the late 1980s (Payne and Dinsmore 1991, Sulouff 1991). As a result of the evolution of fabrication technologies, accelerometers using the capacitance method were first used on automobiles in the late 1990s. **Figure 9** shows the transition of typical accelerometers actually used on automobiles. In 1989, the sensor was large, with the piezogauge sensor element and circuit packaged in a can. As fabrication technologies advanced, it became possible to reduce the chip size, and the sensor size was drastically reduced. To reduce cost, ceramic packages emerged. Since the late 1990s, fabrication technologies advanced further; for example, the dry process replaced the wet process and surface micromachining technology was introduced. As a result, it became possible to reduce the chip size even further, enabling the size reduction of sensors. The detection method also changed from the piezogauge method to the capacitance method (Marek *et al.* 2003, Offenberg *et al.* 1996). Compared with the piezogauge method, the most important advantage of the capacitance method is that it has a self-diagnosis function that generates virtual acceleration, realizing extremely high reliability. Many accelerometer-equipped systems are safety systems, such as air bags, ABS, and stability control. A failure of the accelerometer means that these systems do not operate in an emergency, resulting in critical failure, i.e., failure in protecting passengers and accidents. For this reason, sensors using the capacitance method with a self-diagnosis function have become common, replacing those with the piezogauge method. Sections 3.12.2.1.1 and 3.12.2.1.2 explain the piezogauge method and the capacitance method, respectively.

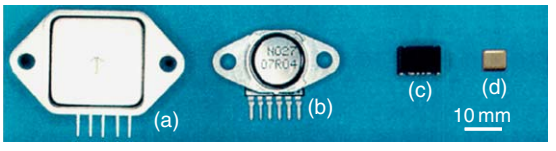

Figure 9 Transition of accelerometer; (a), (b), (c) are a piezo-gauge type, and (d) is a capacitance type.

3.12.2.1.1 Piezogauge-type accelerometer

Semiconductor materials change electrical resistance significantly depending on the strain applied. Among such materials, single-crystal silicon is advantageous because it is superior in reliability and because piezoresistors can be easily formed in the silicon by means of diffused resistance technology, which is used to fabricate integrated circuits. **Figure 10** outlines the structure of the sensing element used in the piezogauge method. The silicon substrate is fabricated to form a mass, and four beams support the mass, the beam being provided with piezoresistors. When acceleration is applied in the direction perpendicular to the substrate, the force of inertia displaces the mass. The amount of strain on the beam due to mass displacement is detected by measuring the changes in the piezoresistors. One of the piezoresistors is provided on the mass side of the beam and the other on the substrate side of the beam. As an example, if the mass is displaced upward from the substrate, the piezoresistor on the mass side receives tensile strain and the piezoresistor on the substrate side receives compressive strain. The tensile strain and the compressive strain increase resistance in one direction and decrease resistance in the opposite

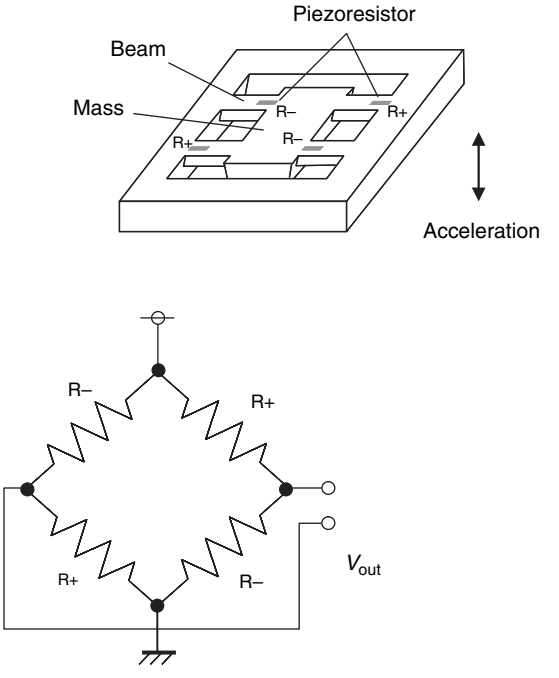

Figure 10 Outline of sensing element and circuit of piezo type accelerometer.

direction. Therefore, a bridge circuit configured as shown in **Figure 10** enables the detection of the change in resistance by doubling it. One problem with respect to piezoresistance detection is that piezoresistance is susceptible to changes in temperature. However, in principle a bridge circuit as shown in **Figure 10** enables piezoresistance detection independently of changes in temperature.

The following summarizes the production process of this structure. In a single-crystal silicon substrate, impurity ions are implanted, piezoresistors and wiring are formed by activation annealing, and aluminum pads are formed by sputtering. The pattern of the beam and the mass is formed on the front surface of the substrate by dry etching.The beam and the mass are formed by anisotropic etching on the backside of the substrate as the final process. Because the third power of the beam's thickness is proportional to sensitivity of this structure, careful control of the thickness is critical. Therefore, etching should be extremely precise to meet the tolerance of thickness.

3.12.2.1.2 Capacitance-type accelerometer

The advantages of the capacitance method are that it is, in principle, independent of temperature change and that it has an actuator function that produces electrostatic force when voltage is applied. **Figure 11** shows the structure of the sensing element using the capacitance method and also with the cross-sectional view of the element. The mass and the beam that support it are formed in the silicon substrate. The mass is provided with comb electrodes that have the function of capacitance. The comb electrode consists of a movable electrode connected to the mass and a fixed electrode connected to the substrate. The two electrodes are placed in opposite directions, producing capacitance. When acceleration is applied in the direction parallel to the substrate, the mass is displaced, whose displacement is determined depending on the spring constant of the beam. As a result of mass displacement, the distance between the movable and the fixed electrodes varies, changing the capacitance and detecting acceleration. Regarding fabrication dimensions, while the wet process used for the piezogauge method is in the range of 10 μm, the dry process has enabled fabrication in the extremely fine range of a few microns. The beam, the mass, the movable electrode, and the fixed electrode are formed in one body of single-crystal silicon or polycrystalline silicon. The silicon operates both as the physical structure and as the electrical wiring. By applying voltage between the fixed electrode and the movable electrode to this structure, the electrostatic force actuates the mass. The displacement is measured by the same electrodes as the change in capacitance, thus performing self-diagnosis. If the beam is damaged or either of the electrodes becomes disconnected, the capacitance changes differently from the normal change in response to a voltage application, indicating a failure.

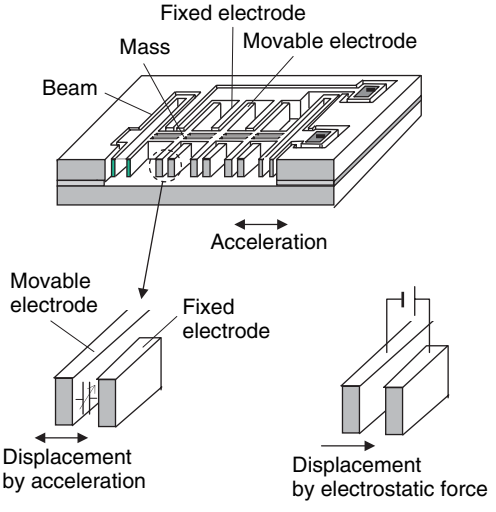

Figure 11 Outline of sensing element and self-test of capacitance type accelerometer.

The following summarizes the production process of this structure. A silicon dioxide film, which functions as the sacrificial layer, is deposited on the silicon substrate. Polysilicon, which forms the structure, is formed for producing a film of a predetermined thickness. The product fabricated by the processes described so far can be substituted by a silicon-on-insulator (SOI) substrate. In this case, single-crystal silicon should be used to produce the structure because it is more reliable. Electrode pads are produced in the next step. The pattern of the beam, the mass, and the electrode is formed at the same time by dry etching the polysilicon or single-crystal silicon. Lastly, the silicon dioxide film, which is the sacrificial layer, is removed by etching, and the beam, the mass, and the electrode are released from the silicon substrate to be movable. If sacrificial layer etching is performed in the liquid phase, the movable section may adhere to the fixed section due to surface tension produced during drying. To prevent this, the movable section should be kept immovable during drying, or etching can be performed in the gas phase. Another fabrication technology that has realized the

capacitance method is high aspect ratio fabrication. In the capacitance method, the greater the capacitance, the higher the sensitivity. To obtain greater capacitance, it is necessary to enlarge the electrodes placed in opposite directions. With high aspect ratio fabrication, the area of the electrodes can be enlarged in depth. As a result, sensitivity has been improved without enlarging the chip size. A new dry etching machine has enabled this technology: inductively coupled plasma system (Kuhl *et al.* 1998, Larmer *et al.* 1999). This machine has evolved further and today it can fabricate a trench of an aspect ratio of more than 50 (Ohara *et al.* 2001).

3.12.2.2 Pressure Sensor

Semiconductor-based piezoresistive pressure sensors were first inbuilt in automobiles in the early 1980s. Later, these sensors were integrated with IC technologies, and an integrated pressure sensor was developed, which consisted of an amplifier circuit, a regulator circuit, and a sensing element on a single chip. An onboard pressure sensor has a wide variety of functions, including the measurement of engine air intake pressure (manifold absolute pressure), fuel injection pressure, fuel tank internal pressure, air conditioner refrigerant pressure, brake pressure, and tire air pressure (Marek *et al.* 2003, Otake *et al.* 1998, Suzuki *et al.* 2001). Accordingly, the sensor is provided with an extremely wide pressure measurement range from 5 kPa to 200 MPa for common rail pressure sensors that detect fuel pressure in the diesel engine common rail system. **Figure 12** shows a MAPS and a refrigerant pressure sensor.

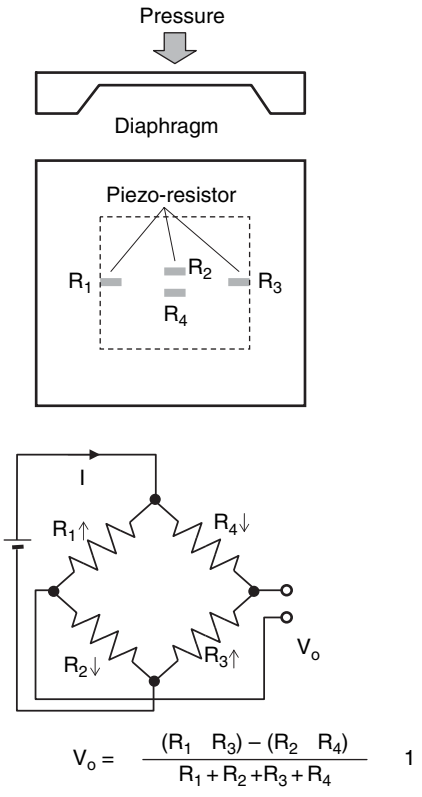
Manifold absolute pressure sensor

Refrigerant pressure sensor

Figure 12 Manifold absolute pressure sensor and refrigerant pressure sensor.

Most pressure sensors use the piezogauge method, which uses the trait of semiconductor materials to considerably change electrical resistance depending on the strain applied. **Figure 13** shows the outline of the sensing element and the circuit of a piezogauge-method sensor. The silicon substrate is processed to form a diaphragm, which is provided with piezoresistance. When exposed to pressure applied from above, the diaphragm sags. The amount of the diaphragm deformation is detected based on the changes in piezoresistance. The piezoresistors are at the center and end of the diaphragm. When the diaphragm deforms downward, the piezoresistor at the end of the diaphragm receives tensile strain while the piezoresistor at the center of the diaphragm receives compressive strain. The tensile strain and the compressive strain increase and decrease the resistance in opposite directions. Changes in the resistance can therefore be doubled in size for detection by configuring a bridge circuit. In addition, though one problem concerning detection using piezoresistance is that the resistance is influenced by temperature, so a bridge circuit compensates temperature dependence in principle.

The following summarizes the production process of this structure. In a single-crystal silicon substrate, impurity ions are implanted, piezoresistors and leads are formed by activation annealing, and aluminum pads are formed by sputtering. A diaphragm is produced using anisotropic etching from the back surface of the substrate as the final process. The diaphragm is normally 20 μm or greater in thickness, although it varies depending on the pressure to be measured. Some high-pressure sensors have a metal diaphragm connected to a silicon chip on which piezoresistors are formed (Tanaka *et al.* 2004). Like the thickness of the beam in accelerometers, the



$$V_o = \frac{(R_1 \quad R_3) - (R_2 \quad R_4)}{R_1 + R_2 + R_3 + R_4} \qquad 1$$

Figure 13 Outline of the sensing element and the circuit of a pressure sensor.

thickness of the diaphragm significantly influences sensor sensitivity. To ensure high thickness precision, some pressure sensors use electrochemical etch stop for anisotropic etching. Further, it has been reported that a satisfactorily etched surface has been successfully realized by controlling the impurity concentration of the potassium hydroxide (KOH) solution used for anisotropic etching in the parts per billion range (Inoue *et al.* 2000, Tanaka *et al.* 1999). The etching condition has been established and compiled in a database. Simulation technology has also been developed for this application. **Figure 14** shows the calculated shapes of etched silicon diaphragms.

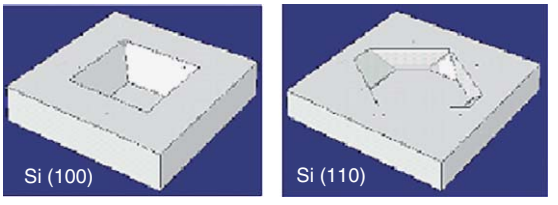


Figure 14 Calculated diaphragm shape of Si(100) and Si(110).

Many used a silicon (110) substrate on which an octagonal diaphragm can be formed. An octagonal diaphragm permits thermal stress distribution well balanced with the piezoresistive gauges, making it possible to minimize distortion of a sensor's offset voltage temperature characteristic.

3.12.2.3 Gyroscope

The gyroscope is commonly used to detect the turning. This turning angle is called yaw angle in the automobile field; therefore, the gyroscope is sometimes called yaw rate sensor. A gyroscope is typically used for stability control and navigation. It is also used in convertibles to detect a rollover rate. When the gyroscope on a convertible vehicle detects the possibility of a rollover, the roll bar rises to protect the heads of passengers (Marek *et al.* 2003). Most onboard gyroscopes use the Coriolis force in their detection mechanism. Vehicles having a high-precision ring laser gyroscope using the Sagnac effect were seen at one time, but today this type of gyroscope is not common due to cost and size (Barbour and Schmidt 2001). Then, Coriolis force-based gyroscopes were mostly of the tuning fork type (Putty and Najafi 1994), triangle pole type (Takeshi 1993), or ring type (Putty and Najafi 1994). These gyroscopes had a piezoelectric film on a metal structure, which was vibrated by the film. The gyroscope detected the deformation of the structure produced by Coriolis force by means of the film. Through the advancement of MEMS technology, these components of gyroscopes are today made from silicon materials. Some newly developed gyroscopes use electrostatic force to excite vibration (Howe *et al.* 1996).

Figure 15 shows the outline of the sensing element of a gyroscope using the capacitance. In the figure, metal leads are omitted. A movable mass is supported by the beams and by the frame. The mass is provided with comb electrodes to excite vibration by electrostatic force. The frame is equipped with comb electrodes to sense capacitance. The specific process of sensing is as follows. The gyroscope allows the exciting comb electrode to produce electrostatic force, and the mass to produce vibration in the x-axis direction. If rotation occurs around the z-axis direction at this moment, Coriolis force is produced on the mass, and the mass and the frame are displaced in the y-axis direction. This displacement is detected from changes in the capacitance of the comb electrode with the frame. The mass is resonated so as to obtain a sufficient degree of vibration speed. The Coriolis

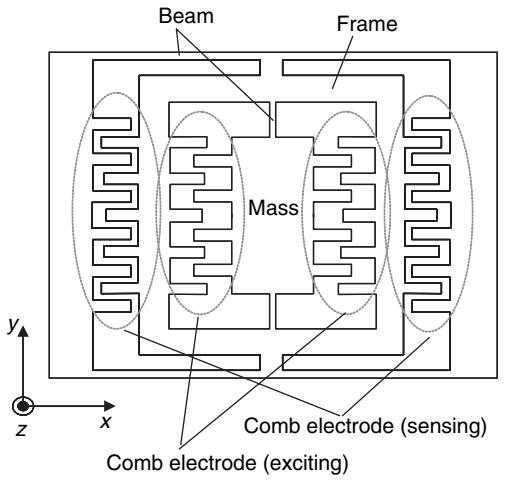

Figure 15 Plain figure of MEMS type gyroscope.

Figure 16 Air flow sensor.

force is proportional to the vibration speed of the mass. In this sensing mechanism, the biggest noise is caused by the vibration of the vehicle (acceleration). To solve this problem, two masses are used and vibrated in different phases whose difference is 180°. Though the displacement of two masses due to acceleration is in the same phase, Coriolis force of the two masses occur in opposite phases, so that the two masses are displaced in the opposite directions along the *y*-axis. By subtracting the displacement signal from another displacement signal, the noise due to the acceleration is eliminated. A gyroscope that detects both angular velocity and acceleration is now emerging (Nagao *et al.* 2004). The production process of gyroscopes is quite similar to the production process of the accelerometer as shown in Section 3.12.2.1.

3.12.2.4 Air Flow Sensor

The air flow sensor measures the amount of air intake into the engine. On the basis of the signals of the air flow sensor, the ECU determines an adequate rate of fuel injection. In the 1970s, a vane-type air flow sensor, which used the phenomenon of plate displacement that occurred depending on the amount of air, was developed. In the 1990s, the hot wire sensor was developed as shown in **Figure 16** (Kowatari *et al.* 1998). This sensor has the heater placed in the intake manifold, and it senses the changes in heat radiation from the heater to air, which occurs depending on the air velocity. The sensor was therefore able to measure the mass flow of air (Cavalloni and Berg 2002).

The hot wire sensor consists of a heater formed by winding platinum wire around a ceramic bobbin (Kowatari *et al.* 1998), a few millimeters in length as shown in **Figure 17**. The sensor is provided with a thermometer because heat radiation is influenced by changes in intake air temperature. In the late 1990s, a thin-film heater sensor was developed using MEMS technology (Ashauer *et al.* 1998, Moser and Baltes 1993, Moser *et al.* 1992, Neda *et al.* 1996, Parameswaran *et al.* 1990). The thin-film heater sensor using MEMS technology was developed to satisfy the needs of an air flow sensor that could handle high-speed changes in air intake resulting from the sophisticated engine control. The former bobbin heater with a millimeter range has too large a heat capacity to measure fast changes in air intake. The thin-film heater with a micrometer range having small heat capacity solves the problem.

Figure 18 shows a typical structure of the sensing element of the thin-film heater sensor. A membrane is formed in the silicon substrate, and a thin-film heater and a thermometer used for flow rate measurement are provided in the membrane. Another

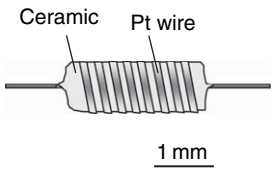

Figure 17 Bobbin heater.

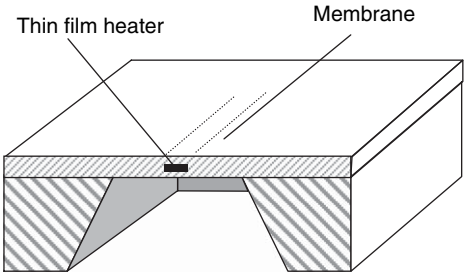

Figure 18 Cross section of MEMS type heater.

thermometer used for air temperature measurement is placed on the silicon substrate side. The membrane size is generally hundreds of square micrometers and a few micrometers in thickness, reducing the heat capacity of the heater while thermally insulating it. Because of these arrangements, the sensor can perform fast-response, power-saving sensing. The sensing process proceeds as follows. Air temperature is measured as the first step, and the heater temperature is retained at a temperature higher than the air temperature by a specific difference. Because the difference between air temperature and heater temperature is unchanged, the variation in heat radiation attributed to changes in air temperature can be corrected and only heat radiation from the air flow can be detected. The amount of electric power applied to the heater represents heat radiation, namely, the flow rate. To measure the air temperature, changes in electrical resistance, which varies with temperature, are used. The sensitivity of the sensor depends on how correctly the electrical resistance can be detected; therefore, a highly sensitive, stable material, such as platinum, is used to produce the heater. The heater can also be used as the thermometer of the heater itself. Some sensors have thermometers before and after the heater to measure the temperature distribution in the membrane, thus measuring both the direction of flow (Moser *et al.* 1992, Moser and Baltes 1993).

The following summarizes the production process of this structure. On a silicon substrate, a silicon dioxide film and a silicon nitride film, both of which serve as membrane materials, and a thin heater film are formed, and then patterning is performed. From the backside of the substrate, the silicon undergoes anisotropic etching, which stops automatically when it reaches the silicon dioxide film or the silicon nitride film. The silicon dioxide film and the silicon nitride film have stresses, which may cause buckling or damage to the membrane. To avoid this, the stress of each material should be identified and adjustments should be made taking the entire structure into consideration.

Figure 16 shows the entire body of the air flow sensor. The sensing element is not placed directly in the intake manifold but in the bypass flow channel. The entire bypass flow channel is placed in the intake manifold. The bypass flow channel plays an important role in the sensor, improving sensor sensitivity and removing disturbance.

3.12.2.5 Air Quality Sensor

Concerning the air-conditioning system for the cabin area, smell of exhaust fumes makes passengers uncomfortable. In an advanced air-conditioning system, exhaust gases are detected, the system switches fresh/recirculation dumper (Frers 2001). This indoor air/outdoor air automatic switching system first emerged in Europe, and is used for high-class vehicles. This system was initially equipped with a sensor that detected NO_x, and later with another sensor that detects CO was developed for use with this system. Though there are many methods for gas detection, most sensors use changes in the electrical resistance of a metal oxide to detect gas (Clifford 1983, Fung *et al.* 1996, Lee *et al.* 1995, Liu 1992, Seiyama *et al.* 1962). In the air, oxygen is trapped on the surface of the metal oxide, producing an electrical depletion layer, which provides the metal oxide with high electrical resistance. When combustible gases such as NO_x exist in the air, the effect of catalyst on the surface of the metal oxide produces oxidation reaction with oxygen, removing the oxygen from the surface of the metal oxide. The electrical depletion layer disappears and lowers electrical resistance (Clifford 1983). **Figure 19** outlines the structure of the air quality sensor's sensing element. The sensor consists of a heater and a thin film; the film is made from metal oxides such as SnO_2, which are usually formed on the ceramic substrate. The heater plays the role of heating the metal oxide and accelerates the reaction. The metal oxide is provided with a

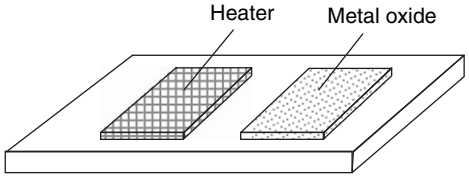

Figure 19 Outline of air quality sensor.

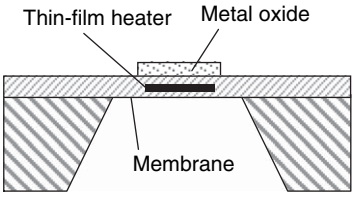

Figure 20 Cross section of MEMS type air quality sensor.

catalyst made of, for example, platinum. As this method detects all combusting gases in principle, it is designed to detect only a specific gas by formulating the materials of the metal oxide and the catalyst, as well as heating temperature. Air quality sensors have not been integrated with the latest MEMS technology (Fung *et al.* 1996, Lee *et al.* 1995, Liu 1992); however, those using the thin-film heater like the previously mentioned air flow sensors have been developed because such a heater is advantageous in various respects, such as power dissipation as shown in **Figure 20**. To improve sensitivity further, many efforts have been made concerning the formulation of the metal oxide, including research on film-forming methods and porous film. The air quality sensor integrated with MEMS technology is expected to spread rapidly in the future.

3.12.2.6 Laser Radar

The laser radar is used in the ACC system (Furui *et al.* 1998, Miyakoshi *et al.* 1999, Osugi *et al.* 1999). The principle of the distance measurement is as follows. A laser beam is emitted from the front of the vehicle in pulses, and the reflection from the target object is received by the photodiode. It was first used in passenger vehicles in the mid-1990s.

Figure 21 shows the laser radar. The laser diode, as shown in **Figure 22** (Abe *et al.* 2001, Atsumi *et al.* 2004, Kimura *et al.* 2000), emits a pulsed laser beam. The laser beam emitted from the laser diode is first reflected by the reflective mirror, scanned laterally and longitudinally by a rotating polygon mirror (2D scanning), and emitted through the emission opening. The beams reflected by the object in front are collected in the photodiode by means of the lens, and converted into electrical signals. These signals are processed by the time-measuring integrated circuit (Watanabe *et al.* 1993, Watanabe *et al.* 1998) and by obtaining the distance between the individual scanned positions. The reason why scanning is performed is that when a vehicle is moving in the horizontal direction the vehicle in front should not be lost on a curve in the road and when a vehicle is moving in the vertical direction the vehicle in front should not be lost in an upward or a downward slope. The radar's maximum measurement distance is currently 120 m, and its distance resolution is 1 m. The radar is useful not only in the ACC system but also in precollision safety (PCS) systems and for supporting parking (Alessandretti *et al.* 2002, Fuerstenberg *et al.* 2002). Installation space is limited in automobiles, and to increase sales of the laser radar, size reduction is essential. Therefore it is necessary that MEMS technology-integrated radars are earmarked for size reduction.

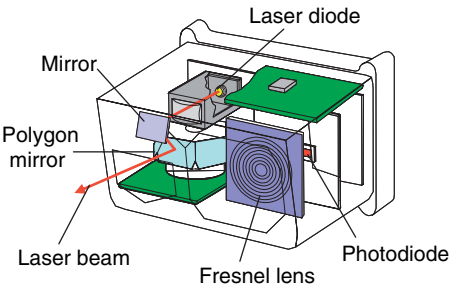

Figure 21 Review and structure of laser radar.

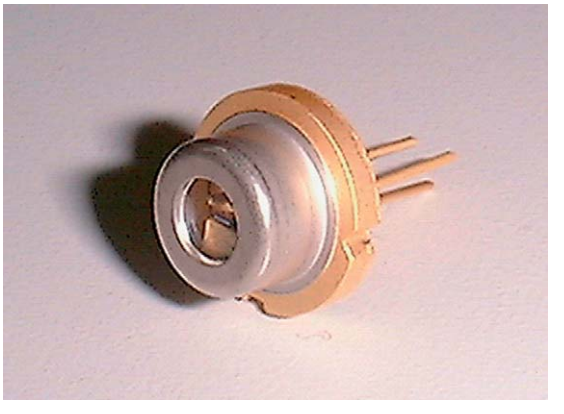

Figure 22 Laser diode for laser radar.

3.12.3 Future Direction of the Automotive Industry

One hundred years have passed since the invention of the modern automobile. While the automobile has provided us with great convenience, one cannot deny the problems it has caused: environmental pollution from fuel emissions in addition to an increase in the number of deaths and injuries due to traffic accidents. Accordingly, future methods of manufacturing cars must target environmentally friendly cars that obtain higher gas mileage ratings and safer cars capable of, if not preventing accidents, reducing the injurious effects of accidents on passengers and pedestrians. In the early 20th century, the basic functions of the automobile were to run, stop, and turn. Recently, in addition to these basic functions, automobiles have a new function, i.e., communication. Advances in electronic technology have contributed to this new function. Through various media, such as satellites, cellular phones, and broadcasts, we have acquired the ability to drive safely and more comfortably. We call this telematics, which is derived from the words telecommunication and informatics. Automotive telematics includes the transmission of information to and from vehicles using advanced telecommunication technologies. In the future, the world is scheduled to evolve into ITS by dedicated short-range communications (DSRC) between roads and vehicles as well as between vehicles. ITS is based on the principle that humans, roads, and vehicles mutually interact and cooperate by sharing information, as shown in **Figure 23**. New systems, such as the advanced cruise-assist highway system (AHS), the advanced safety vehicle (ASV) system, the human–machine interface (HMI) system as well as others, are key technologies for realizing this principle. After the realization of these technologies a new relationship between humans, roads, and vehicles will be created.

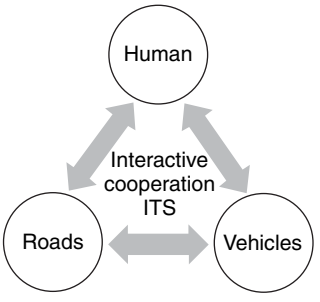

Figure 23 Basic concept of ITS.

Automotive manufacturing technologies for the future must be aimed at creating vehicles that are fuel-efficient and environmentally friendly, as well as safe, i.e., collision-free or minimal in impact to pedestrians and vehicle occupants in the unfortunate event of a collision. It is also important to incorporate advanced information and communication technologies that are coordinated with road infrastructure systems into vehicles, with the aim of ensuring efficient vehicle traffic and for manufacturing safer and more comfortable vehicles in which drivers can share necessary information with other people anywhere and anytime. In future, vehicles are expected to evolve along the three parameters: ecology, safety, and comfort (Hara 2002). It is therefore necessary to develop and manufacture vehicles and automotive systems that comply with these parameters. Of the three parameters, safety should be given the highest priority since it relates to human lives. Microsystem technology is expected to play an immense role in realizing automotive safety.

3.12.3.1 Concept of Advanced Driving Assistance

Taking this viewpoint into consideration, the automotive industry has been implementing R&D with the focus on ITS. A typical example is the development of AHS for which the Ministry of Land, Infrastructure, and Transport has taken the initiative in Japan. Through the AHS, the ministry intends to provide seven basic services that are considered necessary for realizing a safe motorized society in future (ITARDA 2005). The seven services that have been proposed to provide support are as follows:

(1) Prevention of collisions with forward obstacles
(2) Prevention of overshooting on a curve
(3) Prevention of lane drift
(4) Prevention of crossing collisions
(5) Prevention of right-turn collisions
(6) Prevention of collisions with pedestrians on a crossing
(7) Road surface information for maintaining an appropriate headway distance.

The support services for points (1)–(3) are being realized by a radar system (Osugi *et al.* 2001) and a lane keep system by camera, which have already been installed in some vehicles.

At present, however, these systems are costly and affordable only on some luxury cars. It is necessary to reduce the size and cost of these systems further by

using microsystem technology. If these systems are to follow the same course of evolution as automotive sensors, the reduction in size and cost will make the systems and the safety secured by them affordable on general-class vehicles as well. Hence, there are high expectations from microsystem technology.

The support services for points (4)–(7) cannot be realized by on-vehicle equipment alone. Coordination with infrastructure systems is indispensable. In the United States, development of a system that supports a driver's decisions at intersections is under way in a project led by the University of California. A device installed at each intersection identifies vehicles approaching the intersection and advises each driver of the vehicle whether he/she may make a left turn (right turn in Japan) (Shladover 2003). Safety-related support for pedestrians and vehicles at intersections is highly desired for the future. One of the effective and promising measures for such support is a wearable HMI device manufactured by micromachining technology. The HMI device would be embedded in a tag, which is to be worn by vulnerable road users, i.e., by pedestrians. A sensor installed at each intersection would detect the tag information and inform vehicle drivers about the presence of pedestrians. The tag should be manufactured using microsystem technology so that it is extremely small in size and should preferably be provided with, say, elderly certificates, security labels on bicycles, name tags worn by elementary school children, etc. In these tags, a self-power supply system by Power MEMS is more desirable than batteries. At each intersection, an appropriate infrastructure system would inform vehicle drivers of approaching pedestrians and bicycles to help the drivers avoid recognition mistakes and resultant unfortunate collisions.

Many possibilities can be imagined when contemplating the contributions of microsystem technology to the needs of advanced driving assistant systems. Many microsystem technologies, such as a microsensor, a microactuator, an optical MEMS, a RF MEMS, a power MEMS, and an auditory MEMS, are currently in the research stage and are regarded as promising technologies for these systems. It is not an overstatement that advanced driving assistant systems are realizable with integration of various microsystem technologies. Here, the word integration does not mean the simple gathering of device functions. Instead, it means the creation of new standards for production ability and robustness.

3.12.4 Conclusion

The above paragraphs describe some practical automotive application examples of MEMS sensors, and the evolutionary trend of microsystem technology for the future. Microsystem is highly regarded as a key technology with the potential to meet the requirements of the coming ITS-based society and ubiquitous information network society and to create new systems with new functions. Microsystem technology is expected to play an extremely important role in the future direction of R&D in the automotive industry, particularly for achieving new levels of safety. In performing this role, a high degree of integration of microsystem devices is essential so that these systems maintain a high level of reliability and mass productivity. However, a microsystem is basically a manufacturing technology. For further progress in this technology, therefore, it is vital and indispensable to develop a wide variety of core technologies, which is time-consuming.

Biography

Nobuaki Kawahara received the BE, ME, and Ph.D. degrees from Kyushu University, Japan, in 1981, 1983, and 1993, respectively. He joined Denso Corporation in 1983 and has been engaged in the research and development of microdevices, microfabrication, and microsystems. He is now general manager of Denso research laboratory and is responsible for the development of future automotive devices and systems. He is a member of the IEEE, the Japan Society, the Society of Mechanical Engineers, and the Society of Automotive Engineers of Japan and is a visiting professor of Nagoya University.

3.13.1 Introduction

In the field of advanced analytical science and technology, as most of the researches using microsystems have been proposed for analyzing liquid samples, few researches deal with the gas and solid phases. Moreover, few researches have been done on the application of microchip techniques to atmospheric gas analysis because there is no suitable gas sampling method. Because of the large differences between physical parameters of gas and liquid phases, such as viscosity and compressibility, the control of a gas–liquid two-phase flow in a microchannel was relatively difficult. Thus, mostly, gas–liquid two-phase flow on the microfluidic devices is treated as gas–liquid segmented flow. A miniaturized ammonia sensor has been reported. In this system, gas flow and liquid flow were introduced in the reaction chamber, and an electrolyte conductivity sensor was used for the detector. Hibara *et al.* (2005) reported an evaporation utilizing the gas–liquid two-phase laminar flow in the microchannel. However, as this system is dependent on special microchannel structures and surface modification, complicated and advanced fabrication techniques are required. A combination of thermal lens microscopy (TLM) and time-of-flight mass spectrometry helps in ultrasensitive detection, as both the microanalysis systems used in detecting microamounts of samples have excellent sensitivity when compared with conventional analysis systems.

Chemical and biochemical analysis systems using microsystems have many advantages in analytical chemistry. The microsystems realized fast analysis, reduction of reagent consumption, and portability, so that the microsystems have been applied to many analytical researches such as flow injection, solvent extraction, and immunoassay. Furthermore, microsystems can also be used as a microreactor for organic synthesis, and high reaction yields compared to the conventional procedure have been reported. For example, enzyme reaction for horseradish peroxide in a microsystem was compared to the reaction in a cuvette by using TLM, and almost two times higher reaction rate than the bulk scale was reported. It is considered that such advantages of the micro total analysis system (μ-TAS) arise from the unique mass transfer mechanism in microchannels. Therefore, it is important to understand the specific fluidic behavior such as diffusion and mixing of reagents that exists as laminar flows in microchannels of microsystems.

Recently, observation of the fluidic behavior of solutions in a polymer (PMMA, polymethyl methacrylate) microchannel was reported. The mixing and diffusion of dyed solutions was monitored by using a simple commercial charge-coupled device (CCD) camera equipped with an optical microscope, which clearly showed the unique mixing process of liquids at the channel turnings with different shapes and roughness of the inner walls. Microsystems used for μ-TAS are usually made of silicon, polymer, and glass. Among these materials, glass is the most useful material because of its easy processibility. Besides, glass is transparent to visible light, so that it is easy to trace and observe the mixing and diffusion of reagents in microsystems. The specific fluidic behavior of solutions ($KMnO_4$, Basic Blue 3 (BB3), and Oriental Blue (OB)) in a glass microsystem was investigated using the same technique reported for the PMMA microsystem. In the study, however, not only the simple observation of mixing of liquid flows, but also the quasi-steady-state UV-visible absorption spectroscopy was carried out using the microsystem owning to the optical transparency of quartz glass. The spectroscopic results obtained were analyzed based on a convection–diffusion equation in one dimension, and fluidic properties of liquids in different types of microchannels (wet etched and mechanical fabricated) were discussed. It is certain that much more powerful methods will be developed as new microreactors and analytical microsystems for environmental analysis and monitoring are required worldwide (**Table 1**).

3.13.2 Theoretical and Experimental Study on Microfluidics

A microspace such as a microchannel in the microchip system is characterized by a small volume, a short diffusion length, a large specific interface (solid–liquid or liquid–liquid), and small heat capacity. By utilizing these characteristics, micro chemical systems are expected to offer improved performances over conventional systems. Therefore, it is important that microsystems are designed to obey Taylor laminar–convection flow theory in the miniaturized flow space.

The sampling procedure for gas samples can generally be classified into active and passive methods. The active sampling method is performed using a vacuum pump, and has the advantage that adjustment of the amount of sampling is easy. However, as this method needs power, the sampling point is restricted.

Table 1 Required microsystems conditions for environmental analysis and monitoring

Compound	*Sample tested*	*Concentration level*	*Precision (%)*
NO_2	Air, indoor air	1–100 ppbv	±10
SO_2	Air	1–40 ppbv	±20
O_3	Air	60 ppbv	±10
CO	Air, indoor air	0.4 ppmv	±20
NH_3	Air, clean room air	0.1 ppmv	±10
HCHO	Air	2–100 ppbv	±10
Benzene	Air	20 ppbv	±10
Trichloroethylene	Groundwater → air	200 ppbv	±10
Tetrachloroethylene	Groundwater → air	200 ppbv	±10
Boron	Water	0.3 mg l^{-1}	±10
Aluminum	Water	0.2 mg l^{-1}	±10
Fluoride	Water	1.5 mg l^{-1}	±10
Bisphenol A	Water	–	–
Benz[*a*]pyrene	Exhaust particulate, dust	–	–
Polycyclic aromatic compounds	Exhaust particulate, dust	–	–
Polychlorinated biphenyl	Soil, transmittance oil	–	–
Dioxine	Air, water, soil, dust	–	–

On the other hand, the passive sampling method, which samples the object gas by diffusion, is suitable for miniaturization of sampling devices and the multipoint sampling is enabled.

Diffusion denuders, a tube with interior walls coated to function as a sink for the desired gases, have been used since the 1970s for the collection of gases. The original implementation was labor-intensive, wetted denuders in which a flowing liquid is used as the collection surface and their membrane-based counterparts are called diffusion scrubbers. Nowadays, automated continuous collectors are used (Simon and Dasgupta 1993). The first sampling methods based on diffusion to the absorption solution were investigated by Fukui (1963). Although these samplers are light, small, and easily operable, there is a tendency for the absorption rate to change with variations in wind velocity. In order to diminish the effect of wind velocity, a personal (passive) sampler, which has an air column in an acrylic tube, was developed (Palmes *et al.* 1976). Yanagisawa *et al.* (1982) developed a filter badge-type passive sampler, which consisted of an absorption sheet and a diffusion-controlling mat for diminishing the effect of wind velocity. Nowadays, a number of passive samplers adapted for various gases such as SO_2 (Korenaga and Yanagisawa 1995), CO (Lee *et al.* 1992), and O_3 (Helaleh *et al.* 2002) are being developed. However, as the sampling rate in passive samplers is dependent on gaseous diffusion, sufficient sampling time is needed to determine the level. Consequently, it is unsuitable for continuous on-site monitoring of gaseous concentration, which change with the passage of time.

A novel sampling method using the droplet formed on the tip of the capillary has been reported and applied to NH_3, SO_2 (Chang *et al.* 2005, Dasgupta and Kar 1995, Liu and Dasgupta 1995a, b, Yang *et al.* 1997), and nitrogen dioxide (NO_2) (Helaleh *et al.* 2001, Korenaga 1997, Korenaga 2002, Kumemura and Korenaga 2004a, b, Sato *et al.* 2001, Takabayashi *et al.* 2006). In this procedure, gases diffuse from the gas phase into the liquid phase of a droplet. However, as the interface of droplet is in direct contact with the atmosphere, it is easily influenced by humidity and temperature. In such a sampling method using liquid droplets (Kumemura and Korenaga 2004a, b, Kumemura and Korenaga 2006, Kumemura *et al.* 2005), a specific interface area is obtained by a decrease in droplet volume.

3.13.2.1 Downsizing of Flow Systems in Flow Injection Analysis

Downsized flow systems offer a lot of excellent innovations to various fields, such as medical, environmental, biological, and industrial applications. When a microchannel is characterized by a small volume, a short diffusion length, a large specific interface, and small heat capacity, a miniaturized chemical analysis system offers excellent performances over conventional analysis methods. Therefore, it is important that μ-TASs be designed to obey the theory of miniaturized space. For

example, microarray analysis has become a powerful technology for drug screening, disease gene identification, and signaling pathway studies. In order to utilize microchip technologies effectively, it is necessary to grasp the characteristics of microspace and to design based on theory. As mentioned above, microchip devices for analytical chemistry have many advantages compared with the conventional chemistry system. In order to enable broader applications of microchip technologies in the field of chemistry, the selection of suitable materials and fabrication technique is required. Moreover, the detection of low concentrations of analytes in the small volumes of samples present in microfluidic chip requires sensitive analytical techniques. The characteristics of microspace, microfabrication technologies, and detection technologies are described below.

The solute dispersion of an injected sample zone was analyzed by using an experimental apparatus with ideal laminar flow to develop a hydrodynamic model for the downsizing design of sensitive and precise flow injection analysis (FIA) systems (Korenaga 1995, Korenaga and Stewart 1988, Korenaga *et al.* 1988, 1989a–c, 1991a, b, Takahashi *et al.* 1990). The dispersion behavior of the sample slug was first analyzed in detail under the flow systems with different manifold conditions to evaluate the effects of operating conditions such as tube radius, tube length, flow rate, and cell volume to control the molecular diffusion coefficient of the sample solute. The capillary flow properties were also examined for some commercial micropumps to select the most suitable pumping method for the minimized flow injection system. A double-plunger micropump having a linear cam mechanism and a fast, short reciprocation time was proposed to obtain smoother mixing and more stable pumping with good reproducibility (Korenaga *et al.* 1992). The s4-micro flow injection system with a small tube bore, short tube length, small cell volume, and slow flow rate gave regular and reproducible breakthrough peak profiles that reflected stable feeding; other flow systems showed irregular peak profiles at smaller flow rate regions (Korenaga 1992).

The s4-micro flow injection system that drives complete, rapid mixing and low flow rate pumping are strongly desired for reliable downsized flow injection systems for industrial process use. Biosensing devices for protein and enzyme bioassays require lower consumption of valuable reagents (Korenaga *et al.* 1994, Li *et al.* 1995).

Chemical sensors are widely needed and have thus been developed in the field of microelectromechanical systems (MEMS). The substrate material and microfabrication process were performed by applying the semiconductor processing method. Because the method of microfabrication was developed in the semiconductor industry, the analytical miniaturized devices were typically fabricated in silicon substrate in the early days. In recent years, materials such as glass and polymer have been widely used. Some of the attractive features associated with the use of glass include its excellent optical properties, allowing sensitive detection, e.g., fluorescence is used for readout, and also its surface chemical properties, which are well understood and allowed to modify chemistries extensively. Thus, glass substrates are mainly used for microfluidic systems, which are applied to organic extraction process and optical analysis such as spectrophotometric, fluorometric, and chemoluminescence detection methods.

Lithographie galvanoformung abformung (LIGA) process is attracting attention as a fabrication technique for 3D microstructures with a high aspect ratio. The process that has been developed in the field of MEMS is composed of deep X-ray lithography using synchrotron radiation, electroforming, and molding. A resist, e.g., PMMA, is coated on the substrate, and the desired pattern is transferred by X-ray exposure. X-ray lithography on PMMA can produce extremely high aspect ratios due to the small amount of mask undercutting and its ability to penetrate deep into the resist. The exposed resist is removed by development. By using electroforming, Ni is deposited on the bottom of the substrate and a Ni structure is created. A metal structure may be used as a micromachine product in this stage. The resist is removed and a Ni-electroforming molding die is produced. The 3D structures are fabricated in the polymeric materials by molding using a Ni molding die.

Polymeric materials are used widely because of a broad range of materials with different physical properties, flexibility in the choice of the microfabrication method, the ability to produce high aspect ratio microstructures, and potential disposability. Polydimethylsiloxane (PDMS) elastomer and PMMA resin are the commonly used materials now. PDMS elastomer is widely used in microfluidic applications to form components such as channels, valves, and diaphragms. Furthermore, since the absorption in a visible is small and most private fluorescence is not seen as the optical characteristic, it can be adapted also for fluorescence detection widely used in a biochemistry field. One of the advantages of PDMS is that self-adhesiveness over a flat surface is excellent when compared with other

materials. In addition, employing oxygen plasma oxidation of PDMS, irreversible bonds with glass, silicon, and other PDMS structures are achieved. The various microchip fabrication methods using PDMS are studied, as production of the microstructures in PDMS is comparatively easy when compared with that with other materials. PMMA acrylic resin exhibits excellent transparency, and bonding of substrates is achieved easily by thermal adhesive bonding. Other standard polymeric materials are also used such as polyamide (PA), polybutyleneterephthalate (PBT), polycarbonate (PC), polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyethyleneterephthalate (PET).

These microsystem processing methods make use of the new concept of μ-TAS, which is based on the s4-micro FIA system (Korenaga 1992, Korenaga and Stewart 1988) shown in **Figure 1**.

3.13.2.2 Analysis of Diffusion and Mixing Process in Microchannel Laminar Flow

3.13.2.2.1 Liquid flow

The state of the flow in a microspace is distinguished into a laminar flow and the turbulent flow obeying Reynolds number (Re) as follows:

$$Re = \frac{Vd}{v} \qquad [1]$$

where V is the average flow velocity, d is the diameter of the tube, and v is the viscosity. If $Re < 2300$ then the flow is laminar, if >4000 then it is turbulent, and if in between these then it is in the transition zone. In general, in a microsystem, the diameter of the microchannel ranges from several micrometers to several hundred micrometers, the flow rate ranges from several microliters per minute to several hundred microliters per minute, and the aqueous viscosity is $\sim 10^{-6}\,m^2\,s^{-1}$. Therefore, as Re is estimated to be 10^{-6} to 20, the state of flow is stable laminar flow. The dispersion of a solution traveling in a laminar flow along the major axis of the microchannel is described by Taylor dispersion. The flow velocity distribution of laminar flow in the smaller tube radiates when the flow velocity becomes slow as it approaches the wall from the center. However, this is in the case of a cylinder-shaped tube. It is surmised that the flow velocity distribution is distorted partly as a section of microchannel is generally a rectangle or a short form.

3.13.2.2.2 Diffusion in two-phase laminar flows

Mass transfer between two aqueous solutions is dependent on the diffusion at the liquid–liquid interface, because the pressure-driven flow in microchannels is generally laminar. The diffusion time t is expressed with the following formula:

$$t \propto \frac{l^2}{K} \qquad [2]$$

where l is the diffusion distance and K is the diffusion coefficient. Thus, as the diffusion time is proportional to the square of the diffusion distance, it is shown that the diffusion time becomes short in proportion to the square of the miniaturized length.

In addition, the specific interface area, σ, becomes large as the volume of space becomes small.

$$\sigma = \frac{S}{V} \qquad [3]$$

where S is the area of the liquid–liquid interface and V is the volume of the solution. Thus, mass transfer by diffusion is efficiently carried out in microspace.

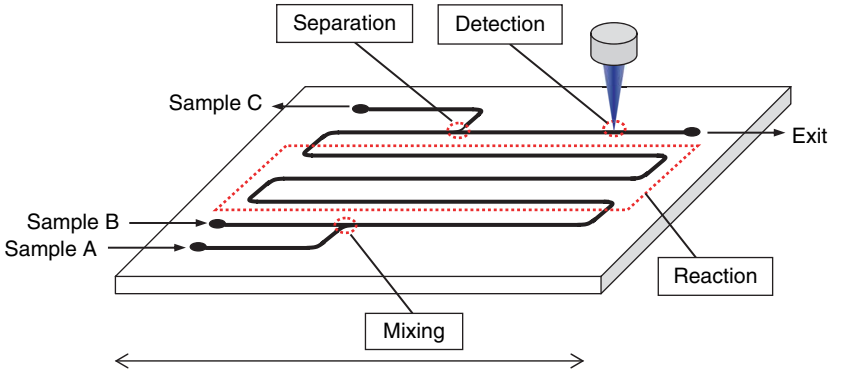

Figure 1 Illustration of a concept of micro total analysis system (μ-TAS).

3.13.2.2.3 Pressure drop

Because fluids are viscous, energy is lost by friction between the flowing fluids and the wall of the microchannel. The effect of the friction shows itself as a pressure loss. The pressure loss is equivalent to the shear stress at the wall P. In a pipe, P is calculated using the Hagen–Poiseuille equation for laminar flow.

$$P = \frac{128\mu QL}{\pi D^4} \quad [4]$$

where L is the distance from the outlet, Q is the flow rate, μ is the viscosity, and D is the diameter. In the case of a microchannel, which has a rectangular profile, the tube diameter D can be replaced using the hydraulic equivalent diameter D_e.

$$D_e = \frac{4A}{U} \quad [5]$$

where A is the cross section and U is the wetted perimeter. Thus, the pressure loss increases with the miniaturization of the microchannel. In order to prevent the breakage of a microsystem and the liquid leak by pressure, this is an important parameter for the design of a microchannel pattern. In this study, in order to perform a gas sampling, porous materials are used. Because these have a low strength when compared with a glass material, it is necessary to take this into consideration for a microsystem design.

The size of the quartz plates used for making microsystems is 50 mm × 26 mm with a thickness of 2 mm. The microchannels in microsystems were fabricated by two methods (wet chemical etching and mechanical fabrication) and different widths of channels having different depths were produced (500 μm × 100 μm, 250 μm × 100 μm, and 100 μm × 40 μm). Detailed procedures for making chemical etching methods have been reported elsewhere. The mechanical fabrication was carried out with the bench micro working machine (Kumakura). In the produced microsystems, two channels for reagents were confluent into the main reaction channel with an incident angle of ∼60°. The top and cross-sectional view of the microsystem (Y-shaped microsystem) used for the experiments are illustrated in **Figure 2(a)** and **2(b)**. The fluidic behavior of reagents was monitored using a commercial digital camera (8-bit resolution) equipped with an inverted optical microscope (Eclipse ME600, Nikon) with a ×10 (NA = 0.3) objective lens (**Figure 2(c)**).

The dyed solutions and counter aqueous solutions were injected into the microsystem using syringe pumps (IC3200, KD Scientific), and syringes were 1 ml gastight (Hamilton). Flow analysis experiments (**Figures 3–5**) were carried out to obtain diffusion phenomena for an aqueous solution of $KMnO_4$ reagent (Wako Pure Chemical), BB3 dye (MP Biomedicals), and arabic gum solution of OB pigment (Holbein Works). The KCl solution of the same density was used as the counter aqueous solution for $KMnO_4$ chemical and BB3 dye and 30% (w/w) arabic gum solution was used for OB pigment solution.

The RGB (red, green, blue) color intensity of the mixing images obtained was monitored and used for the analysis. The laminar flow and molecular diffusion behavior were investigated by visualizing the confluence of some colored and clear solutions. Digital color images from a digital still camera were analyzed resolving the color in the RGB mode. This color contrast is equivalent to the difference in the dye concentration. Numeric data from the RGB color components in the channel images could reveal the diffusion phenomena in the microchannel. τ, a dimensionless number, was used for the analysis of diffusion phenomena (**Figures 6–8**). The microchannel effect of the wet etching process and the mechanically fabricated process are also shown in **Figure 9**.

The concept of lab on a chip is the integration of different steps such as chemical reaction, pretreatment, and detection into a miniaturized space that is a fabricated detailed structure of a micro- or nanoscale on substrates of several centimeters. Such a technology is called μ-TAS or lab on a chip. Recently, various microchip devices have been developed with great progress in microfabrication technology, and advances in microchip analysis have been remarkable. The microchip technology provides a miniaturized analytical system, which leads to downsizing of the experimental equipment as well as high-speed, high-throughput analysis, resulting from on-site monitoring, a small sample volume, and a small experimental space. On the other hand, the studies related to miniaturization of silicon focused on the fabrication of components such as micropumps, microvalves, and chemical sensors.

3.13.3 Phase Transfer Microsystems for Pretreatment of Gas, Liquid, and Solid Samples

The operation of gas absorption is very important in the analytical process as a pretreatment operation for the measurement of gaseous concentration in the atmosphere. The process of gas absorption is used

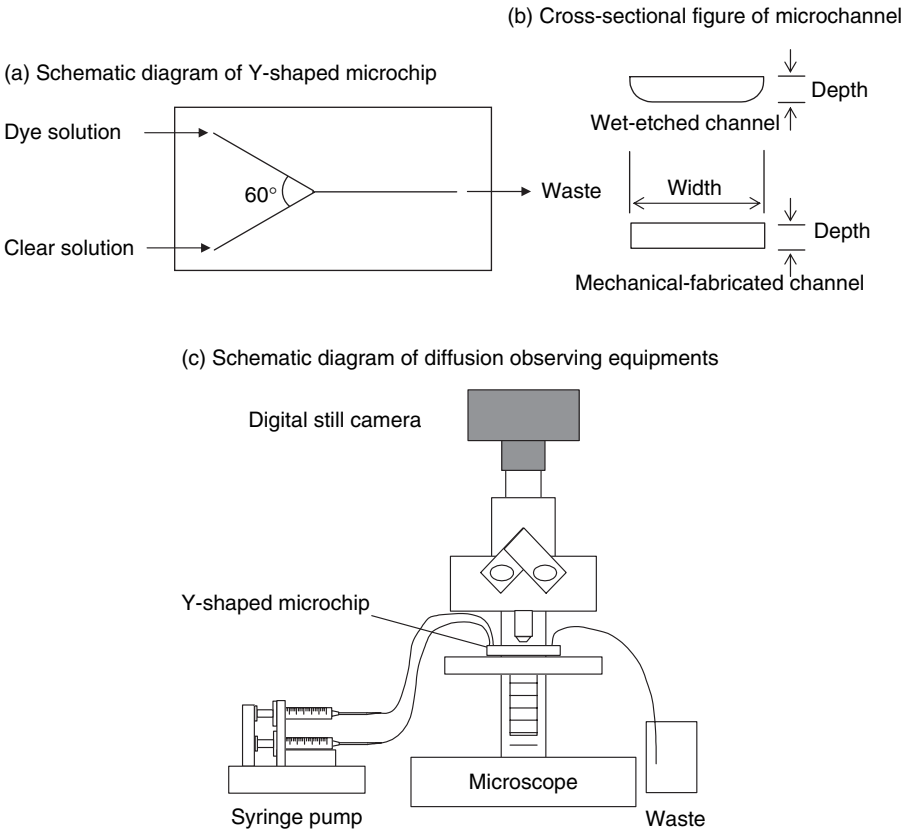

Figure 2 Y-shaped microchip and diffusion observing equipments. (a) Schematic diagram of Y-shaped microchip. (b) Cross-sectional figure of microchannel. (c) Schematic diagram of diffusion observing equipments.

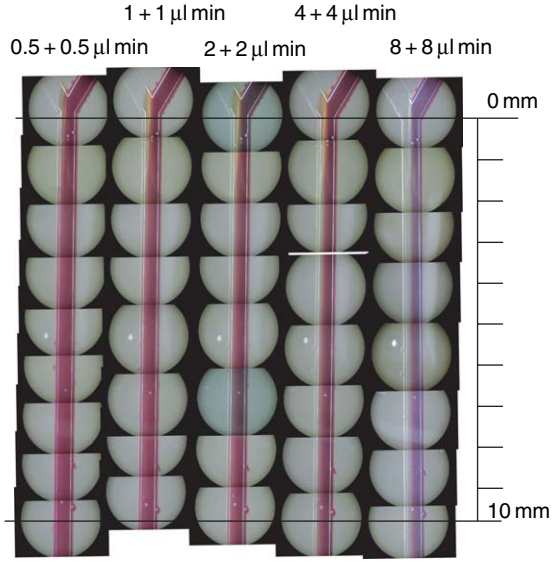

Figure 3 Photographs for diffusion phenomena of $KMnO_4$ reagent in microchannel.

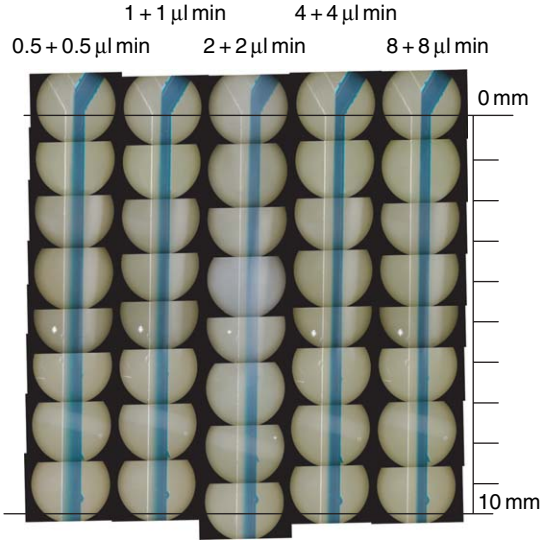

Figure 4 Photographs for diffusion phenomena of Basic Blue 3 (BB3) dye in microchannel.

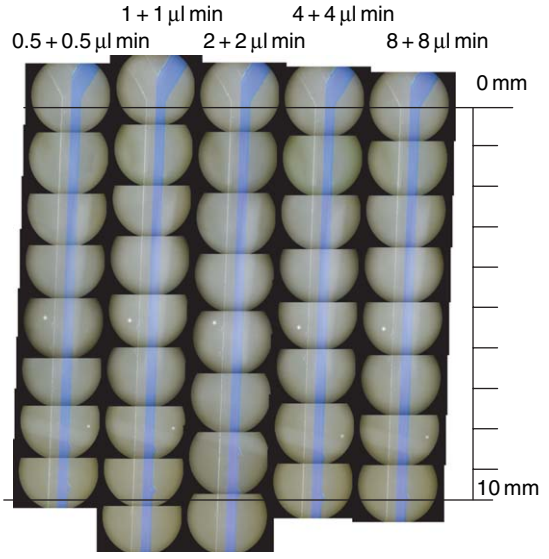

Figure 5 Photographs for diffusion phenomena of Oriental Blue (OB) pigment in microchannel.

in various industries, such as in a chemical plant. Most gas absorption aims at separation of acidic impurities from a mixture of gases. These acidic impurities include carbon dioxide (CO_2), hydrogen sulfide (H_2S), nitrogen oxide (NO_x), hazardous sulfur oxide (SO_x) as SO_2 (Chang *et al.* 2005, Dasgupta and Kar 1995, Liu and Dasgupta 1995a, b, Yang *et al.* 1997), hydrochloric acid (HCl), and organic acid compounds.

NO_2 (Helaleh *et al.* 2001, Korenaga *et al.* 2000, Kumemura and Korenaga 2004a, b, Sato *et al.* 2001, Takabayashi *et al.* 2006), found in the combustion exhaust of automobiles and oil-burning power plants, is a typical example of acutely toxic gases that cause problems such as acid rain, photochemical smog, corrosion, and human respiratory morbidity. The examined value obtained from the Japanese standard ranges from 40 to 60 ppb for the daily average.

A number of methods for measuring NO_2 have been developed in the past few decades. The measurement of NO_2 can be generally classified into wet and dry methods. Incidentally, the continuous analyzers for the concentration of NO_2 in ambient air, which is utilized absorptionmetric method as wet and chemiluminescence method as dry, are prescribed in the Japanese Industrial Standards (JIS).

NO_2 is usually absorbed in a suitable solution first and converted into nitrite; this is followed by the determination of nitrite (Chaube *et al.* 1984). Nitrite is frequently detected using a diazo-coupling reaction, and the spectrophotometric method established

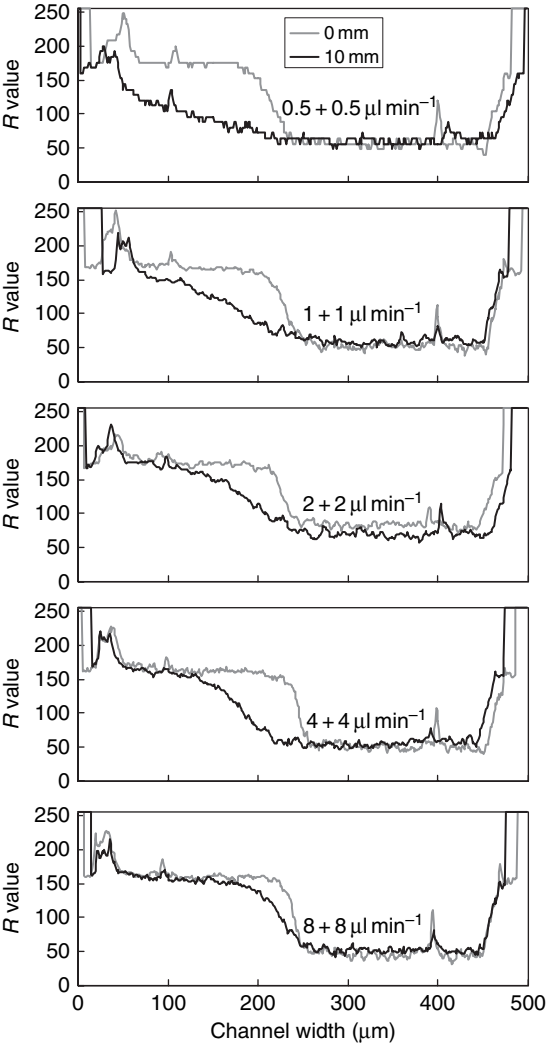

Figure 6 Red, green, blue (RGB) analysis of Basic Blue 3 (BB3) diffusion phenomena in microchannel.

by Saltzman (1954) is used as one of the standard reference methods worldwide. The Saltzman reagent used as a diazo-coupling reagent is a mixture of *N*-1-naphthyl-ethylene diamine dihydrochlorate, sulfanilic acid, and acetic acid. Although the above-mentioned methods are excellent in reproducibility, the sensitivity is poor and they need to extract the azo dye formed to improve the detection limits.

Many methods were developed to detect nitrite ion fluorimetrically, in which fluorescent reagents such as 5-aminofluorescein, 2,6-diaminopyridine, 3-amino-4-hydroxy-coumarin and 3-aminonaphthalene-1,5-disulfonic acid were used (Axelrod and Engel 1975, Dombrowski and Pratt 1972, Motomizu *et al.* 1986, Ohta *et al.* 1986). On the other hand,

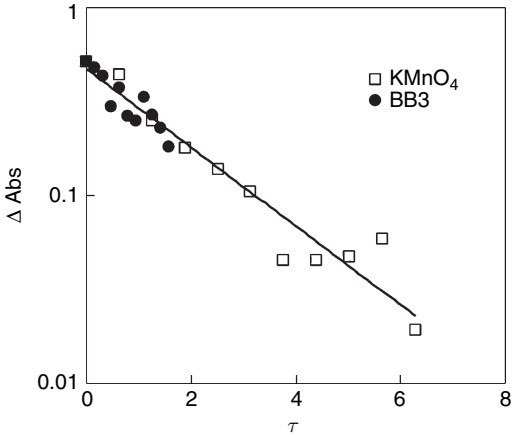

Figure 7 Comparison of $KMnO_4$ and Basic Blue 3 (BB3) by τ where $\tau = tD/R^2$.

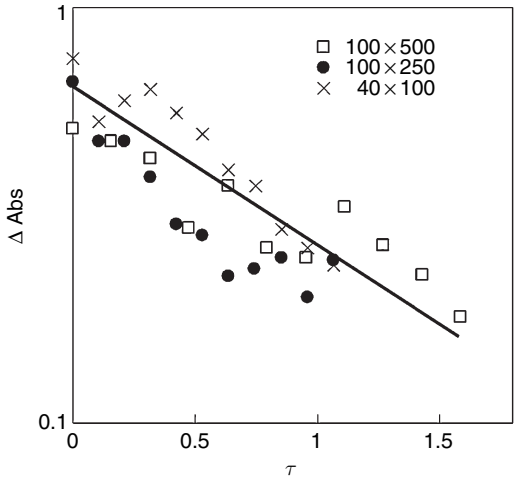

Figure 8 Comparison of diffusion progression by channel size. $\tau = tD/R^2$.

a laser-induced fluorescence detection technique for detection of NO_2 was reported (George and O'Brien 1991). The technique employed a direct determination of NO_2 with high sensitivity (Matsumi *et al.* 2001), but the high cost could prevent it from current monitoring use.

Chemiluminescence methods are also widely applied, which are based on the catalytic or photolytic reduction of NO_2 to NO and subsequent gas-phase reaction with ozone (Fontijin *et al.* 1970, Sigsby *et al.* 1973), or on the chemiluminescence reaction of NO_2 with an alkaline solution of luminol (Maeda *et al.* 1980, Mikuaka and Vecera 1992). These methods are highly sensitive. However, some of the methods encounter interference from species such as SO_2,

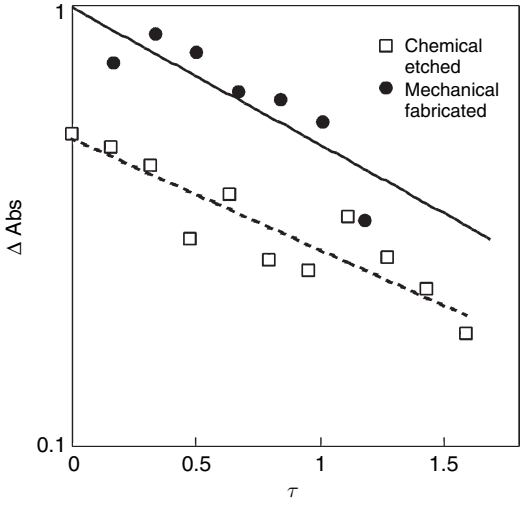

Figure 9 Comparison of diffusion between wet chemical-etched microchannel and mechanical-fabricated microchannel. $\tau = tD/R^2$.

H_2S, CO_2, and O_3. In addition, complex and costly instrumentation is required, and due to the limited stability of the luminal reagent, the systems need to be recalibrated frequently.

A number of small and simple sensors for detecting NO_2 have been reported, such as a solid-state sensor using solid electrolytes (Miura *et al.* 1993), a sensor based on a proton conductor (Albert *et al.* 1996), a sensor detecting the electric resistance using WO_3 as an oxide semiconductor (Akiyama *et al.* 1991, Nelli *et al.* 1996), and a sensor based on a surface acoustic wave (SAW) (Penza and Vasanelli 1997). Tanaka *et al.* 1999 developed a practical NO_2 sensor using a porous glass-doped organic compound, which was a diazo-coupling reagent. However, as the detection system depends on the difference calculus of absorbance, the detection sensitivity is low and it is difficult to adapt it for the measurement of the living environment level. Thus, few sensors suitable for monitoring NO_2 in the atmosphere have been developed as yet because of insufficient sensitivity or gas selectivity.

3.13.3.1 Gas–Liquid Equilibrium and Gas Absorption Pretreatment Microsystems

3.13.3.1.1 The overall mass transfer coefficient

To include the qualitative observations in the correct equations, the example of the gas–liquid interface in **Figure 10** is used. In this case, the gas on the top is

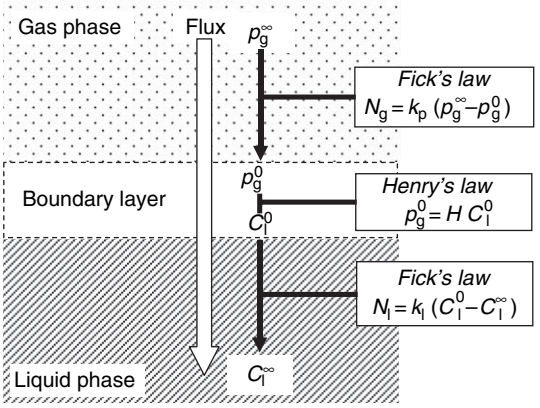

Figure 10 Mass transfer across a gas–liquid interface.

being transferred into the liquid in the bottom. The flux in the gas phase, N, is

$$N = k_p\left(p_g^\infty - p_g^0\right) \qquad [6]$$

where k_p is the gas-phase mass transfer coefficient (typically in $\mathrm{mol\,cm^{-2}\,s^{-1}\,atm^{-1}}$), p_g^∞ is the bulk pressure, and p_g^0 is the interfacial pressure. Because the interfacial region is thin, the flux across is in the steady state and the flux in the gas phase is equal that in the liquid phase. Thus,

$$N = k_l\left(C_l^0 - C_l^\infty\right) \qquad [7]$$

where k_l is the liquid-phase mass transfer coefficient, and C_l^0 and C_l^∞ are the interfacial and bulk concentrations, respectively.

Here, equilibrium exists across the interface.

$$p_g^0 = HC_l^0 \qquad [8]$$

where H is the Henry's constant (here in $\mathrm{cm^3\,atm\,mol^{-1}}$). Combining eqns [6] through [8], the interfacial concentration is found.

$$C_l^0 = \frac{p_g^0}{H} = \frac{k_p p_g^\infty + k_l C_l^\infty}{k_p H + k_l} \qquad [9]$$

And the flux

$$N = \frac{1}{1/k_p + H/k_l}\left(p_g^\infty - HC_l^\infty\right) \qquad [10]$$

k_p is called an overall gas-side mass transfer coefficient and k_l is an overall liquid-side mass transfer coefficient. The expression $1/k_p + H/k_l$ denotes the resistance on the gas absorption, and the reciprocal of that gives the overall mass transfer coefficient on the gas absorption process (Cussler 1997). In this study, the mass transferred because of microsystem-based gas absorption was analyzed based on this theory.

3.13.3.2 Liquid–Liquid Equilibrium and Solvent Extraction Pretreatment Microsystems

In general, three theoretical models can be used when a diffusion phenomenon is employed for analysis. If we consider that a solid chemical dissolves in water, this phenomenon can be analyzed as chemical reaction, mass transfer, and diffusion. The dissolution of a chemical is known to be controlled by the diffusion of the dissolved chemical away from the solid surface of the undissolved materials. If the chemical concentration versus time is measured, the results can be correlated in terms of as few parameters as possible. One way to correlate the dissolution results is to use a mass transfer coefficient. To do this, a mass balance on the solution is expressed as follows:

$$V\frac{dc_1}{dt} = Aj_1 = Ak(c_1(\mathrm{sat}) - c_1) \qquad [11]$$

where V is the volume of solution, A is the total area of the chemical particles, $c_1(\mathrm{sat})$ is the concentration of chemical at saturation and at the solid phase, and c_1 is the concentration in the bulk solution. Integrating this equation allows quantitative fitting of the results with one parameter, the mass transfer coefficient k. This quantity is independent of solubility, the area of the chemical, and the solution volume; however, it does vary with physical properties like stirring rate and solution viscosity. Correlating the effects of these properties turns out to be straightforward. The alternative to mass transfer is diffusion theory, for which the mass balance is given by the following equation:

$$V\frac{dc_1}{dt} = A\left(\frac{D}{l}\right)(c_1(\mathrm{sat}) - c_1) \qquad [12]$$

where l is a known parameter, equal to the average distance across which diffusion occurs. This unknown parameter, called a film or unstirred layer thickness, is a function not only of flow and viscosity but also of the diffusion coefficient itself. Eqns [11] and [12] are equivalent, and they share the same successes and shortcomings. In the former, the mass transfer coefficient must be determined experimentally; in the latter, the thickness l should be determined instead. Those who like a scientific veneer prefer to measure l, for it genuflects toward

the Fick's law of diffusion. Those who are more pragmatic prefer explicitly recognizing the empirical nature of the mass transfer coefficient. The choice between the mass transfer and the diffusion models is thus often a question of taste rather than precision. The diffusion model is more fundamental and is appropriate when concentrations are measured or needed versus both position and time. The mass transfer model is simpler and more approximate and is especially useful when only average concentrations are involved. The way to correlate the results other than the two diffusion models is to assume dissolution is a first-order, reversible chemical reaction. Such a reaction might be described by the following equation:

$$\frac{dc_l}{dt} = kc_l(\text{sat}) - kc_l \qquad [13]$$

In this equation, the quantity $kc_l(\text{sat})$ represents the rate of dissolution, kc_l stands for the rate of precipitation, and k is a rate constant for this process. This equation is mathematically identical with eqns [11] and [12] and so is equally useful. However, the idea of treating dissolution as a chemical reaction is flawed. Because the reaction is hypothetical, the rate constant is a composite of physical factors rather than chemical factors. Therefore, the physical process should be considered in terms of diffusion or a mass transfer model. In this experiment, the mass transfer of Al^{3+}–2,2-dihydroxyazobenzene (DHAB) chelate from continuous phase to TBP droplet was investigated by the mass transfer model.

The droplet volume can be changed by controlling the flow rate in the continuous phase and in the dispersed phase in a T-shaped microchip (**Figure 11**). **Figures 12** and **13** show variation in the extraction amount in different continuous phase

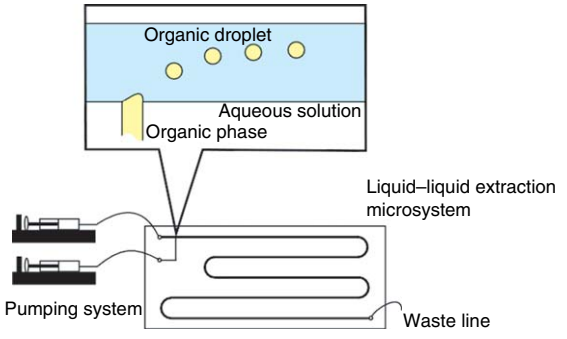

Figure 11 Experimental apparatus for liquid–liquid extraction microsystem from aqueous solution into organic droplet phase.

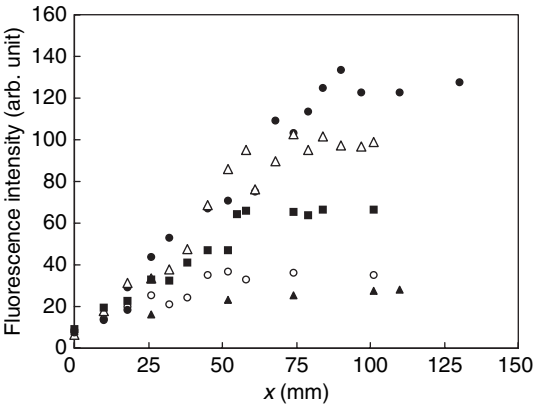

Figure 12 Solvent extraction of Al^{3+}–DHAB chelate at each flow rate of continuous phase in the T-shaped microchannel: 70 μm (wide) × 20 μm (deep) in dispersed phase. x is the distance from the T-junction. Flow rate of continuous phase (mm s^{-1}): ●, 16; △, 26; ■, 37; ○, 47; ▲, 57. Flow rate of continuous phase (mm s^{-1}): 25.

flow rates. The data of **Figure 12** were obtained in the microchip having 70 μm × 20 μm in the dispersed phase and those of **Figure 13** were obtained in the other microchip having 100 μm × 40 μm in the dispersed phase. The plots in both the figures gradually increased and apparently reached equilibrium at each point. The calculated droplet volumes were 0.6, 1.2, 2.7, 5.9, and 11 nl at each flow rate of the continuous phase, which were obtained by substituting the data of **Figure 12**. Smaller droplets could be obtained at faster flow rates in the continuous phase. The

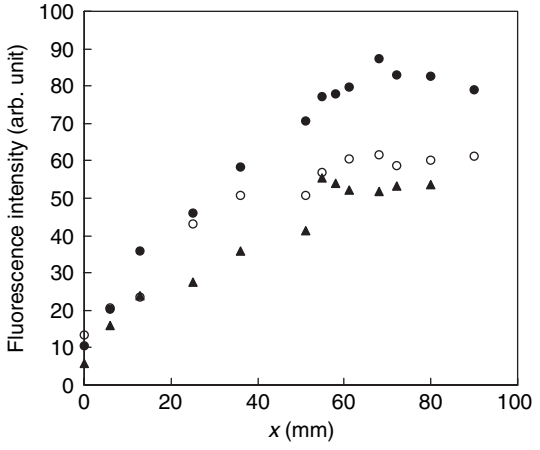

Figure 13 Solvent extraction of Al^{3+}–DHAB chelate at each flow rate of continuous phase in the T-shaped microchannel: 100 μm (wide) × 40 μm (deep) in dispersed phase. x is the distance from the T-junction. fluorescence intensity was increased with increasing distance from the T-junction and reached equilibrium at each flow rate. During the extraction process, only 0.9-s extraction time was sufficient to extract at a continuous-phase flow rate of 57 mm s^{-1}. It was assumed that the difference of fluorescence intensity and the time to reach equilibrium were dependent on the difference in the droplet volume. In order to investigate the mass transfer from aqueous phase to droplet in this experiment, the overall mass transfer coefficient was estimated.

Generally, the equilibrium concentration in the organic phase is given by following equation:

$$C_{o,eq} = kC_{aq,eq} = \frac{kC_{aq,initial}}{1 + k\left(V_o/V_{aq}\right)} \quad [14]$$

where $C_{o,eq}$ is the equilibrium organic-phase concentration, $C_{aq,initial}$ and $C_{aq,eq}$ are the initial and equilibrium aqueous-phase concentrations, V_o and V_{aq} are the organic and aqueous-phase volumes, and k is the distribution coefficient, defined by the following equation:

$$k = \frac{C_{o,eq}}{C_{aq,eq}} \quad [15]$$

When the solute exists in various forms in the aqueous phase, the distribution ratio, D, is expressed as follows:

$$D = \frac{[A_1]_o}{[A_1]_{aq} + [A_2]_{aq} + [A_3]_{aq} + \cdots + [A_n]_{aq}} = \frac{[A_1]_o}{C_{aq}} \quad [16]$$

where $[A_1]_o$ and $[A_n]_{aq}$ are the concentrations of the solute in the organic and aqueous phases, respectively. C_{aq} is the concentration of all forms of the solute in the aqueous phase. When the solute exists as one form in the aqueous phase, D is equal to the distribution coefficient.

$$D = \frac{C_{o,eq}}{C_{aq,eq}} = k \quad [17]$$

Thus, k and $C_{aq,initial}$ must be sufficiently large, and the phase ratio, V_o/V_{aq}, must be reasonably small to avoid detection problems.

The overall mass transfer coefficient, $\bar{\beta}_o$, was obtained from the following equation:

$$\frac{dC_o}{dt} = \frac{A_i}{V_o}\bar{\beta}_o\left(kC_{aq} - C_o\right) \quad [18]$$

where C_o is the concentration of the analyte in the organic phase at time t, A_i is the interfacial area, $\bar{\beta}_o$ is the overall mass transfer coefficient with respect to the organic phase, and C_{aq} is the analyte concentration in the aqueous phase at time t. Assuming rapid transfer across the liquid–liquid interface, the overall mass transfer coefficient can be expressed as follows:

$$\frac{1}{\bar{\beta}_o} = \frac{1}{\beta_o} + \frac{k}{\beta_{aq}} \quad [19]$$

where β_o and β_{aq} are the individual mass transfer coefficients for the organic and aqueous phases, respectively. For compounds with a large diffusion coefficient, k, the mass transfer in the aqueous phase becomes the rate-determining step, and $\beta_{aq} \approx k\bar{\beta}_o$. Thus, β_{aq} can be obtained from the extraction rate curve. The overall mass transfer coefficient was obtained from the fit to the extraction rate curve in **Figure 14**. As a result, the estimated mass transfer coefficients at each volume were not of constant value. There could be two reasons for this. One is the difference in droplet sizes. From the viewpoint of chemical engineering, at a shorter diffusion distance, the concentration gradient became smaller. Namely, for a smaller droplet volume, a molecule is transported faster. Another possibility is the difference in the strength of internal circulation, which occurs because of both the pressure of a fluent shut up in channel wall and the flow of a continuous phase in this experiment. According to the experimental results, the mass transfer coefficient increased with the increase in the flow rate of the continuous phase. The flow rate of dispersed phase was fixed at 25 mm s^{-1}. Therefore, the effect was assumed to occur only because of the flow rate of the continuous phase.

3.13.3.3 Solid–Liquid Extraction Pretreatment Microsystems

Polycyclic aromatic hydrocarbons (PAHs) are solid organic compounds with the greatest environmental effects owing to their widespread distribution in the environment; this is because they are generated by natural causes, for example, forest fires and volcanic activity, and by incomplete combustion of fossil fuels and other organic materials. Air pollutants, especially those from diesel exhaust particles, including PAHs, seriously affect human health. Benzo[*a*]pyrene (B[*a*]P), a PAH, has strong mutagenicity and carcinogenicity and is an endocrine disrupter. Moreover, B[*a*]P and benzo[*k*]fluoranthene (B[*k*]F) have caused an immune disturbance that causes allergic diseases, such as asthma and hay fever in developed countries.

The pretreatment microsystem presents an integrated microfluidic system that performs cleanup for PAHs from diesel exhaust particles on silica gel beads in a microchip. A column chromatography phase was constructed by filling the silica gel beads into a microchannel that had a dam structure 25 μm in height. The height of the dam structure was determined according to the rate of wet etching. This work on the cleanup of PAHs from diesel exhaust particles showed that the microchip-based system has the same performance as the conventional method on the solid-phase extraction column and has advantages, such as less reagent consumption and shorter pretreatment time, over the conventional method.

Figure 15 shows a photograph of a microchannel characterized by a dam structure, which shows a magnified view of the dam structure, which was subjected to 3D image processing after images were obtained by a color laser confocal microscope (VK-8500, Keyence). The dam structure at the bottom of the microchannel was clearly seen. The dam structure shown in the image has a height of 25 μm.

Taking into consideration that etching proceeds isotropically, the height of the dam structure was evaluated by using the following equation:

$$h = d - \sqrt{d^2 - \left(\frac{w}{2}\right)^2} \qquad [20]$$

where h is the height of the dam structure, d is the depth of the microchannel, and w is the width of the metal mask not etched. Figure 16 shows a graph of the experimentally determined heights and their theoretical values obtained from the above equation, when the etched depth was 100 μm. As seen from the graph, the experimental values agree well with the theoretical values.

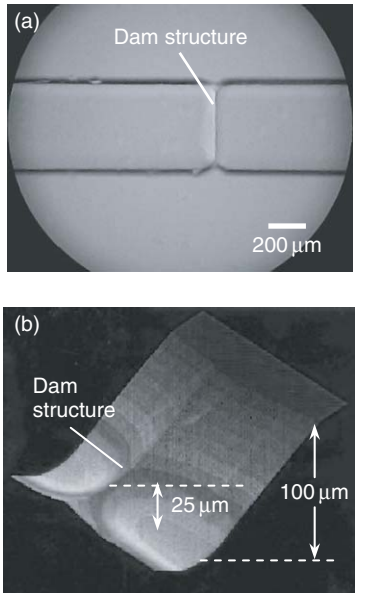

Figure 15 (a) Photograph of the dam structure; (b) 3D image of dam structure.

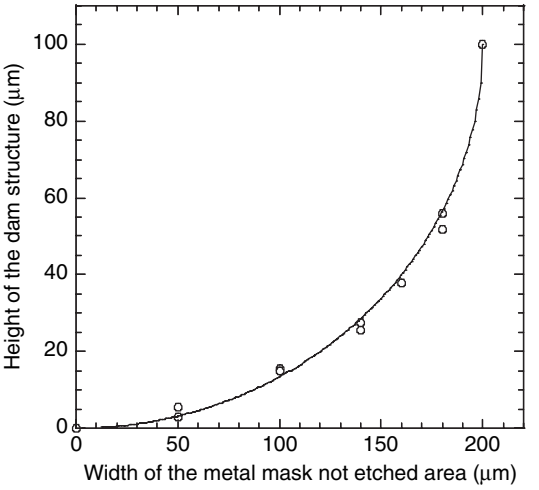

Figure 16 The experimentally determined heights (○) and their theoretical values obtained from the equation (–), when the etched depth was 100 μm.

Consequently, the height of the dam structure can be determined by measuring the width of the metal mask not etched (the width of the masked part in the microchannel at the time when the mask was fabricated) and the etching depth. However, this method for determining the height can be applicable only when the depth of the flow channels is reproducibly

etched, because wet etching processes generally can cause detrimental errors in creating patterns.

3.13.4 Design of Microsystems for Environmental Sample Measurements

The concept of microsystem technology is the integration of different steps such as chemical reaction, pretreatment, and detection into a miniaturized space that is a fabricated detailed structure of a micro- or nanoscale on substrates of several centimeters (Manz *et al.* 1990). Such a technology is called micro total analysis systems (μ-TAS) or lab-on-a-chip system. Recently, various microsystem devices have been developed with great progress being made in microfabrication technology, and advances in microsystem analysis have been remarkable.

The microsystem technology for analytical chemistry in a liquid microspace is especially called a microfluidic system. The concept is that sample treatment, handling, and detection are performed with microflow manifolds by integration of the FIA system. The first realization of microfluidic device was electorophoretic (capillary electrophoresis (CE)) separations in fabricated microchannels on microsystems (Harrison *et al.* 1992). Since this realization of microsystem-based CE separations, many studies dealing with electrically driven separation on a microsystem have been reported, such as CE (Harrison *et al.* 1993), free-flow electrophoresis (Raymond *et al.* 1994), open-channel electrochromatography (Jacobson *et al.* 1994), micellar electrokinetic capillary chromatography (Heeren *et al.* 1996), capillary gel electrophoresis (Effenhauser *et al.* 1994), and sizing of DNA restriction fragments (Jacobson *et al.* 1994). Because electroosmotic flow and electrophoresis are very suitable for manipulation and separation of samples in a microspace such as a microchannel, the study of microfluidic system using electrically driven have been trend, and some of microsystem devices are marketed. However, the electroosmotic driving force can be applied only to a aqueous solution or to a few polar solvents. Moreover, the application of an electric field causes spatial inhomogenization of the components owing to a difference in the mobility. Thus, an electroosmotic driving force is definitely suitable for separation, but not for transportation. Recently, a pressure-driven flow by a pump has been used for transportation in a microfluidic system, and many applications of microfluidic system for general chemical and analytical system, such as solvent extraction (Tokeshi *et al.* 2000), immunoassay (Hadd *et al.* 1999), and organic synthesis (Hisamoto *et al.* 2001a, b), have been presented.

It is expected that microsystem technologies provide technical innovations in various fields, such as medicine, environment, and industry. For example, microarray analysis has become a powerful technology for drug screening, disease gene identification, and signaling pathway studies. In order to utilize microsystem technologies effectively, it is required that the characteristics of microspace be grasped and a design based on theory be created. As mentioned above, microsystem devices for analytical chemistry have many advantages when compared with a conventional chemistry system. In order to enable broader applications of microsystem technologies in the field of chemistry, the selection of suitable materials and fabrication technique is required. Furthermore, the detection of low concentrations of analytes in the small volumes of samples present in microfluidic system requires sensitive analytical techniques. The characteristics of microspace, microfabrication technologies, and detection technologies are described below.

3.13.4.1 Microcolumn with Monolithic Silica for Organic Compounds Separation in Microliquid Chromatography System

A polystyrene–divinylbenzene polymer monolithic (PS–DVB) column was prepared by *in situ* copolymerization of styrene and divinylbenzene as a preconcentration column. First, the wall of the fused silica capillary (250 μm i.d.) was silanized to enable covalent attachment of the monolithic column. After pretreatment, the capillary, which was filled with styrene, divinylbenzene, solvents, and azobisisobutyronitril (AIBN), was heated and washed with methanol. A silica monolithic column was prepared as a separation column by sol–gel reaction. A fused silica capillary (100 μm i.d.) was filled with 1N NaOH and heated at 40°C. Polyethyleneglycol, urea, acetic acid, and tetramethoxysilane were mixed at 0°C. After pretreatment, the capillary, which was filled with the mixture, was heated at 40°C. Then, the capillary was filled with urea and heated. Moreover, in order to improve its separability, a silica monolithic column was used for surface octadecylation. The column prepared above was filled with dimethyloctadecylchlorosilane and heated at 80°C. After washing with tetrahydrofuran (THF),

the column was filled with trimethylchlorosilane and heated at 80°C and washed with methanol. The image of the monolithic silica is shown in Figure 17.

Backpressure indicates the performance of the column, because for FIA, it is necessary to use a pressure pump suitable for the backpressure of the column. If the backpressure is high, a high-pressure pump will be required. Additionally, considering the pressure at the connection point of a microchip and a pump (via a capillary tube), a low-pressure-driven flow is desirable. The backpressure versus the flow rate of sample solution was related to the concentration columns (Chang and Korenaga 2006).

The performance of the separation column was investigated for use of downsized liquid chromatography (LC) with a monolithic silica column (Figure 18). The LC device with a miniatured column requires about 3 ml elution solvent a day in comparison with 500 ml a day for conventional high-performance LC instruments.

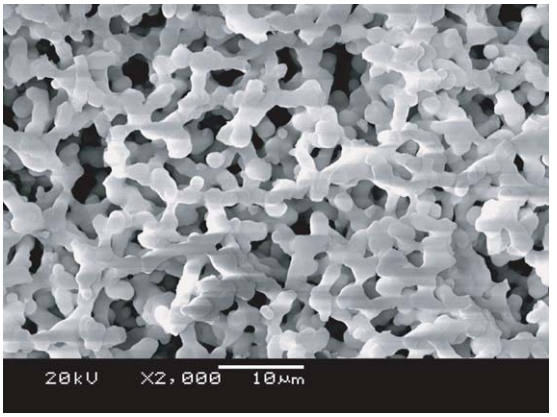

Figure 17 Monolithic silica packing material.

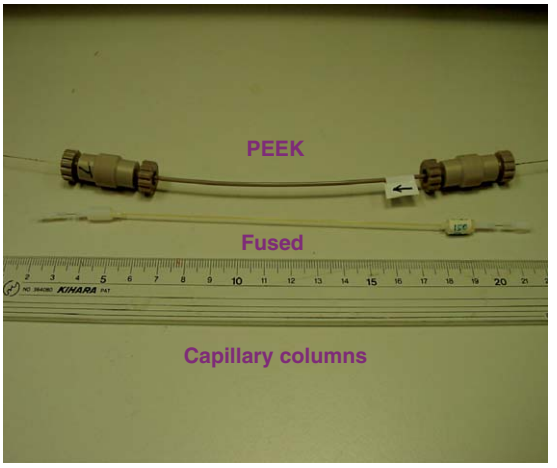

Figure 18 A fused silica capillary and PEEK columns packed with monolithic silica.

3.13.4.2 Microsystem for Inorganic Air Pollutants and Volatile Organic Compounds Monitoring in Gas Samples

A gas absorption microchip that was adapted for NO_2 measurement of a living environment level was designed and fabricated by Takabayashi and coworkers. The results of the basic experiment using a simple gas absorption microchip showed that microchip-based gas absorption was dependent on the gas–liquid contact time related to the absorption area and the flow rate of the gas absorption solution. However, as the form of the gas absorption unit was a huge hexagon-like pool, it turned out that the heterogeneity in a gas absorption rate takes place because of stagnation of the gas absorption solution. In order to prevent the staying of gas absorption solution in the gas absorption unit, it was ideal for all the fluid that flows along several branch lines to gather at a point simultaneously. Therefore, the gas absorption unit was taken as composed of a line and a space, as shown in Figure 19. The gas absorption unit consisted of channels that were 500 μm wide and 100 μm deep; 24 channels were 250 μm wide and 100 μm deep. The internal volume of the gas absorption unit was approximately 6.2 μl. In order to lose the dead volume in the gas–liquid contact, it is desirable that the form of the porous glass plate be the same as the channel pattern (hexagon-like). However, as it was difficult to cut a hexagon precisely, it was decided that a circular porous glass plate be used. Therefore, the actual gas absorption area as the gas–liquid interface was calculated to be approximately 39 mm × 39 mm. The developed micro gas absorption unit was integrated into a microchip for NO_2 determination. The photograph of the structure of the microchip is shown in Figure 20. However, the use of porous glass as the interface of gas and liquid has some disadvantages, for example, there is no suitable bonding technique between the porous glass plate and the quartz substrate. Thus, in order to improve the performance of the proposed method, a poly(tetrafluoroethylene) (PTFE) membrane, which has a thickness of 70 μm, as polymeric porous material, was used. A photograph and schematic illustration of the structure of polymer-based absorption microchip is shown in Figure 21. The microchip was composed of a PTFE membrane and two PMMA

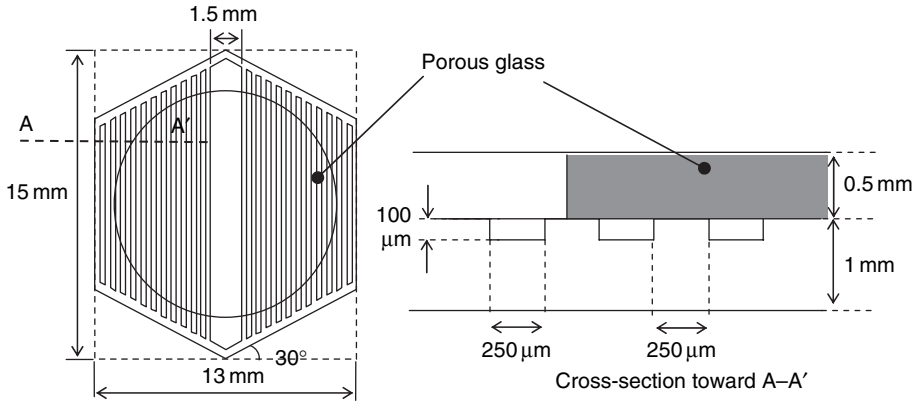

Figure 19 Schematic illustration of channel pattern and cross-sectional view of gas absorption unit.

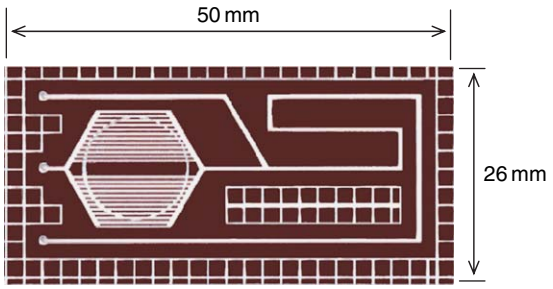

Figure 20 A photograph of NO_2 measurement microchip.

substrates, which are the cover and bottom plates. Each plate was a 12.5 mm × 35 mm rectangle. The thickness, average pore diameter, and porosity of the PTFE membrane (AVDANTEC, FG301) were 70 μm, 0.1 μm, and 64%, respectively. For the bottom plate, a single channel having a width of 1 mm, a depth of 0.1 mm, and a length of 25 mm were formed by mechanical cutting. The penetrated walls were accessible to the PTFE membrane and the inlet and outlet of the absorption solution were mechanically bored on the cover plate. The PTFE membrane was sandwiched between the cover plate and the bottom plate, and these plates were bonded by a thermal adhesive bonding technique. The microchip-based collector using PTFE membrane depends on the effect of wind velocity (ranging from 0 to 1.5 $m\,s^{-1}$), relative humidity (ranging from 30% to 80%), and the form of the absorption unit. The overall mass transfer coefficient was approximately six times higher at 1 $m\,s^{-1}$ than that with no air circulation. For the effect of relative humidity on gas absorption rate, the change of the overall mass transfer

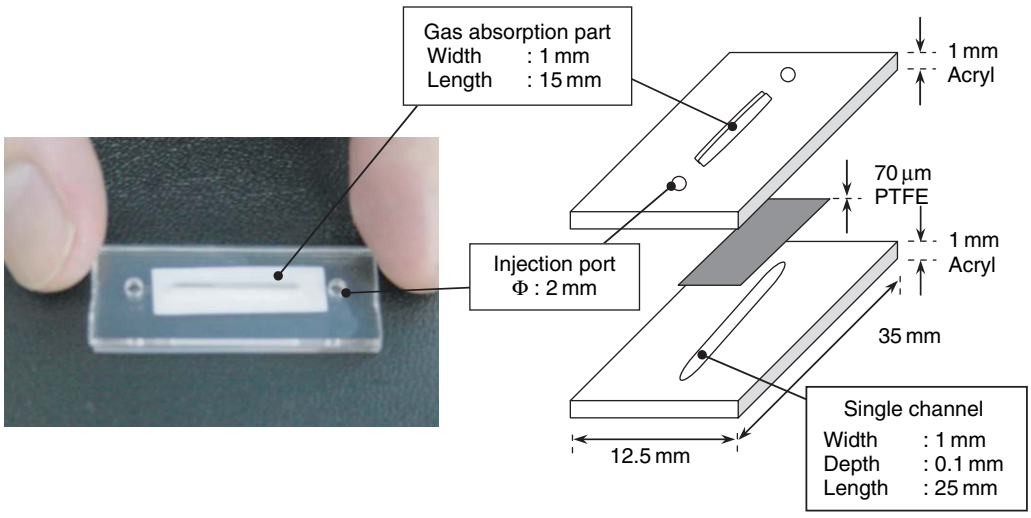

Figure 21 A photograph and schematic illustration of the structure of polymer-based absorption microchip.

coefficient at high (80%) and low (30%) relative humidity was found. However, it was shown that a good linear relationship exists between NO_2 concentration and absorbed NO_2^- concentration under a constant relative humidity. Under optimized condition, the detectable limit was 0.5 ppb. Considering the absorption area of 15 mm × 15 mm and an internal volume of 1.5 ml, the excellent results obtained by this work are promising and will be applied in devices monitoring air pollutants.

For monitoring volatile organic compounds in air, a micro preconcentration unit was developed by fabricating monolithic silica in a fused silica capillary (Chang and coworkers). The micro preconcentration unit is also expected to integrate into a microchip to achieve a microchip-based micro preconcentration system for the monitoring of volatile organic compounds.

3.13.4.3 Microdrop Formation System for Trace Metal Preconcentration and Determination in Liquid Samples

The droplet generation in a microchannel utilizing its geometric pattern was performed and the formation of a droplet during flow in a microchannel was observed. The droplet was formed at the confluent point of the continuous phase and the dispersed phase by flowing two immiscible solutions, water as aqueous phase and tributyl phosphate (TBP) as organic phase. By varying the flow rate of the two solutions, the droplet volume could be controlled. The dynamic formation of TBP was observed in a 600-μm-wide continuous phase and a 300-μm-wide dispersed phase. The shape of the fluid was varied from slug to droplet. On the other hand, in another microchip having a 600-μm-wide continuous phase and a 100-μm-wide dispersed phase, TBP droplets were formed precisely and continuously at 90- to 200-μm diameter in the range of 5–55 mm s^{-1} in the continuous phase and 47–370 mm s^{-1} in the dispersed phase.

A quick extraction system using dispersed droplets in the T-shaped microchannel has been constructed and investigated for determination of aluminum. The droplet was formed in the T-shaped microchannel 600 μm wide and 50 μm deep in the continuous phase and 70 μm wide and 20 μm deep in the dispersed phase by flowing two immiscible solutions, aqueous buffer solution containing aluminum and TBP as organic phase. Using this droplet generation in the microchannel, aluminum in the aqueous phase was extracted with DHAB as a metal chelate into tributyl phosphate for several seconds. The characteristics of extraction in this microchannel, such as extraction time, volume-to-area ratio of the droplet, and mass transfer, were investigated. Furthermore, this extraction system was applied to environmental analysis for evaluation of its validity, and it was found that the result was in good agreement with that from the conventional extraction method.

DHAB has been used as a chelating agent for spectrophotometric detection of metal ions such as Al^{3+}, cobalt cation (α), iron cation (β), vanadium cation (δ), indium cation, and gallium cation. Metal chelates produced by reacting these metals with DHAB have absorbance in the range from 400 to 600 nm. These chelates are highly colored, kinetically inert, and water soluble. Also, DHAB has been used as a chelating agent for spectrofluorometry detecting Al^{3+}, gallium cation, and magnesium cation. These metals can be determined at each excitation (Ex.) and emission (Em.) wavelength: Ex. 485 nm, Em. 560 nm for Al^{3+}; Ex. 470 nm, Em. 580 nm for magnesium. Selective determination of these analytes can be achieved by choosing these specific wavelengths.

The aluminum standard solution containing DHAB was flown as the continuous phase and the TBP was flown as the dispersed phase. The Al^{3+}–DHAB chelate is composed in the continuous phase, and then it is extracted into the TBP droplet. The extraction reaction starts by contact between the TBP and the Al^{3+} standard solution at the confluent point. The variation of fluorescence intensity to pH for a reaction in the microchannel was investigated. Standard solutions and TBP were flown into the T-shaped microchannel and the fluorescence from droplet was detected in each solution. The fluorescence intensity was highest at pH 6.3. It was shown that the fluorescence intensity was lower in acid and alkali media. The variation in the fluorescence intensity obtained from this experiment corresponded with the value from the conventional extraction method that was reported by Watanabe and coworkers. Additionally, the concentration of DHAB was optimized. The concentrations of each solution were 20, 100, 200, and 1000 μg l^{-1}, which corresponded with 0.093, 0.467, 0.935, and 4.672 μmol l^{-1}, respectively. The concentrations of aluminum in aqueous phase were 0 and 500 μg l^{-1}. In a concentration of DHAB at 1000 μg l^{-1}, two peaks were obtained in the spectrum at 524 and 560 nm. It was

Table 2 Equilibrium and kinetic parameters for extraction of Al^{3+}-DHAB chelate from continuous phase into each droplet

Flow rate of continuous phase (mm s^{-1})	*Fluorescence intensity (arb. unit)*	*Droplet volume (nl)*	*Extraction time (s)*	$\frac{dc_o}{dt}(\times 10^{-6})$	$\frac{\beta_o(\times 10^{-4})}{(mm\ s^{-1})}$	*Nernst film (δ_{aq})*
16	122	11	5.4	0.77	0.62	1.1
26	95	5.9	3.0	2.2	1.5	0.41

41	37	1.2	1.1	9.1	3.5	0.18
57	26	0.6	0.91	13	4.5	0.14

Chelating agent – 2,2-dihydroxyazobenzene (DHAB).

assumed that the peak at 524 nm originated from DHAB unreacted with Al^{3+}. The highest peak was obtained from the 200 μg l^{-1} DHAB solution and the intensity of the blank at 560 nm was lower. Therefore, the concentration of DHAB was optimized to 200 μg l^{-1}.

Table 2 shows the data obtained at $x = 40$ mm on the microchannel by PMA. Each peak represented fluorescence from a droplet. The coefficient variation was 2–20%. The flow rate of the continuous phase and the dispersed phase were 37 and 25 mm s^{-1}. The fluorescence intensity of the Al^{3+}–DHAB chelate in the droplet was gradually increased and reached at about 60 mm from the T-junction, which was assumed to be in equilibrium. This variation of fluorescence intensity indicated that the Al^{3+}–DHAB chelate was extracted from the aqueous phase to the droplet by increasing the connection time. The extraction time was about 2 s, which was calculated as the length from the T-junction to the equilibrium point divided by the flow rate of the continuous phase.

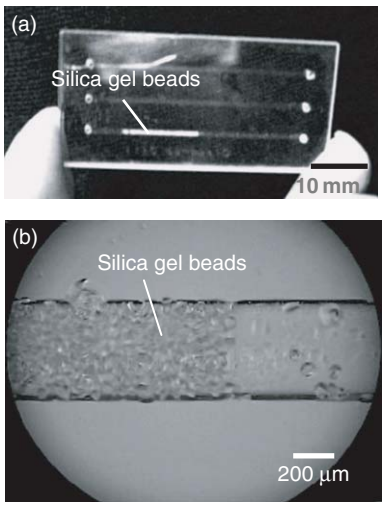

Figure 22 Solid–liquid extraction pretreatment microsystem. (a) A total photograph of the microchip; (b) A microscopic photograph of the microchannel where silica gel beads are packed by the wet etched dam structure.

3.13.4.4 Microsystem for Organic Compounds Pretreatment and Analysis in Solid Samples

As an example of the removal of impurities using a microchip, a monolithic porous column for on-chip solid-phase extraction has been reported. However, the disadvantages of inserting a microchip into a monolithic column are that the duplicability of each chip is bad and the system cannot be used permanently. Moreover, the sample, including fine particles or high-viscosity solution, does not flow properly because of the high pressure in the channel.

Using PAHs containing particles as samples for cleanup operations, the microchip method (Figure 22) and the batch method were compared. The following three samples were used for comparison: diesel exhaust particles that were obtained from the engine whose displacement was controlled by chassis dynamo test, particles sampled with a high-volume sampler at the sides of an expressway, and particles sampled in a tunnel duct. Because a good correlation was found even when the source of particles was changed, the effect of the matrix effect and of the change in the foreign substance on the microchip method would be minimal. In addition, the reproducibility was 5.37% for B[*a*]P and 6.21% for B[*k*]F. These values of reproducibility were almost identical to that obtained with the batch method.

Because the condensation operation is eliminated, the microchip method requires an operation time of not more than one-tenth and a volume of solvent of not more than one-hundredth of that required for the batch method. Furthermore, in the microchip method, silica gels can be activated while being kept in their packed state, and contamination problems at the time of packaging can be resolved.

3.13.5 Development of a Microsystem Detection Device for Environmental Monitoring

In order to detect analytes in a miniaturized space such as a microchannel, a high-sensitivity detection technique is required. For example, for the optical analysis, the size of the space where the analytes exist is important. The small volume in a microchannel is disadvantageous for the analysis of any substance. In order to tackle such a situation, high-sensitivity detection methods are studied and developed. Optical analysis, electrochemical detection, and mass spectrometry (MS) are the detection techniques frequently used for analysis utilizing the microsystem.

Many optical analyses for detection for microfluidic devices have been explored, such as refractive index (Burbbraf *et al.* 1998), absorption (Liang *et al.* 1996), fluorescence (Wang and Morris 2000), and chemiluminescence. Fluorescence detection is mainly used for on-system detection, because it allows selective and sensitive detection. Optical microspectroscopic methods are making rapid progress in their spatial resolution and sensitivity due to the development of microscopic techniques and powerful light sources such as laser. Among them, laser-induced fluorometry (LIF) is one of the most sensitive methods and confocal laser fluorescence microscopy has the highest spatial resolution (Hadd *et al.* 1997, Jin *et al.* 2001). For another optical method, a TLM has been used for ultrasensitive detection of nonfluorescent species in a microchannel (Harada *et al.* 1999).

Electrochemical detection is the technique for measuring the oxidation–reduction current on the surface of an electrode. Metals such as platinum and gold are used as electrodes, and as metal deposition can be easy in a microsystem fabrication process, many examples of applications in microsystems with a built-in electrochemical detection system have been reported. The electrochemical detection methods, such as amperometric detection (Wang *et al.* 1999, Wooley *et al.* 1998), conductivity detection (Lugere *et al.* 2001), cyclic voltammetry (Rossier *et al.* 1999), and electrochemical detection using an electrically isolated potentiostat, are used for microfluidic devices. Because metal layers used as an electrode can be easily deposited in a microfabrication process, electrochemical detection is widely used for microfluidic devices.

3.13.5.1 A Micro Photometric/Fluorometric Detector for Lab-on-a-Chip System

In the field of analytical science, as most of the researches using microsystem have been proposed for analyzing liquid samples, few researches deal with the gas phase. Moreover, there are few reports on the application of microsystem techniques to atmospheric gas analysis because there is no suitable gas sampling method. Because of the large differences between physical parameters of gas and liquid phases, such as viscosity and compressibility, the control of a gas–liquid two-phase flow in a microchannel was relatively difficult. Thus, mostly, gas–liquid two-phase flow on the microfluidic devices is treated as gas–liquid segmented flow. A miniaturized ammonia sensor has been reported (Timmer *et al.* 2004a, b). In this system, gas flow and liquid flow were introduced in the reaction chamber, and an electrolyte conductivity sensor was used for the detector. Tokeshi *et al.* (2002) reported an evaporation utilizing the gas–liquid two-phase laminar flow in the microchannel and applied the technique for the gas analysis system. However, as this system is dependent on special microchannel structures and surface modification, complicated and advanced fabrication techniques are required. In addition, because of the use of TLM for ultrasensitive detection, the system is far from a general-purpose analysis system.

3.13.5.2 A Highly Sensitive Micro Dual-Beam Fluorometric Detector for Lab-on-a-Chip System

A micro dual-beam fluorometric detection device (**Figure 23**) was developed for highly sensitive detection of B[*a*]P and B[*k*]F. The device uses a UV light-emitting diode (UV-LED) that emits light with

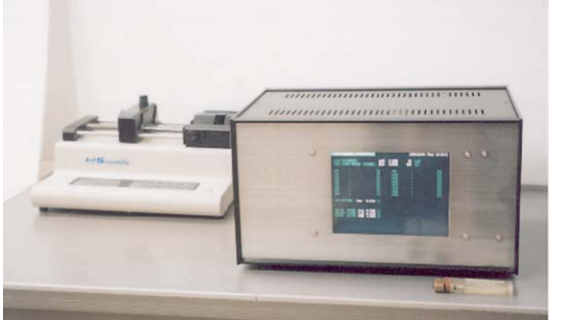

Figure 23 Picture of the micro dual-beam fluorometric detection device.

a wavelength of 370 nm and a violet laser diode that emits light with a wavelength of 395 nm as excitation light sources. The detection method is based on the following observation: characteristic fluorescence is emitted from both B[*a*]P and B[*k*]F, having intensities up to 10 times greater than those from 22 other PAHs. The excitation and emission wavelengths for fluorescence from B[*a*]P and B[*k*]F are 370 and 429 nm, and 395 and 429 nm, respectively.

The microchip was 50 mm in length, 26 mm in width, and 2.0 mm in thickness, and the microchannel was 500 µm in width and 100 µm in depth. All solutions were injected into the microchip using an external syringe pump (IC3200, KD Scientific). The chip used in this study was specifically designed to serve as an optical flow cell considering the simple pattern used in the detection system.

Fluorescence spectra were recorded with a Shimadzu RF-5300PC spectrofluorometer. A modular component liquid chromatographic system was used, which consisted of a Jasco PU-1580 ternary pump, a Jasco DG-2080-53 degasser, a Shimadzu fluorescence detector, and a Jasco RF-10AXL integrator. In the experiments, 20 µl of the sample was injected through a Jasco AS-1555 auto injector. A Supelco 5-mm LC-PAH column (150 mm × 4.6 mm ID) was used for the detection. The experimental results for the determination of B[*a*]P and B[*k*]F in diesel exhaust are given in **Table 3** (Masaki *et al.* 2005).

3.13.5.3 A Highly Sensitive Thermal Lens Microscope for Lab-on-a-Chip Detection

A detection method for the measurement of a microscopic object is required in order to detect specified objects contained in the channel of a chip. A thermal lens microscope was developed by the University of Tokyo as a detection tool for microchip chemistry (Tokeshi *et al.* 2004). The principle of a thermal lens microscope is shown in **Figure 24**. If a material absorbs both an excitation laser and a probe laser through an objective lens, the light energy except the energy absorbed by the sample is all released to the solvent as thermal energy, and the phenomenon produces an increase in temperature. According to the spatial distribution of temperature, a high gradient of the temperature distribution is formed around the optic axis of the laser by the intensity distribution and the thermal diffusion of the laser. In the case of fluids such as water, a lower refractive index at the center of the optic axis and a higher refractive index at the banlieue of the optic axis are formed because the refractive index is lowered by the temperature rise.

The refractive index distribution is equivalent to the concave lens and it is also called thermal lens. The sensitivity of the thermal lens is proportional to the calorific value generated, i.e., it is proportional to the amount and the concentration of a sample; therefore, the quantity of a sample can be determined by measuring the sensitivity of the thermal lens. For an actual measurement, the excitation laser is modulated and the intensity change of the probe laser is simultaneously detected. The subject of ultrasensitive detection of nonfluorescent molecules is extremely important in the field of analytical chemistry and measurement technologies. Although it is presently possible to detect a single fluorescent molecule, it is very difficult to detect nonfluorescent molecules at a single-molecule level. The principle of a thermal lens microscope, which can detect nonfluorescent molecules at the single-molecule level,

Table 3 Comparison of the dual beam fluorometric detector and HPLC/FLD for the determination of B[*a*]P and B[*k*]F in diesel exhaust

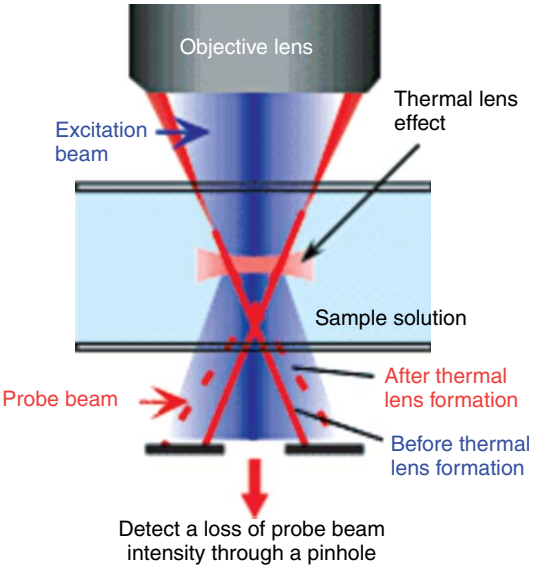

Figure 24 Schematic illustration of a thermal lens microscope.

and its performance and applications are described. A desktop thermal lens microscope and a palmtop thermal lens detection device were also developed.

The thermal lens microscope is a promising measurement method not only for analytical chemistry but also for biological, material, and environmental fields. But the thermal lens microscope setup is relatively large as compared with a chemical microchip. This means that even if a microchip is small, the total analysis setup may become large. A portable size instrument of thermal lens spectroscopic analysis was developed by making use of our fiber optical communication technology.

3.13.5.4 A Downsized Mass Spectrometer for Lab-on-a-Chip Detection

In the field of analytical sciences, a usage at the field of biotechnology and nanotechnology which represents the main themes of the frontier research to elucidate the life sciences, molecular analysis has been heading for not only easily analyzing, but also with higher quality, and understanding the results of analyses for anyone. For its challenging, for example, preparation for their analyses, downsizing and higher quality of instruments have been developed. A downsized mass spectrometer is needed with sample pretreatment microsystems. For the molecular analyses of proteins in the postgenome age, high-performance liquid chromatography–mass spectrometry (LC-MS) or MS/MS are frequently used in the frontier research of proteomics technology.

The downsized MS has been accomplished with a very high-resolution, lightweight, and compact body using a hybrid vacuum system and MEMS technology. We adopted the time-of-flight mass spectrometer (TOF-MS) due to its compact body, high resolution, and very high sensitivity. The property of TOF-MS was tested and the significance of this very small and high-performance instrument was discussed based on specific results (Korenaga 2005).

The adrenocorticotropic hormone (ACTH) was used for the resolution tests for this TOF-MS. The ACTH concentration in the blood plasma reflects the amount of secretion from the pituitary. Thus, ACTH analysis is significant for recognizing the degree and the position of the abnormal part of the pituitary, hypothalamus, and adrenal cortex. The ACTH measurement is indispensable to clarify the diagnosis and the condition. ACTH (0.123 mg) was dissolved in 141 µl of acetonitrile/H_2O (35:65). This solution was diluted to 3.54 pmol μl^{-1}. Four microliters of the diluted solution was used and this was mixed with 4 µl of the matrix solution (CHCA, α-cyanohydroxycinnimic acid). Two microliters of the mixed solution was added on the sample plate. To find the various TOF-MS conditions, the acceleration voltage, the pulse delay of the N_2 laser, and the voltage of the reflectron and of the electronic circuits were changed. Assuming an approximation to the normal distribution-obtained mass spectrum, the gaussian fitting for this mass spectrum was calculated and from the results of fitting, the resolution of ACTH was estimated.

Figure 25 shows a very small TOF-MS. The length of molecular flight is about 50 cm, equipped with a reflectron to reflect molecules and a microchannel plate (MCP). MEMS technology was used in the high-voltage electricity of TOF-MS. The total volume and mass are approximately 14 l and less than 20 kg, respectively.

The mass spectrum of ACTH is shown in Figure 26. The measurement condition was optimized such that the first and the second acceleration voltages and the reflectron voltage were 4.95, 3.35, and 5 kV, respectively. The pulse delay of acceleration after N_2 laser ablation was conditioned to 6 µs. As a result of the gaussian fitting of the ACTH mass spectrum peaks, a surprisingly high resolution of 4966 was obtained.

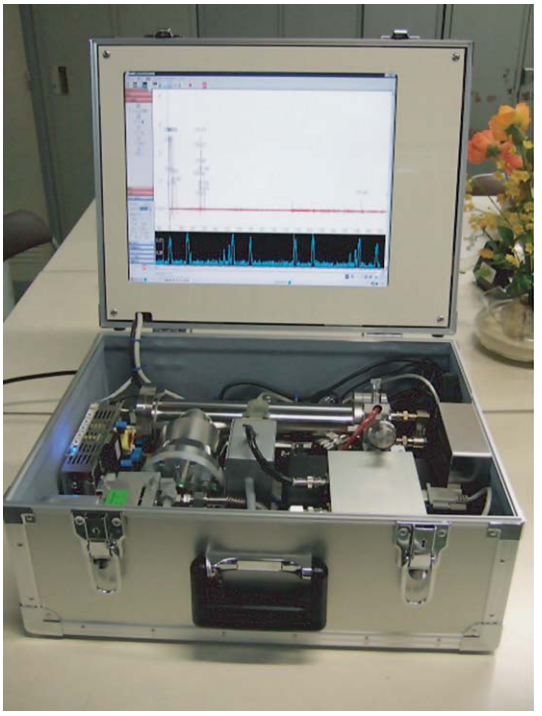

Figure 25 A photograph of the small and high-performance time-of-flight mass spectrometer (TOF-MS) prototype device.

The usage of a high-performance small TOF-MS is described below:

(1) For on-site analysis and on-site monitoring of environmental organic compounds such as dioxins, agricultural chemicals, and halocarbons in water it should be effective.
(2) For explosive organic compounds and drugs, it would also be suitable where many people gather at a public place such as a station or an airport.
(3) For academic purposes such as earth science and archaeology, where it is likely to be accepted.
(4) Probably, for its use in medicine by analyzing proteins as described above with this high-performance TOF-MS. For example, a doctor in a hospital could make a decision immediately by using this.

Futhermore, as the cost performance of this machine could be very high, a quick result without waiting for the tests would be expected in large institutes using very large and expensive machines for a long time. Also, medical researchers at other institutes should be able to use the machine easily. A significant contribution from a high-performance small TOF-MS is expected in the near future.

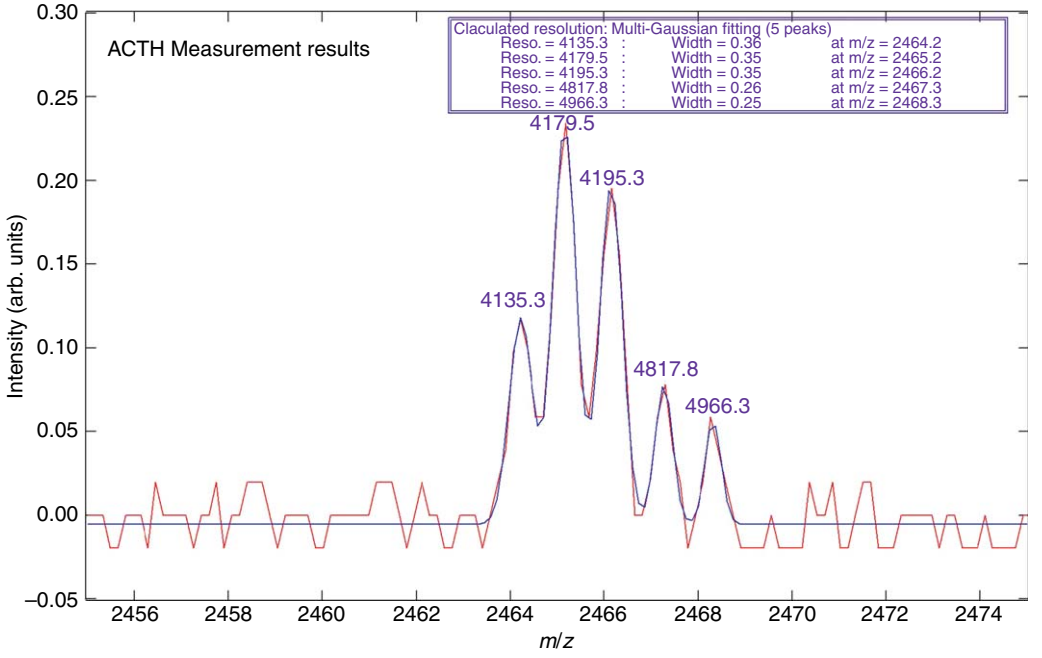

Figure 26 Mass spectrum of adrenocorticotropic hormone (ACTH) obtained by the downsized time-of-flight mass spectrometer (TOF-MS) prototype device: multiple peaks indicate their isotopes from *m/z* 2464 to 2468. High resolution 4966 was observed at *m/z* 2468 as the results of the gaussian fitting.

3.13.6 On-Site and Real-Time Environmental Monitoring Device with Microsystems

The microchip technology provides a miniaturized analytical system, which leads to downsizing of the experimental equipment as well as high-speed, high-throughput analysis, a small sample volume, and a small experimental space. Based on these advantages of the microchip technology, the microsystems have been used for on-site and real-time monitoring of all kinds of environmental pollutants.

3.13.6.1 Industrial Nitrogen Dioxide Gas Monitoring in Atmospheric Environment

A design and a photograph of the NO_2 monitoring microsystem are shown in **Figure 27**. The microsystem integrates three functions:

(1) NO_2 gas absorption
(2) Fluorescent derivatization
(3) Fluorescence detection

The microsystem was constructed by the Technology Research Laboratory, Shimadzu Corp. (Kyoto, Japan). The microsystem substrate consists of a 50 mm × 26 mm quartz glass plate 2.0 mm thick. The microchannels were fabricated using photolithography and wet chemical etching with dimensions ~500 μm wide and 100 μm deep, with a channel width in the absorption region of 250 μm.

The sampling of NO_2 was performed by extracting NO_2 from the atmosphere through the use of a porous glass plate embedded in the microsystem device. It was designed to absorb the gas and then allow it to react with TEA within the microchannel. The NO_2 gas absorption area is a disk-form porous glass plate (Vycor(r) 7930; Corning International K.K.) 11 mm in diameter and 0.5 mm in thickness, having a 28% void volume and a 200 $m^2 g^{-1}$ ratio between its area and weight.

The on-system fluorescence detection system is 320 mm in width, 230 mm in depth, and 177 mm in height. This device is equipped with a UV-LED (NSHU590E; Nichia Corp., Tokushima, Japan) excitation light source of maximum emission wavelength at 370 nm. The observed fluorescence was filtered with a band-pass filter (S76-L42; SURUGA SEIKI Co. Ltd., Shizuoka, Japan) to get the integral fluorescence at wavelengths more than 420 nm, and detected using a photomultiplier tube (PMT). All reagents were injected into the microsystem using syringe pumps (IC3200; KD Scientific) equipped with Hamilton GASTIGHT(r) syringes (25, 100, and 1000 μl). For on-site experiments, it is necessary to keep the wind velocity constant; so the fan to adjust the wind velocity is placed at the outer cover of this device.

An NO_2-absorbing solution, TEA, and a suitable fluorescence reagent were injected into the microsystem via the central and adjacent ports. The flow rate was controlled with syringe pumps. The NO_2 gas is absorbed from the atmosphere into TEA to form the absorbing solution via a porous glass plate. Here, the absorbed NO_2 reacts with water to produce NO_2^-, which is then transferred into the chemical reaction channel, where it reacts with 2,3-diaminonaphthalene (DAN) in acidic solution to produce 1-[*H*]-naphthotriazole (NTA), a highly fluorescing species in alkaline media. At the detection point, NTA is excited at 370 nm (UV-LED) to detect the fluorescence light. For highly sensitive determination, pH adjustment after reaction and before detection are needed, so other systems were used.

In order to determine the optimal conditions for the chemical reaction, the NO_2 absorption area was sealed and the TEA solutions with known NO_2^- concentration were introduced into the microsystem via the central port of system A. Here, the NO_2^- was reacted with the fluorescent reagent (DAN), introduced from a side port on system A, resulting in the formation of NTA. The highly fluorescent NTA was then passed through the PTFE tubing to system B,

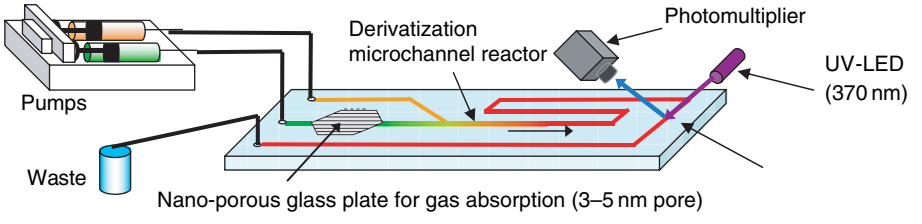

Figure 27 Micro NO_2 monitor prototype device installed with a microchip.

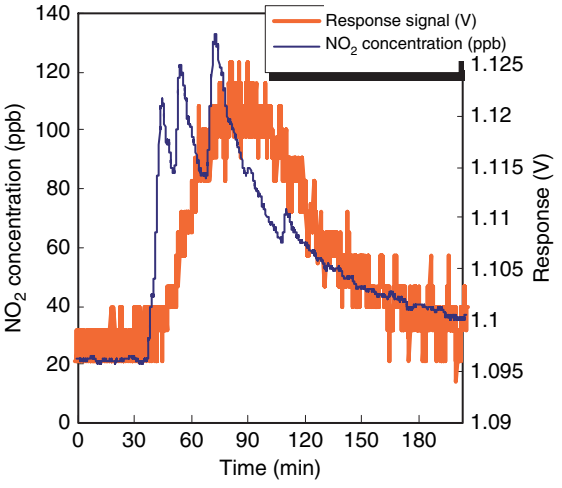

Figure 28 Experimental results for continuous NO_2 monitoring.

where it was combined with the pH buffer solution and delivered to the detection point as shown in Figure 28.

3.13.6.2 Trace Metal Ion Measurement in Aqueous Environment

A schematic illustration of the experimental setup based on laser-induced fluorescence microscopy is shown in Figure 29. Ar^+ laser (488 nm wavelength, 2101-40MLA; JDS Uniphase Corporation, California, USA) was used as the excitation beam source. The excitation beam from Ar^+ laser was introduced into an optical microscope (TE300; Nikon, Tokyo, Japan) via an optical fiber, and, through an objective lens (NA 0.3), was irradiated onto a microchip put on the microscope stage. A dichroic mirror, an absorbing filter and a reflection filter, was placed in the microscope to block off a scattered and reflected excitation beam. A CCD camera, which was mounted on the microscope, displayed a picture image from inside the microchannel. Fluorescence from the extracted solute in the droplet was collected by the same objectives, and led to a polychromator–multichannel photodetector (PMA-11 C7473-36; Hamamatsu Photonics, Shizuoka, Japan) through an optical fiber to record a fluorescence spectrum. The spectrum data were obtained by PMA every 19 ms for 3–10 s, and the variation of fluorescence intensity depending on the contact distance of two solutions was observed by moving the 3D stage of the microscope. The direction from the confluent point to the channel outlet is set to *x*. The performance of this laser-induced fluorescence microscopy system was thoroughly investigated. For the detection of Al^{3+}–DHAB chelate, which is used in this study, a filter block was prepared to block off the scattered and reflected excitation beams. A filter block designed to transmit light at 530–670 nm was used. The transmittance of the filter block was 0% at 488 nm (excitation wavelength, Ar^+ laser) and 88% at 560 nm (emission wavelength), respectively.

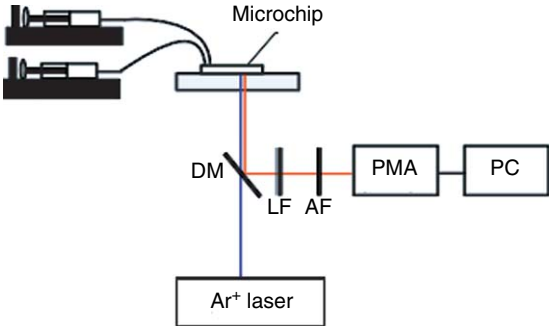

Figure 29 Schematic illustration of experimental setup. AF, absorbing filter; DM, dichroic mirror; RF, reflection filter.

Aluminum exists in our environment; the amount is as much as the oxygen and silicon in the earth. The metal is known to be harmless and easiy to process as an industrial material, and is widely used in industry. However, in recent years, the elution of aluminum as metal ion from soil and rocks, which is especially caused by acid rain, is a problem for plants and microorganisms. Individual chemical formation of aluminum has an effect on this ecological system in varying degrees. Many researchers are engaged in the study in order to clarify the behavior of aluminum in the soil, the chemical formation in the soil and river, or the effect on plants and microorganisms. Tsunoda and coworkers reported the effects of aluminum on the environment. They found the chemical formation of aluminum that existed in rivers. Aluminum exists as ion or compounds with organic matter in lakes in Japan. In the Uzoriko Lake (Aomori, Japan), it was clarified that over 90% of aluminum existed as Al^{3+}, and in the Inawashiroko Lake (Fukushima, Japan), almost all the aluminum formed compounds with organic matter. The chemistry of aluminum in water is complicated, and many chemical parameters, including pH, determine which aluminum species are present in aqueous solutions. In pure water, aluminum has a minimum solubility in the pH range from 5.5 to 6.0; concentrations of total dissolved

aluminum increase at higher and lower pH values. Also, the study of the effects on plants is still continuing. Especially, it is known that growth of the root of a plant is affected by aluminum ions. As described above, the effect of chemical substances on the environment is an important problem that confronts the analyst.

The World Health Organization does not regulate the aluminum in drinking water as a health-based guideline value, owing to limitations in the animal data as a model for humans and the uncertainty surrounding human data. However, they recommend that permissible levels based on optimization of the coagulation process in drinking water and plants using aluminum-based coagulants are 0.1 mg l^{-1} or less in large water treatment facilities and 0.2 mg l^{-1} or less in small facilities.

The maximum value in the extraction of Al^{3+} from aqueous phase to droplet in this microchannel is limited, because the distribution of the amount depends on the ratio of the aqueous phase and the organic phase. If the amount of Al^{3+} in the field sample is large, the extracted amount will saturate in the droplet. For avoiding this problem, some ideas can be proposed. First, the sample solution can be diluted to adjust to a suitable concentration. Second, the extracted amount should be detected before reaching saturation in the droplet. Third, a larger droplet can be used for extraction, which has a larger maximum value in extraction when compared with a smaller droplet. Therefore, a microchip having a larger channel size in the dispersed phase (300 μm × 50 μm) was used for determination. By using this microchip, 18 nl of droplet can be generated. For avoiding saturation, the extraction amount was detected at a fixed position, which is 50 mm from the T-junction.

The calibration curve of Al^{3+}–DHAB chelate was obtained by detection at 50 mm from the T-junction. The correlation coefficient was $r = 0.992$ with a coefficient variation of 5–13%. The detection limit was 2 μg l^{-1} ($\sigma = 3$) and the extraction efficiency was 89%. Generally, the concentration of Al^{3+} in city water was below 80 μg l^{-1}. Therefore, this droplet extraction method has sufficient sensitivity for its application in the determination of Al^{3+} in these samples.

This droplet extraction method was applied for the determination of Al^{3+} in field samples. The sample waters were obtained from the Asakawa River and the Nagaike Pond in Tokyo on August 2004, and city water was also used. These sample waters were filtered with a pore size of 0.2 μm (DISMIC-13cp; ADVANTEC, Tokyo, Japan) and were adjusted to pH 6.3 by adding buffer solution. They were then added to the DHAB solution. As for reference, the conventional extraction method was performed. The result of the determination of Al^{3+} is shown in Table 4. These results show a relationship between the determination by this droplet extraction method and that determinedby the conventional method. The correlation coefficient was 0.92 with the conventional extraction method.

Table 4 Determination of Al^{3+} in water

	This method (μg l^{-1})	*Conventional method (μg l^{-1})*
Asakawa River	55	80
Nagaike Pond	148	155
City water	32	24

Mean ($n = 3$).

3.13.6.3 Polycyclic Aromatic Hydrocarbons Analysis in Solid Samples

An integrated microfluidic system that performs cleanup for PAHs from diesel exhaust particles on silica gel beads in a microchip is described. A column chromatography phase was constructed by filling the silica gel beads into a microchannel that had a dam structure 25 μm in height. The height of the dam structure was determined by the rate of wet etching. This work on the cleanup of PAHs from diesel exhaust particles showed that the microchip-based system has the same performance as the conventional method on the solid-phase extraction column and has advantages, such as less reagent consumption and shorter pretreatment time, over the conventional method.

B[*a*]P and B[*k*]F standards were purchased from Wako Pure Chemicals. Dichloromethane used was from Kanto Chemicals as analytical grade solution. The silica gel beads used for cleanup were C-300HG (40–60 μm, >80%) from Wako Pure Chemicals. The quartz glass plates purchased from Tobita-Rika Glass were 50 mm in length, 26 mm in width, and 1.0 mm in thickness, and they were mechanically polished. Silica gel beads were activated at 120°C immediately before use.

The exhaust gas gathered from a diesel car was processed with a fixed constant volume sampler (CVS) device, and the diesel exhaust particles containing PAHs from the quartz filter were sampled

using a high-volume air sampler. The diesel car was run with a chassis dynamometer to simulate running on a road. The stainless-steel dilution tunnel was 6.5 m in length with a 0.6-m inner diameter; diesel exhaust particles were sampled from the tunnel with a flow rate of 40–120 $m^3\,min^{-1}$. Two 20-mm-diameter disks were cut from the collected filters with a belt punch for PAH analysis, and then 4.0 ml of benzene:methanol (3:1) was added and extracted by ultrasonication. The solution including PAHs was concentrated and the residue taken up in 1 ml dichloromethane solution.

A cleanup operation is one of the pretreatments indispensable for measuring samples collected in an environment. The samples are examined after a pretreatment microchip enables effective cleanup operations when applied to diesel exhaust particles, particularly many foreign substances. Inside the microchip, a dam structure was designed based on calculations so that silica gel can be freely placed and removed, which results in highly reproducible cleanup operations. In **Figure 30**, the cleanup operation is only with solvents extracted from diesel exhaust particles without using an elution solvent. These advantages enable a direct detection of substances immediately after the cleanup operation, and condensation is not required. By employing an appropriate column packing, the range of applications for cleanup operations may be expanded, and complicated cleanup operations can be easily performed in a short time (Masaki *et al.* 2006).

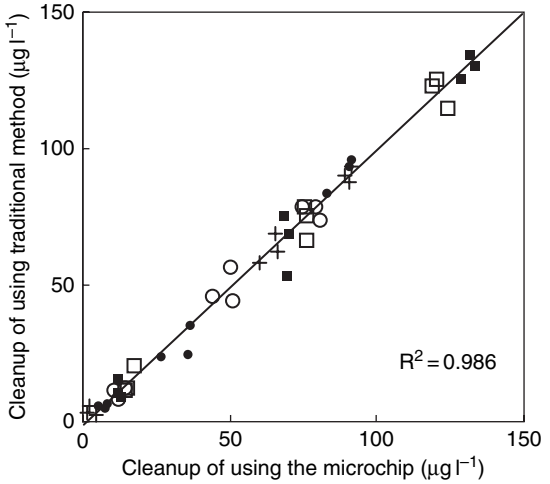

Figure 30 Determination of B[*a*]P (○), B[*k*]F (●), B[*a*]A (■), B[*ghi*]P (□), and DB[*a*,*h*]A (+) by a sample cleanup procedure with the microsystem pretreatment and coventional method in three kinds of particles.

3.13.7 Concluding Remarks

Because microsystem technology has many attractive characteristics, application in a broader field is expected. For environmental monitoring, one of the merits of this technology is miniaturization of analytical instruments that allows on-site and multipoint continuous measurements. In addition, it also saves environmental loads, energy, and valuable resources. A novel gas sampling method was proposed, which is based on gaseous diffusion and gas–liquid contact via a porous material. By the application of this technique to a microfluidic system, a microsystem device for monitoring trace gases will be provided. Additionally, considering that many situations of gas–liquid equilibrium exist in the environment, the technique will have a large ripple effect on the growth of microsystem technology. The basic characteristic of microsystem-based gas absorption was demonstrated. Porous glass was used as the porous material and NO_2 was chosen as the analyte gas. In order to realize the sensitivity of gas absorption, a porous PTFE membrane was also used as a gas–liquid separator in the plastic microsystem. The optimal condition for gas absorption was investigated. Aiming at a practical microsystem for measuring NO_2, a polymer-based NO_2 measurement microsystem was developed. The fluorescence determination of nitrite ion with DAN was demonstrated. The application of the microsystem device to monitoring of NO_2 in the living environment was described.

The monolithic silica synthesized in capillaries and microchannels by the sol–gel process was investigated for all kinds of application in micro analytical systems. With a bimodal pore structure, the monolithic silica has proven to provide better stability and higher performance than conventional columns packed with particles. Monolithic silica can be used without retaining frits or other special structures, especially in micro analytical systems, owing to the stability of the continuous bed. The different kinds of analytical applications of monolithic silica in microchannels showed it was a powerful tool in micro analytical systems.

The possibilities for on-site analysis using the downsized mass spectrometer with chemical instrumentation including microsystems were discussed. A downsized MS system was developed to connect with chemical pretreatment microsystems. The downsized mass spectrometer has been accomplished with very high resolution, lightweight, and compact body using

a hybrid vacuum system and MEMS technology. A chemical microsystem designing was also developed to change easily and quickly from the traditional way such as the method of wet chemistry in the laboratory room. Because the chemical microsystem is currently able to operate separation, extraction, heating, and so on, each design would have a wide variety as required by the operator such as in medical, biological, and environmental studies. Thus, a method using microsystems would be an alternative for wet chemistry in the future. It would have a big potential bringing the data more quickly by the on-site medical, environment, and biological analyses with this system. Measurement and analysis in the nanotechnology and biotechnology field play one of the most important roles for the progress represented as recent proteomics. In the field sample application, MS is often used to determine the configuration of amino acids in proteins and to discover new biomarkers for various diseases.

Biography

Takashi Korenaga was born in Okayama in 1949. He attended Okayama University, graduating with a B.S. and M.S. degree in analytical chemistry. He obtained a Ph.D. degree from Kyoto University in 1985 for engineering on automation of water quality monitoring for flow injection analysis. He worked as an industrial process analytical chemistry researcher at Japan Exlan Co., Ltd. from 1974 to 1977. In 1978, he joined the Faculty of Engineering, Okayama University and served as research assistant professor. In 1987, he spent a few months at the Department of Biochemistry and Nutrition, Virginia Polytechnic Institute and State University as a visiting professor. In 1993, he was promoted to associate professor of chemical engineering at Okayama University. Then he was appointed a professor of Toyama National College of Technology from 1993 to 1995. In 1995, he moved to The University of Tokushima as a professor, and then spent a sabbatical leave at the School of Public Health, Harvard University, and also Massachusetts Institute of Technology as a Monbusho Visiting Fellow. He was joined as a professor of the Department of Chemistry, Faculty of Science, Tokyo Metropolitan University from 2001 to the present date.

His specialty and research interest include instrumentation of the downsized analytical chemistry measurement device such as mass spectrometer, fluorimetric detector, and microfluidic chemical and biochemical pretreatment systems.

He was the recipient of The Japan Society for Analytical Chemistry Award for Younger Researchers in 1984, The 26th Japan Environmental Award in 1999, and The Takeda Techno-Entrepreneurship Award 2001. He is President of the Japanese Association of Environmental Safety and Waste Management for Universities and successfully hosted the 8th Asian Academic Network for Environmental Safety and Waste Management in Chennai, India in 2006.

3.14 Medical Applications

Glossary

Acute A medical condition that occurs abruptly and lasts for a relatively short time. It may also mean a condition that requires urgent medical attention

Aneurysm A widening of a blood vessel

Angina pectoris Intermittent pain in the chest due to ischemia

Arrhythmia An abnormal heart rhythm

Arteriosclerosis Hardening and thickening of the arterial walls. A form of arteriosclerosis where plaques are formed within the inner layers of large- and medium-sized arteries

Arthroplasty Surgical restoration of the integrity and functional power of a joint

Astigmatism Defect of an optical lens causing rays from a point to fail to meet at a focal point resulting in a blurred and imperfect image

Auditory Relating to hearing

Biomarker A specific biochemical in the body that has a particular molecular feature that is generated in response to a pathological event, exposure to environmental factors, progress of a disease, or the effects of treatment

BMI Body Mass Index (weight (kg) divided by height squared (m^2))

Bradycardia A heart rhythm that is abnormally slow

CAD Coronary Artery Disease

Cardiac output The average rate of blood flow generated by the heart, usually measured in $l\,min^{-1}$

Cataracts A clouding of the lens of the eye or of its surrounding transparent membrane that obstructs the passage of light

CF_x Carbon Monofluoride

CMOS Complementary Metal Oxide Silicon

Cochlea A division of the bony labyrinth of the inner ear of higher vertebrates that is usually coiled like a snail shell and is the seat of the hearing organ

Cochlear nerve Part of the vestibular nerve associated with hearing

Coronary artery disease The narrowing of the coronary arteries, restricting blood flow to the heart. This condition is usually the result of arteriosclerosis

CRT Cardiac Resynchronization Therapy

CVD Cardiovascular Disease

DELAS Diagnostic Endo Laser Scanner

ECG Electrocardiogram

EMI Electromagnetic Interference

EWL Excess Weight Loss (weight lost divided by the excessive weight)

FCC United States of America Federal Communications Commission

FDA United States of America Food and Drug Administration

Fibrillation A condition of the heart in which there is a complete lack of synchronization of the contraction process, resulting in the loss of cardiac output and in death

GERD Gastroesophageal Reflux Disease

GI Gastrointestinal

Glaucoma A disease of the eye marked by increased pressure within the eyeball that can result in damage to the optic disk and gradual loss of vision

Hypertension Abnormally high arterial blood pressure

IGS Implantable Gastric Stimulation

In vitro In an artificial environment outside the living organism

In vivo Within a living organism

Incidence The number of people per year who are newly diagnosed with a specific chronic condition or have suffered a specific event

Intramedullary Within the bone marrow

IPG Implantable Pulse Generator

Ischemia Deficiency of blood to an organ or a tissue due to functional constriction or actual obstruction of a blood vessel

ISFET Ion-Sensitive Field Effect Transistor

IST Information Society Technologies

IVP Intracorporeal Video Probe

LED Light Emitting Diode

LVAD Left Ventricular Assist Device: a mechanical pump that is surgically connected to a damaged heart to increase the flow of blood to a patient

Macula An anatomical structure (as the macula lutea) having the form of a spot differentiated from the surrounding tissues

MEMS Microelectromechanical System

MI Myocardial Infarction

MIS Minimally Invasive Surgery

Myocardial infarction A localized area in the heart of necrosis due to an interruption of the blood supply to the area

Myoelectrical Utilizing electricity generated by muscle

Necrosis Cell death

OCT Optical Coherence Tomography

Ophthalmic Of, relating to, or situated near the eye
Ophthalmologists A physician who specializes in ophthalmology
Optometrists A specialist licensed to practice optometry
Orthopedics Prevention or correction of injuries and disorders of the skeletal system and associated muscles, joints, and ligaments
Orthotics Use of specialized mechanical devices to support or supplement weakened or abnormal joints or limbs
Otolaryngologists A medical specialty especially concerned with the ear, nose, and throat
PPM Part Per Million
Prevalence The total number of people who are living with a specific chronic condition or have suffered a specific event
Retina The sensory membrane that lines the eye, is composed of several layers including the one that contains the rods and cones, and functions as the immediate instrument of vision by receiving the image formed by the lens and converting it into chemical and nervous signals that reach the brain by way of the optic nerve
RF Radio Frequency
Sinoatrial node Specialized cells in the right atrium of the heart that begin the contraction sequence
ST segment elevation A condition in which the ST segment of the ECG is elevated above the baseline. This is usually associated with an acute myocardial infarction
Tachycardia A heart rhythm that is abnormally fast
USA United States of America
Vestibular nerve Associated with hearing
VF Ventricular Fibrillation
Visual acuity The relative ability of the visual organ to resolve detail that is usually expressed as the reciprocal of the minimum angular separation in minutes of two lines just resolvable as separate and that forms in the average human eye an angle of 1 min
VNS Vagus Nerve Stimulation
Vulnerable plaque A lesion in the wall of the artery that is filled with a soft lipid material and is covered by a thin fibrous cap
Wafer fab The physical facility, including property, plant, and equipment, where integrated circuits are fabricated on silicon, or other semiconductor, wafers. Testing of finished wafers can be performed in the same facility

3.14.1 Clinical Applications of Medical Microsystems

3.14.1.1 Cardiovascular Applications

3.14.1.1.1 Introduction to cardiovascular disease

Cardiovascular disease (CVD) is a large and growing problem in the United States and the industrial world. There are an estimated 71 300 000 people in the United States who have one or more cardiovascular conditions (Thom *et al.* 2006). CVD includes a number of conditions of the heart and the vasculature including coronary artery disease (CAD), arteriosclerosis, heart failure, hypertension, arrhythmia, heart valve disease, congenital heart defects, aortic defects, and peripheral vascular disease. CVD is the cause of common events such as myocardial infarction (MI), cardiac arrest (sudden death), stroke, heart failure, and aneurysms.

CVD is by far the leading cause of death in the United States. **Table 1** shows the extent to which CVD has grown and its devastating effects in lives lost. In 2003, CVD accounted for more than 37% of all deaths, more than the total of the next four causes combined.

This section contains an overview of the current strategies to meet this enormous challenge. In

Table 1 Prevalence, incidence, and number of deaths per year (2003) for many of the manifestations of cardiovascular disease (Thom 2006)

Condition	*Prevalence*	*Incidence*	*Deaths per year*
Coronary heart Disease – total	13 200 000	1 200 000	479 000
Myocardial infarction	7 200 000	565 000 (First MI) 300 000 (Recurrent)	171 000
Heart failure	5 000 000	550 000	57 000
Stroke	5 500 000	700 000	158 000

Section 3.14.1.1.2, the clinical needs and different manifestations of CVD are described. This is followed by a description of the current strategies to diagnose and manage patients each with specific condition. Research to find new ways to diagnose and manage CVD is very active. In Section 3.14.2, some specific microsystems that hold great promise for improving the management of these patients are described.

3.14.1.1.2 Clinical needs for CVD

The clinical needs for managing CVD are associated with two overlapping strategies: increasing life expectancy and improving quality of life. Current medical practice heavily focuses on patients who have already had one or more significant medical events. The treatment is aimed at getting the patient through the acute event, followed by a separate strategy to manage the consequences of the event. In this section, the technologies for diagnosing the diseases as well as the treatment of the diseases are described.

3.14.1.1.3 Current solutions to the management of CVD

3.14.1.1.3.(i) Coronary artery disease CAD is characterized by the narrowing of the coronary arteries sufficiently to prevent adequate blood supply to the heart muscle. If the condition persists, it may lead to cardiac cell death (necrosis) called an MI, heart failure, and/or an arrhythmia. This condition is usually the result of atherosclerosis that causes plaque deposits inside of the coronary artery and may obstruct the flow of blood. The common perception of this condition is of a hard plaque due to cholesterol that may grow over time leading to chest pains (angina pectoris) during exercise or to an MI. Research since the mid-1990s has pointed out that atherosclerosis is actually a much more complex disease (Ross 1999). An inflammatory process resulting from an injury to the arterial wall can cause a lipid-filled region covered by a thin fibrous cap to form. If the cap ruptures, the immediate formation of a clot can cut off all blood flow through that artery. This lipid-filled region is known as a vulnerable plaque (Muller *et al.* 1994) and may be responsible for approximately 70% of fatal acute MIs and the associated sudden coronary deaths (Naghavi *et al.* 2003).

3.14.1.1.3.(i).(a) Diagnosis of CAD In clinical practice today, the typical way for the diagnosis of CAD is in the emergency room or in the physicians' clinic after the symptoms have appeared. Consider a patient who arrives with chest pains or other threatening symptoms. The confirmation can involve a number of tests, each having its own ability to identify people who are having an MI while rejecting those who are not. Today, nearly everyone who shows up at the emergency room complaining of unexplained chest pain will start on a defined protocol (Braunwald *et al.* 2002). One test is the 12-lead electrocardiogram (ECG). Certain characteristics of the ECG, such as ST segment elevation, are highly predictive that the patient is having an MI. Unfortunately, less than 50% of the people coming to the emergency room while suffering an MI will test positive immediately (Slater *et al.* 1987).

Chest pain patients in the emergency room who had a negative ST segment test are given a series of blood tests looking for specific chemical markers indicating cardiac necrosis. When cardiac cells become starved for oxygen or are damaged, they inject different enzymes and other molecules into the blood stream. Elevated levels of such markers of heart damage may help identify an acute MI in a patient with severe chest pain, diagnose ischemia, or triage patients who are in the highest risk due to CAD. In each case, the goal is to point to the correct treatment.

Following an MI, proteins that normally reside within the heart muscle cells are released from the damaged tissue into the blood stream. By measuring the levels of these proteins in the blood, emergency room personnel can quickly determine whether patients have actually suffered an MI. Several key cardiac marker proteins have been identified. Each biomarker has a response time when it can be first measured in the blood. It also has a time at which it reaches its peak and begins to be cleared from the body. **Table 2** shows the response times of various biomarkers after an acute MI.

Myoglobin is one of the first biomarkers to appear in blood after the onset of an MI. Emergency room personnel will often test for myoglobin to get an early indication of an MI but, unfortunately, myoglobin can be elevated in blood due to a number of other conditions. Troponin I takes a few hours longer to appear after the onset of an MI. It is, however, very specific to necrosis of cardiac cells and is becoming the gold standard because of its specificity.

Testing for these markers was historically performed in a central lab using the blood drawn from the patient. Recently, however, a number of companies have introduced small, portable systems that can be used at the point of care. **Figure 1** shows the

Table 2 Cardiac biomarkers used in the diagnosis of acute myocardial infarctions (modified from Braunwald *et al.* 2001)

Cardiac marker	*Range of times to initial elevation (h)*	*Mean time to peak elevations*	*Time to return to normal range*
Heart fatty acid binding protein	1.5	5–10 h	24 h
Myoglobin	1–4	6–7 h	24 h
Troponin I	3–12	24 h	5–10 days
Troponin T	3–12	12 h–2 days	5–14 days
Creatine kinase – MB	3–12	24 h	2–3 days

Figure 1 Triage MeterPlus portable fluorimeter and diagnostic devices from Biosite. (Courtesy: Biosite.)

Biosite® Triage® MeterPlus and four different protein arrays from Biosite Incorporated (San Diego, CA). One of the protein arrays, the cardiac panel, measures three key cardiac markers: myoglobin, CK-MB, and troponin I. Results are delivered approximately 15 min after a blood sample is injected into the panel and the panel is inserted into the meter.

The technology to perform the measurement involves the use of microfluidics, signaling chemistry, and fluorescence. A diagram of one of the protein arrays is shown in **Figure 2**. In order to measure the analytes of interest, a sample of blood is added to the protein array. The blood comes in contact with a fibrous filter inside the array that separates the red blood cells from the plasma. Capillary action draws the plasma through the filter where it enters the reaction chamber. In the reaction chamber, analytes in the plasma bind to specific antibodies that are linked to fluorescent particles. The plasma containing the analytes and antibodies is then pulled by the capillary action into the diagnostic lane that contains discrete zones of immobilized antibodies that bind to any analytes bound to a fluorescent particle. Each discrete zone is scanned by a laser diode inside of the Triage MeterPlus and the fluorescence is measured to quantify the concentration of the analyte that had been present in the sample of blood.

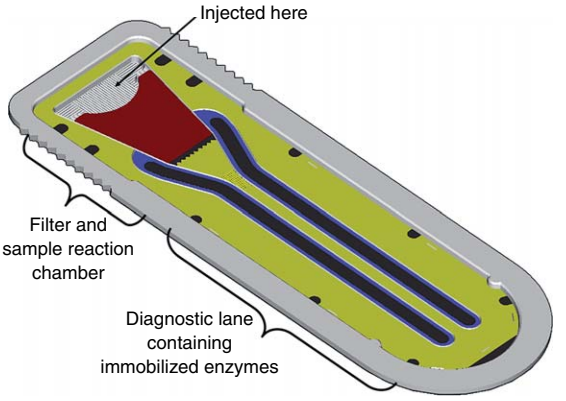

Figure 2 Diagram of protein array used in the Triage MeterPlus. (Courtesy: Biosite.)

3.14.1.1.3.(i).(b) Therapy for CAD The coronary artery bypass graft has been the standard of care to repair a blocked coronary artery. In 2003, an estimated 268 000 (Thom *et al.* 2006) patients had bypass surgery in the United States. This operation involves opening the chest of the patient and cutting through the sternum to expose the heart. The surgeon sews one end of a length of vessel that was removed from elsewhere in the patient above the blockage in the coronary artery, and the other end below the blockage, allowing blood to bypass the occluded region.

In the last few years, the treatment of choice has shifted away from bypass surgery to angioplasty with the placement of coronary stents. Over 660 000 percutaneous coronary interventions were performed in the United States in 2003 (Thom *et al.* 2006). In angioplasty, the physician threads a catheter from an entry point in the femoral artery, through the vasculature to the occluded artery. The catheter contains a deflated balloon at its end. This balloon is inflated once it is inside of the occlusion, effectively opening up the vessel to allow blood flow. In order to keep the vessel open, a stent is usually placed over the balloon before it is inflated. The stent is a tubular wire mesh that, when expanded inside of the occlusion, provides enough structural support to keep the vessel open.

Although far less invasive than the coronary bypass procedure, stenting is plagued by the possibility that tissue or clots will form inside of the stent (restenosis) occluding the vessel and requiring further repair. The prevention of restenosis is an area of aggressive research, involving not only designs of the metal mesh but also the coating of the stent with drugs that are intended to prevent the formation of clots. Restenosis in state-of-the-art devices has been reduced to 5–9% (Lemos *et al.* 2004).

3.14.1.1.3.(ii) Aneurysms One manifestation of CVD is a weakening in the wall of a blood vessel that results in a localized widening of the artery or vein. This widening is called an aneurysm, and it is particularly dangerous if it occurs in the aorta or in a blood vessel in the brain. The risk is that the aneurysm will rupture, causing excessive injury or death. There are an estimated 15 000 deaths per year in the United States (Thom *et al.* 2006) due to the rupture of an abdominal aortic aneurysm (AAA).

Figure 3 is an illustration of an AAA. The diameter of the abdominal aorta below the renal arteries is typically around 2 cm. A diameter of 3.5 cm or greater is classified as an aneurysm. The prevalence of AAA appears to be increasing. The prevalence of AAAs found in screening studies from various countries is about 4% to 9% in men and 1% in women (U.S. Preventive Services Task Force 2005).

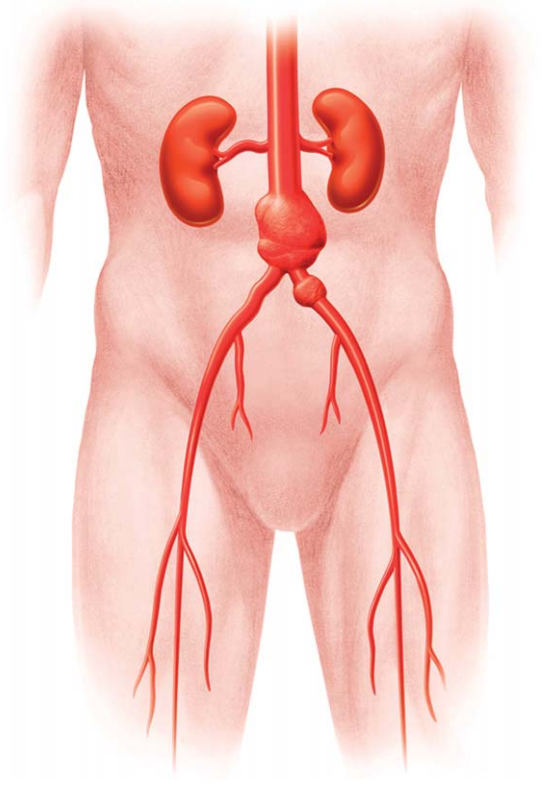

Figure 3 Drawing of an abdominal aortic aneurysn. (Courtesy: Medtronic.)

If the AAA rupture (Harris 1991), the prognosis for the patient is extremely dire. Current statistics indicate that only 10% of the patients are still alive 30 days after AAA ruptures (Kazmers *et al.* 2001).

3.14.1.1.3.(ii).(a) Diagnosis of AAAs The diagnosis of an AAA can be done in a number of ways. Very often, the AAA is discovered on an X-ray or image when diagnosing a completely different condition. This highlights the fact that an AAA usually does not have any symptoms. Due to the high mortality rate associated with an AAA rupture, the United States has passed a law allowing a one-time, free screening test using abdominal ultrasonography for men between the ages of 65 and 75 who have ever smoked. Medicare will also cover the procedure for men and women with a family history of AAA (US Preventive Services).

3.14.1.1.3.(ii).(b) Therapy for AAAs Historically, open abdominal surgery was the standard treatment for AAAs that had grown to the size of 5.5 cm or larger. In this procedure, the damaged section of the aorta was removed and a graft made from Dacron or other fabric was placed in its place. The repair, while usually successful, was also associated with an on-table mortality of about 3.8% (Lee *et al.* 2004). In 1991, the first endovascular stent graft was used to repair an AAA (Parodi *et al.* 1991). An illustration of a stent graft that was placed to repair an AAA is shown in **Figure 4**.

A stent graft is a long tube made of a thin metal framework (stent) covered by a thin material such as Dacron or polytetrafluoroethylene (PTFE). The physician places the stent graft via a catheter that is inserted into the femoral artery in the patient's groin. Once the stent graft is in position, the stent portion is expanded against the sidewall, effectively channeling all the blood through the inside of the stent graft. This effectively excludes the aneurysm and removes the pressure from the aneurysmal wall. Although this approach is far less invasive than the open surgical approach, the current designs of stent grafts may not be 100% successful at excluding the aneurysm. If blood continues to leak around the stent graft or if the graft develops a leak, the patient remains at risk. Hence, monitoring of this repair is done using X-rays once or twice per year.

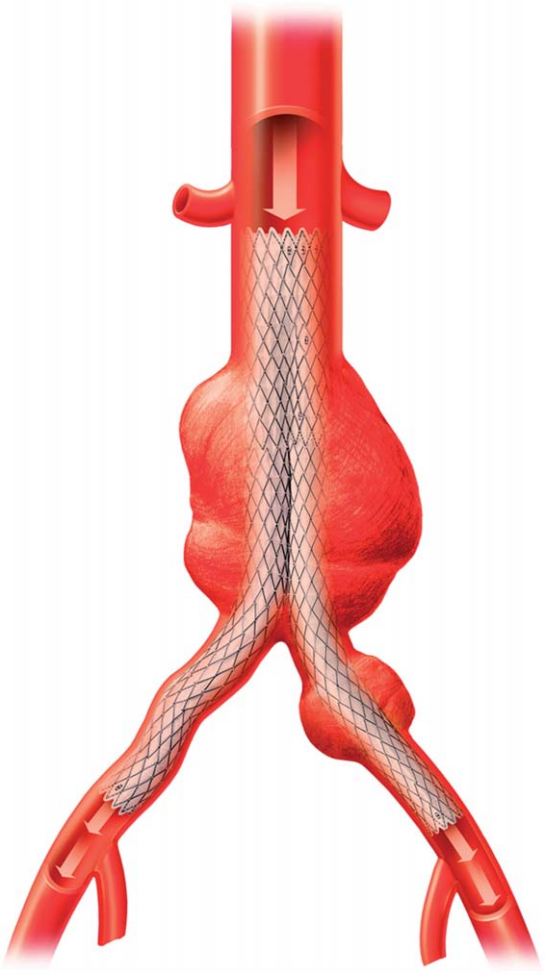

Figure 4 Drawing of stent graft placed in an abdominal aortic aneurysm. (Courtesy: Medtronic.)

3.14.1.1.3.(iii) Arrhythmias The heart's rhythm is controlled by an electrical impulse that is generated from a clump of cells in the right atrium called the sinoatrial (SA) node. These cells trigger the heartbeat based on the changing environment including oxygen in the blood, presence of specific chemicals, and neural inputs. If these cells become damaged or if cells other than the SA node begin to trigger heartbeats, then arrhythmias can result. Bradycardia, or slow heartbeat, can result from damage to the SA node or the cells that conduct the signal to the rest of the heart. Implantable devices called pacemakers have been developed to take over the job of starting the heartbeat at a rate required to meet the needs of the patient.

On the other end of the scale, various disease states or drugs can cause the heart to beat too fast. This is called tachycardia. If the heart rate becomes exceedingly fast, the ability of the heart to pump blood decreases and the patient can become symptomatic. In ventricular fibrillation (VF), the contraction process of the heart is completely uncontrolled and little or no blood is pumped. If this happens, the patient may die suddenly, i.e., in a matter of minutes. Of the 330 000 sudden deaths from coronary disease, most are believed to be from VF (Thom *et al.* 2006).

3.14.1.1.3.(iii).(a) Diagnosis of an arrhythmia Arrhythmias are diagnosed using instruments that can measure the electrical activity of the heart. The standard is to measure an ECG using electrodes that are pasted on the chest of the patient.

In some patients, arrhythmias are not present all the time and can be missed during a physical examination at the medical clinic. These patients are given a Holter monitor to wear for 24 or 48 h. A Holter monitor is similar to an ECG machine but usually has only two or three electrodes on the patient. The signals generated between the electrodes are stored in the memory of the Holter. Once the Holter is returned to the physician, the memory is analyzed to determine whether any arrhythmias are present.

The Reveal® Insertable Loop Recorder (Krahn *et al.* 1999) takes this concept one step further. A photograph of the Reveal® recorder is shown in **Figure 5**. It is about the size of three sticks of gum and is inserted underneath the skin in the chest of a patient who has infrequent but recurring fainting spells. The Reveal® recorder measures the electrical activity of the heart and, when the patient faints, stores a few seconds of the rhythm for review by the managing physician. This was the first implantable device for a monitoring-only application.

Figure 5 Photograph of the Reveal® Insertable Loop Recorder. (Courtesy: Medtronic.)

3.14.1.1.3.(iii).(b) Therapies for arrhythmias The standard of care for treating bradycardia is an implantable pacemaker. There are approximately 200 000 pacemakers implanted each year in the United States (Thom *et al.* 2006). As shown in **Figure 6**, a pacemaker is implanted under the skin in the pectoral region. The pacemaker is a device about the size of a matchbook that is electrically connected to the heart through wires, called leads, that enter the large vein just below the collarbone and advance into the heart. There are two leads in the illustration. One lead is attached to the wall of the right atrium and the other is attached to the right ventricle.

The pacemaker contains a significant amount of processing capability and other electronics to perform multiple functions. It senses the activity of the heart and can also deliver an electrical stimulating pulse to start the heart contraction. Most pacemakers today also have the ability to estimate the rate at which the patient's heart should be beating in order to supply sufficient blood flow to meet the demands of the patient's activity level. This capability is called rate-responsive pacing and requires the input from one or more sensors. The most prevalent method of sensing the patient's demand is through the use of a vibration sensor built into the pacemaker itself. This sensor may be a small piezoelectric crystal attached to the side of the pacemaker or an accelerometer attached to the pacemaker's circuit board. In either case, daily activities like walking or running will generate vibration signals picked up by the sensor. An algorithm inside of the pacemaker converts this level of physical activity into a heart rate for the patient.

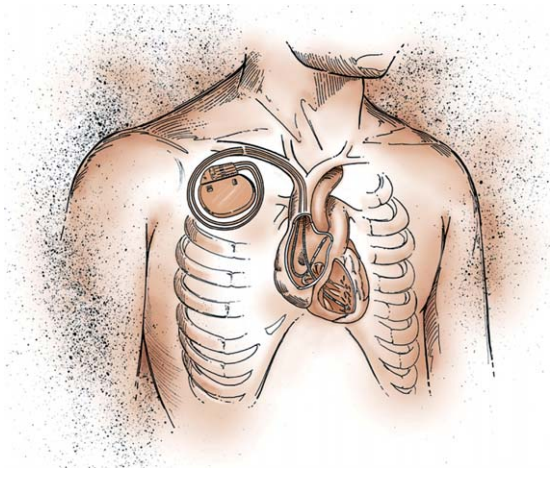

Figure 6 Illustration of implanted pacemaker with two leads into the heart. (Courtesy: Medtronic.)

Figure 7 is a photograph of the inside of a rate-responsive pacemaker. The accelerometer is attached to the circuit board inside the pacemaker. The large silver object that covers the right half of the pacemaker is the battery. These batteries are primary cells, so when they are depleted, the pacemaker must be replaced. Advances in electronic circuitry and battery technology have made it possible to add valuable features to the pacemaker for therapy and diagnostics while simultaneously increasing the lifetime of the device. Currently, pacemakers generally last between 6 and 12 years before needing to be replaced.

Implantable cardioverter defibrillator (ICD) is a more recent invention than the pacemaker (Mirowski *et al.* 1980). The ICD is intended to monitor the electrical activity of the patient's heart, looking for rhythms that can be classified as either VF or life-threatening tachyarrhythmia. If either of these conditions is detected, the ICD will provide appropriate electrical therapy to try to break the arrhythmia.

In 2003, approximately 64 000 ICDs were implanted in the United States (Thom *et al.* 2006). This number is growing rapidly as new classes of high-risk patients are identified and the therapy becomes more accepted.

3.14.1.1.3.(iv) Heart failure Heart failure is a condition in which the heart is compromised to such an extent that it can no longer pump enough blood to meet the body's requirements. The condition may be the result of various causes but is usually associated with damage to the heart muscle

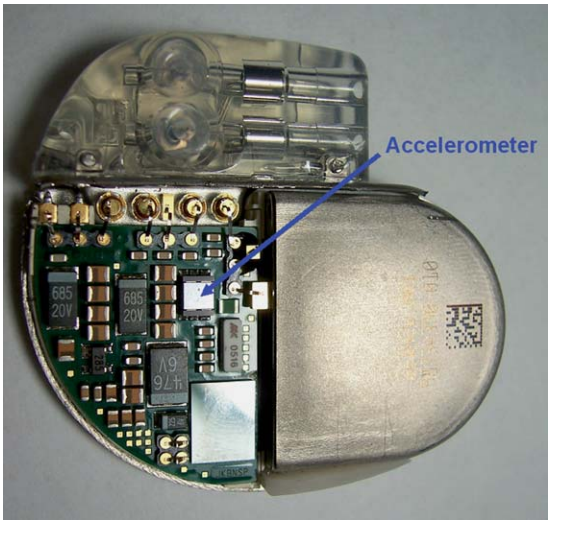

Figure 7 Photograph of the internal circuitry, accelerometer, and battery of a pacemaker. (Courtesy: Medtronic.)

associated with an MI, infection, or congenital defect. When this happens, the patient will have symptoms such as fatigue, shortness of breath, inability to sleep comfortably at night, or lung congestion.

3.14.1.1.3.(iv).(a) Diagnosis for heart failure

Most patients are diagnosed with heart failure after the onset of symptoms that brings them to their physician or the emergency room. Heart failure can be confirmed through the use of history and physical, chest X-ray, and 2D echocardiography. Recently, the B-type natriuretic peptide (BNP) blood test has become a standard method to diagnose and manage heart failure (Morrison *et al.* 2002). BNP is a substance secreted from the ventricles, or lower chambers of the heart, in response to changes in pressure that occur when heart failure develops and worsens. The level of BNP in the blood increases when heart failure symptoms worsen, and decreases when the heart failure condition is stable.

If a patient has severe or unstable heart failure, the managing physician may decide to place a catheter in the patient's heart to more closely monitor the heart's performance. The catheter is a thin, flexible tube that is inserted through one of the large veins (the inferior or superior vena cava) that return blood to the heart. A small balloon at the end of the catheter allows the catheter to follow the flow of blood through the right side of the heart and into the pulmonary artery. Once there, the catheter is purposely positioned in a small branch of the pulmonary artery and a balloon at the end of the catheter is inflated to stop the blood flow through the pulmonary branch. This allows the measurement of a pressure called the pulmonary capillary wedge pressure in front of the temporarily inflated and wedged balloon.

An alternative to the cardiac catheter to measure intracardiac pressure is a small catheter that contains a silicon pressure sensor. **Figure 8** is a diagram of a pressure catheter that is only 0.36 mm in diameter manufactured by Radi Medical (Uppsala, Sweden). This catheter is small enough to fit into small blood vessels to measure pressure. It is also inserted through coronary occlusions in order to assess the effect that the occlusion have on blood flow.

Figure 8 Illustration of an ultrathin PressureWire® sensor. The diameter of the guidewire carrying the sensor is 0.36 mm. (Courtesy: Radi Medical Systems.)

A tiny silicon pressure sensor die is mounted on a small circuit board inside of the catheter, as shown in the close up diagram of **Figure 9**. The silicon sensor is side-mounted a few centimeters back from the tip of the catheter and is protected by a polymer coating.

3.14.1.1.3.(iv).(b) Therapy for heart failure

It is generally accepted that heart failure is a disease that can be controlled for a time, but not cured. One possible exception to this is the heart transplant in which a patient's damaged heart is replaced by a healthy heart from a donor who has died. In 2004, however, only 2016 heart transplants were performed in the United States (Thom et al. 2006).

The left ventricular assist device (LVAD) is a mechanical device that can overcome the issue of shortage of hearts for transplant. An LVAD, such as the HeartMate II from Thoratec (Pleasanton, CA, USA), is an auxiliary pump implanted in the chest of a patient with an extremely damaged heart. The input of the pump is surgically attached to the left ventricle and the output is inserted into the aorta. The effect is to off-load the left ventricle while providing an adequate blood supply to the patient. The LVAD has shown itself to be of value as a bridge to heart transplant (Long 2001) and has recently been approved for a long-term use in those patients who are not eligible for a heart transplant (Rose *et al.* 2001). However, their use is still very limited because of the size, surgical invasiveness and cost of LVADs.

The standard of care for heart failure patients is through various medications that are intended to improve quality of life and increase life expectancy. Quality of life is affected by optimizing the pumping capability of the heart. The heart is a pump and has the property that increasing the input pressure increases the output of the pump. This relationship is called the Frank–Starling curve and is illustrated in **Figure 10**.

Figure 9 Illustration of silicon PressureWire® sensor inside recess in guidewire from Radi Medical Systems. (Courtesy: Radi Medical Systems.)

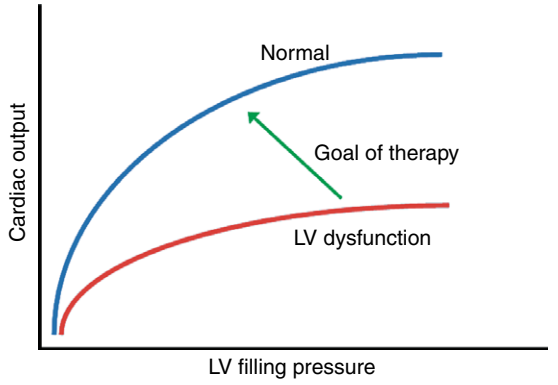

Figure 10 Schematic representation of the relationship of the Cardiac output to left ventricular filling pressure for a normal heart and one with a dysfunctional left ventricle. (Courtesy: Medtronic.)

If the heart is damaged and its pumping capability is diminished, the cardiac output at a specific input pressure is reduced. The body, however, has compensatory mechanisms that attempt to achieve the desired cardiac output by increasing the input pressure. This is done by shutting down the kidneys and increasing the volume of blood in the system, resulting in an increasing input pressure. Unfortunately, the Frank–Starling curve for the damaged heart shows only a minor increase in the cardiac output for the increase in pressure. This high pressure on the input of the heart is also applied to the lungs. If the pressure is high enough, the fluid is forced out of the blood, through the thin tissue membrane that separates the pulmonary blood from the air sacs, and into the lungs. The result is called congestive heart failure and can often lead to a patient coming to the emergency room with extreme breathing difficulty. The goal of the physician is to keep the patient's symptoms under control in order to avoid hospitalization. The first line of treatment for heart failure is drug management. Diuretics activate the kidneys and remove excess fluid, reducing the filling pressure. Vasodilators reduce the vascular resistance and allow blood to flow more easily. The desired outcome is to move the patient's Frank–Starling curve up and to the left.

In the last few years, there has been an emergence of a new type of implantable device called cardiac resynchronization therapy (CRT), which paces both sides of the heart approximately simultaneously to coordinate the contraction and to improve the pumping ability (Leclercq *et al.* 2000). The clinical results for CRT have been very impressive. In the MUSTIC randomized clinical trial (Cazeau *et al.* 2001), not only were there improvements in the hemodynamic measurements, but those patients who received CRT had approximately two-thirds fewer hospitalizations than the control group.

3.14.1.1.4 Cardiac solutions on the horizon

Because of the severity of the problem of CVD, cardiovascular research is extremely active. This section describes a number of areas of active research and new product development.

3.14.1.1.4.(i) Diagnostic tools for CAD The applications for cardiovascular catheters containing sensors continue to increase. The ultraminiature pressure wires described in Section 3.14.1.1.3.(iv).(a) are now being used to monitor the effectiveness of using a stent. In addition to measuring whether an occlusion has stopped blood flow in a coronary artery, the pressure pulse in a coronary artery measured by these catheters can be analyzed, providing an estimate of the level of occlusion by calculating indices such as fractional flow reserve (Bech *et al.* 2001).

A second device that continues to improve is the intravascular ultrasound (IVUS). The device provides images that are used to guide the placement of stents and to assess the procedure afterward (Schiele *et al.* 1998). The original versions of this catheter contained a single ultrasound element that was rotated at high speed to obtain a view of the vessel wall and lesion (Elliott and Thrush 1996). Volcano Therapeutics Inc. (Rancho Cordova, CA, USA) has developed an advanced version of this catheter, as shown in **Figure 11**. It contains 64 elements and has higher resolution, giving it the ability to determine the structure and the composition of the interior of the vessel walls. This is extremely helpful in the identification of vulnerable plaques.

3.14.1.1.4.(ii) Monitoring of AAAs The quality of stent grafts for protecting patients from AAAs continues to improve. In addition, the screening of

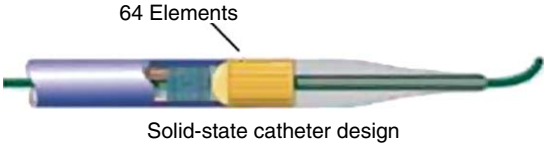

Figure 11 IVUS catheter from Volcano Therapeutics containing an array of 64 ultrasound elements. (Courtesy: Volcano Therapeutics.)

AAA has been recommended as a reimbursable procedure (US Preventive Services Task Force 2005). Therefore, more AAAs will be diagnosed and more patients will get AAA stent grafts. Unfortunately, the stent grafts are not perfect and a percentage of these devices do not seal correctly, maintaining a dangerous level of blood pressure in the aneurysm. A number of companies have begun to investigate the use of small, chronically implanted pressure sensors to monitor the pressure inside of the aneurysm. **Figure 12** is a wireless pressure sensor manufactured by CardioMEMS (Atlanta, GA, USA). This device is about the size of a small paper clip and is placed in the region of the aneurysm that is excluded by the AAA graft at the time the graft is implanted. This sensor consists of a silica-based capacitor that varies as a function of pressure and an antenna that doubles as an inductor forming a resonant circuit. The resonant circuit is interrogated using an external instrument that can precisely determine the resonant frequency. This resonant frequency is translated to pressure and the physician can determine whether the pressure inside of the excluded region of the aneurysm has dropped or is still dangerously high.

3.14.1.1.4.(iii) Advanced therapy for arrhythmias

Currently, there is a significant amount of activity directed at improving the algorithms used by an ICD to determine whether or not the patient is having a lethal arrhythmia and whether a shock should be delivered. Much of this effort is directed at looking for different sensors that can provide a measure of the hemodynamic status of the patient. St. Jude Medical (Sunnyvale, CA, USA) presented an abstract that evaluated the use of an optical device integrated into the side of an ICD (Weiss *et al.* 2006). The optical device is intended to identify the presence or the absence of pulsatility in the arteries using the light emitted into the underlying tissue by light emitting diodes (LEDs). This device is in the investigation stage but points out the need to improve the ability of ICDs to accurately identify fatal arrhythmias.

Figure 12 Implantable, ultrasound-based pressure sensor. (Courtesy: CardioMEMS.)

3.14.1.1.4.(iii).(a) Advances in heart failure therapy

The CRT device has proven to be an extremely effective device in the treatment of heart failure. One issue that it faces, however, is that the time delays between the delivery of the electrical pulses to the heart have a significant effect on the performance of the device (Porciani *et al.* 2005). The optimization procedure is currently a time-consuming process involving the use of echocardiography or other techniques to visually confirm that the selected timing resynchronizes the contraction of the left ventricle. The use of implanted sensors that could perform the same function would be a significant advancement in this procedure. The Sorin Group (Via Crescentino, Italy) announced the NewLiving CRT device that contains a sensor for automatic optimization. This device includes a small accelerometer at the end of the lead that measures peak endocardial acceleration (PEA™). The PEA sensor was originally developed to provide rate response to pacemakers (Langenfeld *et al.* 1998) by measuring a value closely correlated with the strength of the heart's contraction. This sensor was designed into a CRT device called NewLiving chf and is used to automatically optimize the timing of the device by maximizing the strength of contraction.

3.14.1.1.4.(iii).(b) Advances in heart failure diagnostics and monitoring

In addition to the effort to improve heart failure therapy devices, there is a significant effort in the development of devices for monitoring heart failure patients. Because heart failure is a chronic condition, many of these devices are intended to be implanted permanently in the patient. One such device is the Chronicle® implantable hemodynamic monitor (**Figure 13**) from Medtronic Inc. (Minneapolis, MN, USA). The Chronicle system consists of an implanted pacemaker-sized monitor and a pressure-sensing lead placed in the right side of the heart. Pressures inside

Figure 13 Chronicle pressure sensing monitor for the management of heart failure. (Courtesy: Medtronic.)

Figure 15 Photograph of implantable, battery-powered pressure sensor with ultrasound-based communication. (Courtesy: Remon Medical.)

the heart are measured continuously and stored in the device. The data are then intermittently transmitted by the patient to a secure website accessible by treating clinicians. Information from the Chronicle system, together with other patient-specific data as available, such as symptoms, daily weight, and physical signs, are used to guide treatment decisions. (Bourge *et al.* 2005).

A close up of the Chronicle pressure sensor is shown in **Figure 14**. The sensor is a titanium housing that has been machined to have a thin diaphragm in one section. This diaphragm is one plate of a capacitor and deflects due to cardiac pressure and produces a change in the capacitance. This change is measured by a circuitry inside the capsule and is transmitted to the Chronicle device for processing and storage.

Other companies are also developing implantable pressure monitors to manage heart failure patients. The device, shown in **Figure 15**, is a pressure sensor being developed by Remon Medical (Caesarea, Israel) that is intended to be placed in the pulmonary artery of a patient suffering from heart failure. The device is an advanced version of the wireless pressure sensor described in Section 3.14.2.1. This device contains a microelectromechanical system (MEMS) pressure sensor, an ultrasound transducer, an integrated circuit (IC), a miniature battery, and a Remon's proprietary acoustic switch (Penner and Doron 2003). This sensor is dormant until a short low-intensity ultrasonic activation pulse is sent to it from a master device that is either inside or outside the patient's body. The ultrasound pulse flexes the piezoelectric ultrasound transducer, generating sufficient energy to close a switch that connects the battery to the circuit. The device then starts measuring the pressure and transmitting the measurements using acoustic communication. After a predefined time (10 s in the pulmonary artery sensor), or upon a deactivation pulse sent from the master, the implant becomes dormant again. The miniature battery can last for more than 10 years at two to three measurements per day without charging.

Figure 14 Close-up of Chronicle® pressure sensor capsule. (Courtesy: Medtronic.)

The measurement of cardiac pressures using a batteryless implanted sensor that is interrogated using an external device has attracted a number of competitors. ISSYS (Ypsilanti, MI, USA) is developing a small pressure sensor that is powered and interrogated using a radio frequency (RF) external signal. Savacor (now St. Jude Medical) has also developed a pressure sensor that is inserted into the right atrium and poked through the interatrial septum into the left atrium.

The chronically implanted accelerometer and pressure sensors are the first entries into implantable systems for disease management. It should be expected that, in the not too distant future, new sensors such as flow sensors or blood chemical sensors will appear to either allow the managing physician to better prescribe medications or to control a therapy-providing

device. Providing this new level of control will allow patients with CVD both to live longer and to live with a higher quality of life.

3.14.1.2 Neurological Applications

Neurology is the medical study focusing on wellness and disorders of the nervous system. Physicians specialized in the field of neurology are called neurologists, and neurosurgeons are specialized neurologists with neurosurgical training.

Some of the diseases and conditions of the neurological system include autonomic nervous system disease, basal ganglia disease, brain tumors, cerebral palsy, cerebellar disease, cerebrovascular disease, cervical spondylosis, CNS infections, coma, dementia, demyelinating diseases, epilepsy, hydrocephalus, migraine, movement disorders, multiple sclerosis, neurological syndromes, neuromuscular disorders, Parkinsonism, phakomatoses, peripheral neuropathy, speech and language disorders, spinal muscular atrophy, and tension headache (GP Notebook 2006).

Over 50 million people in the United States suffer from chronic pain and another 25 million Americans experience acute pain each year (MedTech Insight, February 2005). The estimated cost associated with pain including health care costs, disability, and loss of productivity exceeds $100 billion annually in the United States (MedTech Insight 2005a, b). In addition to pharmaceuticals, medical devices based on neurostimulation and drug delivery are available to provide treatment for patients suffering from acute or chronic pain. Neurostimulation devices are also market-released to provide treatment for patients suffering from Parkinson's disease and epilepsy. Applications of microsystems in these three areas of neurology are discussed below.

There is a growing awareness of the connection between the heart and the brain, and the field of neurocardiology is emerging. The Earl and Doris Bakken Heart Brain Institute was created at the Cleveland Clinic with the goal of advancing the understanding of the heart–brain connection (The Cleveland Clinic 2006).

It should be noted that in chronically implanted medical devices, the implant materials must adhere to stringent requirements, especially those related to biostability. The interface between the foreign material and its surrounding tissue becomes stable within 1–2 weeks after implant, which then provides continued and unchanged performance for the duration of the implant. This is true for electrical stimulation, and also for (unblocked) delivery of drugs at the targeted sites. This implies that the choice of materials is restricted to only a few known biocompatible metals and polymers. All the materials in transient or in permanent contact with tissue and body fluids must adhere to the biocompatibility standard (ISO 10993).

To achieve uninterrupted performance, reliability standards are applied, and components are being subjected to a very rigid assessment. Very often, this implies the design of specific components, not commercially available components. Most critical are batteries and feedthroughs to achieve hermetic-sealed enclosures in the harsh biological environment. Implanted battery-powered devices require a carefully designed power management to achieve the longevity goals and to reduce the replacement (surgical) frequency.

3.14.1.2.1 Chronic pain

Depending upon the underlying cause, electrical stimulation with a neurological stimulator or local drug delivery with an implantable drug pump provides methods for alleviating pain. While the pump provides pharmacological intervention, an electrical stimulation system blocks sensory signals (**Figure 16**).

Intrathecal morphine delivery has been studied in a prospective clinical trial, managing chronic nonmalignant pain (Anderson and Burchiel 1999). Anderson and coworkers concluded that continuous infusion, with carefully selected patients, resulted in a long-term improvement in several areas of daily function. The treatment of intractable chronic benign pain by intrathecal morphine administration has been found favorable in a retrospective multicenter survey by Njee *et al.* (2004). Vogelzang *et al.* (1987) evaluated prospectively the performance of the implantable Medtronic SynchroMed pump used in systemic chemotherapy and concluded a favorable infusion performance. The treatment of failed back surgery syndrome by electrical stimulation of the spinal cord has been evaluated by Van Buyten (2006) and concluded that spinal cord stimulation provided a long-term 50% reduction in pain in over 60% of the patients. Furthermore, pain medication could be reduced.

The drug delivery system consists of an implantable infusion-rate programmable pump that works like a roller pump but with a precise motor-driven mechanism. The device is refillable (transcutaneously) and is reprogrammed by telemetry means. In order to allow for local delivery of the drug, catheters from

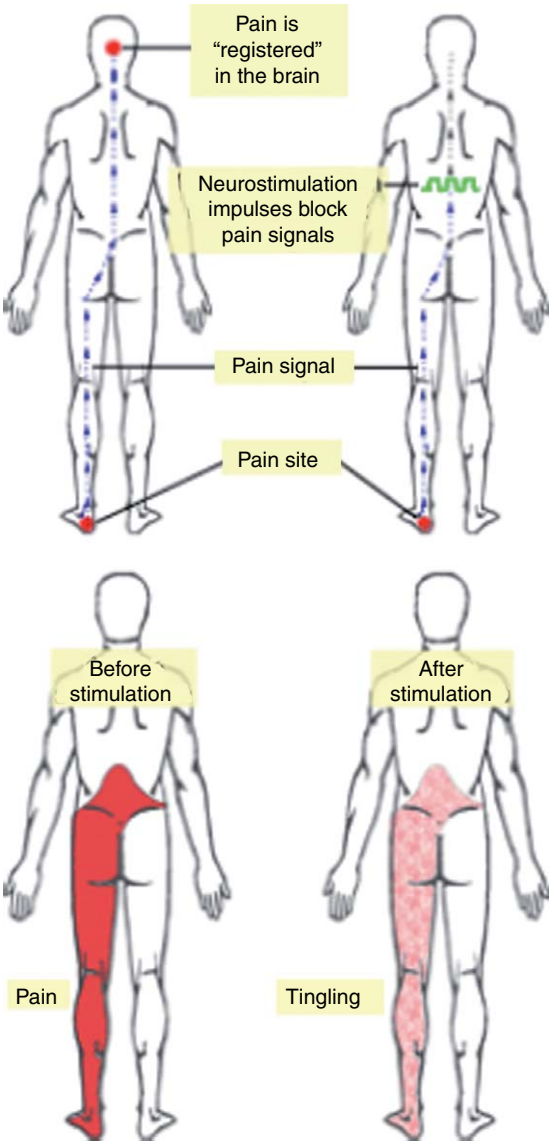

Figure 16 A simplified diagram of an electrical stimulation system blocking sensory nerve signals. (Courtesy: Medtronic.)

polymeric materials connect the target site to the pump. Figure 17 shows the system components.

A system providing electrical stimulation consists of an implanted stimulator, one or more electrodes, a patient activator, and a programming unit. The implantable pulse generator (IPG) is a versatile stimulator generating customizable pulse trains as required in the therapy. The patient activator allows for some intervention by the patient, like switching the stimulation on and off. The treatment of multifocal pain requires an extreme stimulation scheme urging the need for rechargeable batteries in

Figure 17 (*Left*) The implantable pump with catheter and (*right*) the device to reprogram the pump via telemetry. (Courtesy: Medtronic.)

neurostimulators. Figure 18 shows the several system components including a modern rechargeable implant.

3.14.1.2.2 Parkinson's syndrome

Parkinson's syndrome is characterized by movement rigidity, resting tremor, and bradykinesia, causing a serious impairment in the functioning of severely disabled patients. The incidence is up to 346 cases per 10 000. Pioneer Professor Benabid *et al.* (1998) studied the long-term effect of electrical inhibition of deep brain targets in movement disorders. The stimulation frequency (in the brain) used in suppressing these movement disorders is higher than practiced for pain suppression (in the spinal cord). Devices used successfully in the past years are Medtronic's Kinetra devices, now indicated for essential tremor and Parkinson's disease. Before implanting devices, a rigid clinical procedure aimed at precise implantation of special deep brain electrodes is executed. This procedure includes the use of a stereotactic frame, magnetic resonance imaging (MRI) recordings, and screening/signal recording with temporary microelectrodes in order to achieve the correct implant target size. After localization of this target lesion, electrodes are implanted for the definite therapeutic procedure.

3.14.1.2.3 Epilepsy

Epilepsy, from the Greek word epilepsia meaning 'a taking hold of or seizing', is a neurologic disease commonly affecting those younger than 18 years and those older than 65. Clinically diagnosed epilepsy affects approximately 1% of the population and is derived from congenital defects in the brain, tumors, trauma, illness, or strokes. But these known causes only account for 35% of the cases; there is no known cause for the remaining 65% of those afflicted. The susceptible age span of under 18 and

Figure 18 (*Top*) Physician programmer (*left*) and external and implantable rechargeable neurological stimulator. (*Bottom*) Traditional implant with extension cable and stimulating electrode (*left*) and patient activator (*right*). (Courtesy: Medtronic.)

over 65 years comes from the fact that most children born with epilepsy tend to outgrow it, and those people over 65 have increased risk due to age-related maladies such as stroke and anomalies. In any case, those with epilepsy live full lives with the proper management of the disease.

3.14.1.2.3.(i) Epilepsy overview Epilepsy manifests itself with seizures. Seizure is a state when normal, orderly electrical activity in the brain breaks down and a storm of activity occurs. There are two types of seizures: partial and generalized. Partial seizure is further subdivided into simple and complex seizures. A partial seizure involves a localized portion of the brain and may not even be noticed by observers (simple seizure) or create a loss of normal awareness (complex seizure) such as a blank stare or a repetitious movement or sound. A general seizure encompasses the entire brain in the storm of electrical activity manifesting itself in the more banal conception of an epileptic seizure. These seizures carry the terms petit mal and grand mal (among other types) and have symptoms ranging from unresponsiveness for the former to muscle rigidity and convulsions for the latter. These seizures last for as little as 30 s to as long as several minutes. Any person having two seizures is clinically diagnosed with epilepsy.

3.14.1.2.3.(ii) Disease treatments As stated, a person is clinically diagnosed with epilepsy when two seizures have occurred. To further understand when a seizure occurs, doctors employ several tests and pieces of equipment including electroencephalogram (EEG) to measure the electrical activity in the brain, magnetic resonance imaging (MRI) to image the activity of the brain, single-photon emission-computed tomography (SPECT) to measure blood flow in the brain, and magnetoencephalography (MEG) to measure electrical current loops in the brain. Each of these measurement methods is a tool to identify when the brain loses its orderly electrical process. Once the diagnosis has been made, there are four current practices in which to manage it: medication, diet, surgery, and vagus nerve stimulation (VNS). Of these four methods, only surgery has the opportunity to cure epilepsy. The remaining therapies can only manage it.

The vast majority of people with epilepsy manage the seizures through antiepileptic drugs (AEDs). This regime often requires taking a daily pill and living with their inevitable side effects. In some cases though, people are resistant to drugs and thereby require alternative treatments.

For those who have tremendous willpower, or are solely dependent on a caregiver, a ketogenic diet may control the seizures. This diet consists of forcing the body to produce ketones, a by-product of energy production from the burning of fat, not carbohydrates. Hence, the diet must virtually consist of all high-fat foods and none containing carbohydrates. Apart from being extremely unpalatable, it has its own medical consequences because of kidney and heart problems.

The third option that is often of last resort is surgery. This procedure involves either the removal of the problematic portion of the brain (curative) or simply severing pathways between areas of the brain (reduction of symptoms). Surgery is an option only when partial seizures occur since generalized seizures involve the entire brain and localized therapies therefore do not exist.

3.14.1.2.3.(iii) Vagus nerve stimulation The final solution is also the most recent: VNS. This therapy was first conceived in the 1930s but could not be realized due to the lack of contemporary technology. Finally, with the advent of microelectronics, specifically in the field of cardiac pacing, the United States of America Food and Drug Administration (FDA) approved the use of a pacemaker-like device for VNS in 1997. As with other treatments for epilepsy, researchers do not know how VNS relieves seizures, but efficacy has shown that 45% of people had fewer seizures, with 20% of those people reducing their seizure frequency by 75% (Schachter 2002).

This option is often much more acceptable to the patient than is brain surgery or even complete dependence on medication. Though the FDA has not allowed exclusive VNS therapy (medications are still required), it has been able to reduce the amount of pharmaceuticals required thereby lessening the side effects from them.

VNS does require surgery, but the surgery is minor in comparison to brain surgery, often with the patient going home on the same day of the procedure. Like the implantation of a cardiac pacemaker, a small pocket is made just below the shoulder on the left side of the body. A lead is then run subcutaneously up to the base of the neck where an electrode is then wrapped around the vagus nerve. Once activated, the stimulating device will pulse the nerve with electrical signals using parameters such as an amplitude of 1–12 mA, a pulse width of 120–1000 μs at frequencies of 1–145 Hz for intervals up to 270 s on and 180 min off (Cyberonics 2006 http://www.cyberonics.com). For emergency situations, a hand-held magnet that recognizes the onset of a seizure can be waved over the device to provide instant therapy for the patient.

The microsystems for these devices are extremely similar to those used in cardiac pacemakers. The key technology involved is microelectronics, which continues to provide capacity for an ever-growing set of features, miniaturization, and increased longevity. Because these devices are programmed in the doctor's office postoperatively, RF communication is a necessary component. Finally, advances in energy storage continue to increase the implant life of VNS devices and also allow the reduction of their volume for increased patient comfort (and acceptance).

VNS does offer many benefits with few side effects. Because the vagus nerve is being stimulated, patients have complained of annoyances such as tickle in the throat, difficulty swallowing, and coughing or hoarseness of the voice, but all diminish or disappear over time.

3.14.1.2.3.(iv) Epilepsy solutions on the horizon Today, researchers are investigating the use of electrical stimulation to disrupt the storm of activity associated with epileptic seizures. Currently, deep brain stimulation is being used to address movement disorders (e.g., Parkinson's disease) by placing electrodes deep within the brain and pulsing electrical currents into specific areas of the brain to disrupt the disorderly electrical activity. It appears that the same approach can be applied to epilepsy using devices similar to the cardiac pacemaker.

3.14.1.3 Spinal and Orthopedic Applications

3.14.1.3.1 Introduction

The orthopedics industry encompasses all aspects of human musculoskeletal system, including major and minor joints, bones, muscles, spine and the surgical tools, and the equipment necessary to correct and repair traumatic, degenerative, and congenital defects. Orthopedics has naturally evolved into categories with each utilizing different approaches to care. These

categories commonly consist of major joints, including the knees, hips, and shoulders, and are frequently the subject of replacement and revision. Minor joints include wrists, elbows, fingers, and toe joints, which, because of their size and ability to convalesce without severe impact to daily routine, do not receive the level of attention that major joints currently receive. Bones, aside from the obvious need to repair those broken, can require extensive surgery and extended therapies when it is necessary to correct them when affected by severe trauma, congenital defects, or degenerative conditions including sports-related injuries (**Figure 19**).

The field of spinal repair is extensive. Special focus is afforded to the spine because of the criticality of the spinal column and the spine's ability to be extraordinarily flexible while also providing a key structural role to the construction and the locomotion of the human body. The spine consists of 33 vertebrae, 24 having different degrees of mobility (cervical, thoracic, and lumbar) with the remaining 9 (sacrum and coccyx) being fused. Each of the three mobile portions consists of a vertebra responsible for providing protection to the spinal cord, points of exit for nerve bundles, anchor points for the muscular system, and shock-absorbing intervertebral discs (Cleveland Clinic Spine Institute 2006).

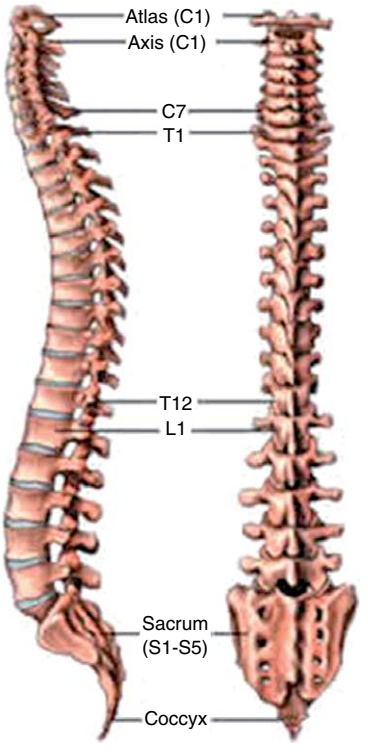

Figure 19 Anatomy of the spine. (Countesy: Medtronic.)

Orthopedics also includes the surgical tools and equipments necessary for repairing the skeletal system. Though traditionally this field has included the creation of specialized surgical tools, plates and screws, there is a growing use of microsystem- and biology-based solutions. In addition, the surgical field includes the navigational tools required to minimize the invasiveness of surgery, enabling new, previously impossible procedures and allowing the patient to return to normalcy sooner than otherwise.

In 2005, the worldwide orthopedic industry reached $19 billion in sales and was continuing its steady, double-digit growth. Hip and knee arthroplasty, or joint replacement, are the dominant segments followed by spine, sports medicine, and trauma repair. The industry's continued growth is expected to continue, supported by studies showing a strong correlation between the major joint replacement (primarily knee) and the increase in age and weight of the US and Western Europe populations. In addition, China, India, Latin America, and Mexico are beginning to emerge as new markets for orthopedics, which will further improve the continued growth of the industry (Quirk and Clair 2005).

3.14.1.3.2 Orthopedic and spinal diseases

There are two primary drivers for corrective procedures: degenerative conditions and trauma. Regardless of the reason, the need to return the patient to normal activity of daily living drives all advancements in technology (Szivek *et al.* 2002). These technological advancements themselves have two fields of focus: first is to provide higher quality information as to the state of injury and the second is to reduce the trauma induced by the corrective procedure. The first focus often implies placing sensors *in vivo,* while not exacerbating the condition or inconveniencing the patient, followed by the transmission of the collected data out of the body so that the doctor has the required information to make actionable decisions (Morris *et al.* 2001). The second focus is to develop methods to place corrective devices (e.g., artificial joints, rods, screws, intramedullary nails, or sensors) and to minimize the trauma required for adequate placement.

Today, there is limited use of microsystems in orthopedics. There are three reasons speculated as to why this is. The first reason is that traditionally the surgical solutions have been founded in the mechanical engineering discipline. Because of this, the knowledge to apply microsystems was not as readily on hand as were mechanical solutions. The second reason is that

there is little space in the patient's joint to contain the added functionality provided by microsystems. Regardless of the additional benefits that microsystems can provide, there is still a minimal amount of physical material needed to repair the damaged joints (e.g., prosthesis). Historically, the addition of sensors, electronics, and telemetry systems could not fit into the space left without debilitating or discomforting the patient. Finally, until recently microsystems could not provide the benefit for justifying the high costs of inventing, producing, and implanting the technology. Today, the advancement of these three areas is such that microsystems are now beginning to appear in commercialized use.

Of the orthopedic conditions warranting monitoring and correction, osteoarthritis (the deterioration of the cartilage meniscus between the ends of the bones) is the leading cause for both knee and hip replacement and continues to increase in prevalence due to an aging worldwide population. The repair of knees for osteoarthritis involves the use of a fixed bearing implant where a metal tray is fused with the tibia (lower leg) and the cartilage meniscus is replaced with a polyethylene bearing. For hip prostheses, the deteriorated joint is replaced with four parts consisting of a stem, ball, cup, and liner (**Figure 20**).

There are three conditions where the surgeon would like *in vivo* data with regard to the described knee and hip replacement. First, when a knee is replaced, the surgeon must ensure that the pressure across the joint is evenly distributed to ensure patient's comfort and minimize wear on the bearing (D'Lima *et al.* 2005). Today, the materials selection and loading models used to design the prosthesis are based on empirical data, mathematical models collected from cadaver studies, and nearly 40 years of clinical experience (Morris *et al.* 2001). After the joint has been implanted and is in use by the patient, this approach often uncovers discrepancies in the loading, wear, and the use of the joint. A second need for data comes after the surgery with the desire to know how well the cement-to-bone fusion is, or during the life of the prosthesis, if loosening occurs within that interface from the stresses of use (Cristofolini *et al.* 2000, Jeffers *et al.* 2005). The difficulty arises because radiographic techniques are unable to detect these microcracks and bone erosion until the interface has weakened to the point where major revision may be

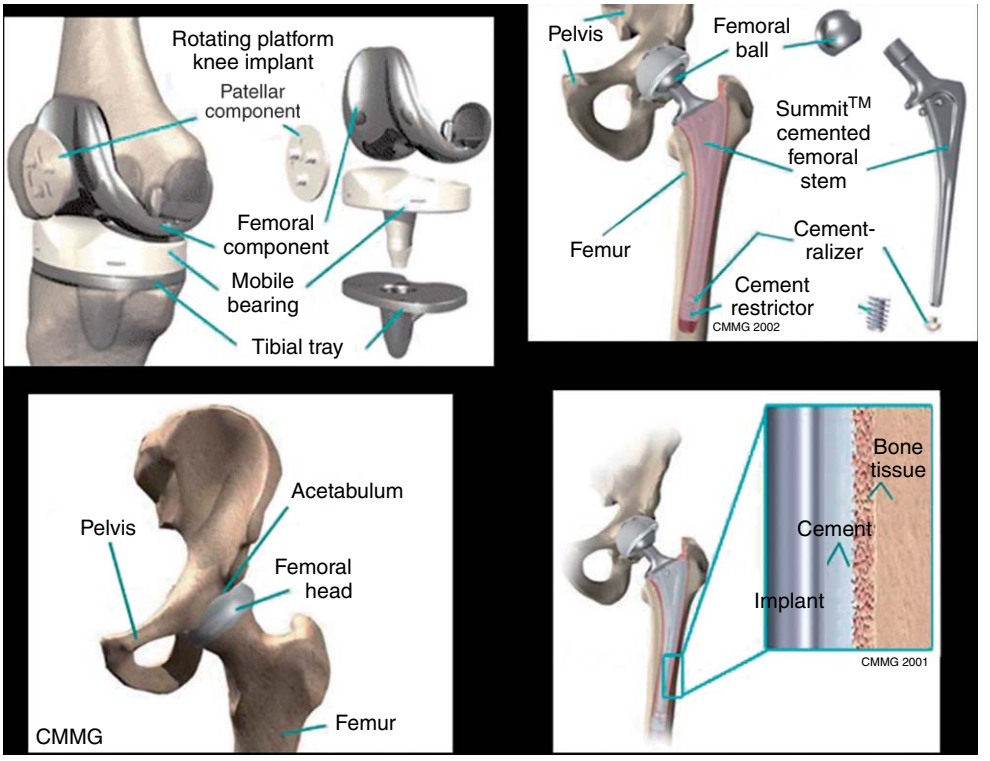

Figure 20 Construction of artificial knee and hip. (Courtesy: DePuy Orthopaedics Inc. and Medical Multimedia Group, LLC.)

required (Robinson 1997). The third situation that patients of knee and hip replacement face is the formation of osteolytic lesions. Fine debris is naturally generated from the friction between the prosthesis' metal tray and the polyethylene bearing. When this debris comes into contact with the living bone around the artificial joint, the body attacks the foreign material and destroys the living tissue in the process. Large voids evolve around the joint leading to loosening and eventual revision (Gallo *et al.* 2002). Knowing that this is a natural evolution to a joint replacement, which ultimately leads to loosening and revision, the treating physician has to monitor the progression of the lesion and intervene prior to significant damage.

Spinal procedures and subsequent corrections are the fastest growing segments of the orthopedic and spine market with 895 000 corrective procedures conducted in 2003, yielding $2.9 billion in sales. Like the rest of orthopedics, spinal disorders fall into degenerative and trauma-based causes. Disc injuries, such as herniated discs and degenerative disc disease, are the most common malady such that "approximately 80% of Americans experience at least a single episode of significant back pain in their lifetime, and for many individuals, spinal disorders become a lifelong malady" (Traynelis and Haid 2001). But, of these episodes, only 200 000 culminate with a surgical correction. In addition to discs, other spinal disorders include osteoarthritis (inflammation of the facet joints), spondylolithesis (slippage of vertebra), scoliosis (curvature of the spine), and traumatic events resulting in vertebral compression fractures (Quirk and Clair 2005) (**Figure 21**).

There are several progressions to the treatment of disc-related ailments. During the initial onset, bed rest, limited activity, and the use of nonsteroidal, anti-inflammatory drug (NSAID) often goes far toward reversing the pain. But, if the disc herniates or does not respond to the previous therapy, surgery may be required, including decompression of neural elements, discectomy, fusion of the adjacent vertebrae, or the implant of an artificial disc (WebMD 2001). For spondylolithesis and scoliosis cases, rods and fusion are treatments for the more advanced cases. Similar to the situations found in knee and hip replacement, physicians dealing with the spine need *in vivo* information. This information includes the pressure distribution across an artificial disc or the state of a vertebral fusion's progress. Because the doctors lack this information, they are forced to err on the conservative side potentially resulting in delayed return to normal or in limited range of motion. Potentially, the ability to monitor intervertebral pressures or prosthesis position during surgery can avoid postsurgical complications.

Figure 21 BRYAN® Replacement cervical disc. (Courtesy: Medtronic. BRYAN® (Cervical Disc System incorporates technology developed by Gary L Michelson, MD.)

Surgery, along with the need to keep the trauma induced by the surgical procedure itself to a minimum, is a critical part of orthopedic and spinal corrections. Tremendous strides have occurred in recent times toward this end with the development of tools such as endoscopes, Medtronic Sofamor Danek's (Memphis, TN, USA) Sextant Rod Insertion System, and surgical navigation equipment. Each of these solutions serves to reduce the size of the incisions and the resulting trauma by providing greater placement control of the surgical tools and corrective devices.

3.14.1.3.3 Current solutions

The orthopedics and spine industry has historically been dominated by mechanical engineering solutions. Today, microsystems are beginning to appear more prevalently in research and are showing early signs of being incorporated into products.

The most significant use of microsystems in orthopedics and spine has been with strain gauges. These devices are thin film (on the order of 0.076 mm in thickness and of planar dimensions on the order of 10 mm × 10 mm) sheets of polymer with metal, serpentine traces embedded in them that change the impedance when deformed (Szivek *et al.* 2002). Placing a gauge (or multiple gauges) in a Wheatstone bridge configuration allows the detection of minute strains while nulling out the effects due to temperature, aging, etc. Within this scope of use, companies such as Microstrain Inc. (Williston, Vermont, USA) have made significant headway with the use of strain

gauges to solve the previously described challenges. The direct application of these gauges have provided the *in vivo* data needed for measuring hip joint movement long before radiographic techniques could (MicroStrain 2001), for monitoring bone elongation (Noonan *et al.* 2004) and for the study of load-bearing effects on spinal ligaments (Roberts *et al.* 1998).

A notable use of strain gauges was realized during the collaboration between The Center for Orthopaedic Research and Education at the Scripps Clinic (La Jolla, CA, USA), DePuy Johnson and Johnson (Warsaw, IN, USA), NK Biotechnical Corporation (Minneapolis, MN, USA), and Microstrain Inc. Collaborating in the e-Knee project, they addressed the need for *in vivo*, real-time, joint pressure distribution data by creating a tibial tray specifically designed to transduce the pressures exhibited across the joint into electrical signals and telemeter the data to an external recorder. Four cavities were located on each of the four corners of the tibial tray with resistive strain gauges mounted on the roofs of each cavity. Pressures from a metal upper plate attached to the femur were collected by posts separating this upper plate from a similar lower plate that contained the strain gauges. The pressures transferred by the posts, each located over a corresponding cavity in the lower plate, deformed the cavity roof, which was then converted to a proportional electrical signal via changes in the resistance in the strain gauges (Kovacevic 1993). These data were then collected by a microprocessor, also embedded in the prosthesis, and were telemetered out of the patient to a data logger via an embedded RF circuitry and an antenna threaded into the end of the stem (Morris *et al.* 2001). The current version does not have a self-contained power source but is powered through an external inductive coil. Several companies, including Microstrain Inc., are continuing to research advanced energy harvesting techniques creating the possibility that the next generation of e-Knee is powered through the normal motion of the joint (**Figure 22**).

The e-Knee is a major advancement toward the understanding of the long-term dynamics of an artificial joint and how particular surgical methods and material effect the ultimate success of the replacement (D'Lima *et al.* 2005). Similar types of measurements have been made for hip implants (Bergmann *et al.* 1988, Davy *et al.* 1988) with creative solutions to address the limited space available for the electronics achieved only through the cooperation of the mechanical and the electronic disciplines.

Figure 22 e-Knee and inductive power coil (Source: Morris BA, D'Lima DD, Slamin J, Kovacevic N, Arms SW, Townsend CP, Colwell CW Jr 2001 Evolution of the electronic knee prosthesis: Technology Development. *J. Bone Joint Surg Am 83* (Supp 2), S62–S66. © The Journal of Bone and Joint Surgery, Amc.www.ejbjs.org.

The study of human joints in motion is an important area of study in order to understand how changing loads generating axial and lateral pressures on the bones, cartilage, and ligaments affect joint wear, longevity, and the patient's quality of life. One of the factors that goes into the study is how fatigue, footwear construction, and the characteristics of locomotion change a person's walking or running gait, which in turns changes the kinematics of their joints (Arndt 2003). Novel GmbH (Munchen, Germany) offers a complete system to fully analyze the pressures across the soles of the foot under varying conditions. This system is based on an array of capacitive sensors and their supporting electronics and power. These sensors are constructed of two parallel conductive plates separated by an insulator. As pressure from the foot is applied to the sensor, the two plates are compressed toward each other thereby changing the capacitance between the plates. The supporting electronics can detect this change in capacitance and can transduce it to a pressure measurement, then transmit it to a PC-based data collection system, or a handheld PDA, via a wire harness (suited for controlled lab conditions) or wirelessly using Bluetooth. These sensors can also be applied for similar studies on the hand and body surfaces subjected to long durations of pressure (e.g., the upper legs for those confined to wheelchairs or those wearing artificial limbs). Novel GmbH also offers their line of capacitance-based sensors with

different coatings and in arrays for *in vivo* joint studies.

As described previously, knee and hip joint replacements constitute the largest part of the orthopedic industry. A major reason for joint revisions is due to the interfacial failures between the prosthesis and the cement. The materials and designs selected for the artificial joint replacement are based on finite element analysis models and studies done *in vitro*, but these methods do not always provide a complete picture of the stresses experienced by the joint. As stated earlier, strain gauge is a solution to obtain *in vivo* data, but piezoelectronic sensors do offer an alternative means to obtain these data (Cristofolini *et al.* 2000). Thin-film strain gauges are ideal for measuring tensile stresses along its X–Y-axes but are unable to accurately measure compressive stresses in the same plane and completely unable in a plane perpendicular to that containing the serpentine traces. Piezoelectronic sensors are ideally suited for this particular case, i.e., for measuring forces perpendicular to the surface of the prosthesis, which are those that impact the integrity of the cement bond.

Though the piezoelectronic sensor has the added advantage of requiring a lesser use of surface area than would a thin-film strain gauge, there are two significant detractions with its use. First, they consume more volume than the thin-film strain gauges, and second, they are unable to hold the charge resulting from the physical deformation for long periods of time. This means the charge accumulated on its surfaces will leak off back to a neutral voltage over a period of tens of minutes. Consequently, the sensor has to be measured on a relatively frequent basis to measure the changes in stresses across the sensor.

The use of accelerometers is still another method to detect loosening in the cement–bone interface. A micromachined accelerometer, a device used to measure accelerations induced by movement, can be placed into the head of the artificial joint. At periodic checkups, the doctor applies a vibration at the distal end of the bone with the artificial joint and collects the vibratory motion at the proximal end (where the accelerometer is located within the prosthesis). The resulting signal from the accelerometer is collected and converted to meaningful data by microelectronics and is telemetered out of the body to be analyzed by a computer. If the joint has loosened, the proximal end of the bone, as well as the accelerometer, vibrates in a nonlinear manner generating harmonics of the sine wave. It is the detection and the measurement of these harmonic amplitudes that allow quantification of the joint failure (Puers *et al.* 1999). The primary advantage of this approach is that a qualitative measurement of the entire cement–bone interface can be acquired versus the status of a point location. Another use of this technique also includes the quantification of progress with the fusion of a bone fracture.

A final sensor method used in orthopedics involves the use of acoustic emissions. Though this technique does not have *in vivo* applications yet, it has been used to research the materials used for prosthesis in studies (Jeffers *et al.* 2005). Based on piezoelectronic sensors, "the acoustic emission technique can be used to obtain information about the microstructural changes that are occurring in any loaded material" (Surgeon 2004). The principle of the technique is the measurement of the stress waves that are propagated as microscopic bonds begin to break. These stress waves are recorded and processed, resulting in a picture of what is occurring within the joint under study as different loading conditions are applied. The limitation at the current time is the amount of processing required. But as microelectronics continues to increase in processing power while shrinking their physical size and power consumption, it will be a short time before the technology improves to the point of allowing the microelectronics to be implanted in the artificial joint to listen to the joint kinematics resulting in extremely precise, real-time analysis.

With orthopedic implants comes the necessity for surgery. The direction of technology development is to further minimize invasive surgery. Some of the more extreme surgeries in orthopedics involve the need to place rods along bones and the spines to stabilize them until they have healed, or fused. In time past, this would have required an incision of the full length of the rod through the skin and the muscle. Today, companies such as Medtronic Sofamor Danek are making tools such as the Sextant that minimize this surgical trauma. Through a very few, small incisions, cannulated multiaxial screws are attached to the bone followed by a rod slid and secured into place. This avoids the disruption of blood supply and innervation seen with previous procedures.

In conjunction with the tools for minimally invasive surgery (MIS), which by definition severely restricts or eliminates direct viewing of the procedure, comes a need to navigate through the body. Endoscopic surgery allows the surgeon to view inside the body through a few, 6.4 mm incisions. Larger

pieces of equipments using state-of-the-art computed tomography (CT) and 3D tracking continue to advance the state of remote surgery. Previous generations used optical cameras arranged in an array to identify markers on surgical tools with respect to references on the patient. This information is then displayed on a monitor superimposing the surgical tool tips onto the CT image, which provides the view for the surgeon. A major drawback of this system is a loss of tracking if something or someone is placed between the cameras and the tools. This issue is being resolved as the next generation of navigation tools, which utilize an array of electromagnetic sensors tracking comparable references on the tools, is rolled out to the market. This advancement eliminates the temporary loss of information during surgery and allows the surgical staff to move in a normal manner within the operating room.

Microsystems are proving to make the operating room safer as well as reducing the opportunity for errors. Collaboration between orthopedic surgeon Alfred Durham, Virginia Tech Applied Biosciences Center (Blacksburg, VA, USA) and Carilion Biomedical Institute (Roanoke, VA, USA) has created a handheld device that allows the surgeon to align a drill with pre-drilled holes in an intramedullary nail placed down the center of a broken bone. In the past, the surgeon attempted to align the drill bit with the hole using real-time X-ray resulting in exposure of the surgical staff to the radiation. By utilizing the principles of magnetic fields, the team created custom electronics to determine the placement of a drill sleeve with respect to a fixed embedded magnetic sensor in the nail providing feedback to the surgeon as to the direction needed to achieve the alignment. Location and alignment are obtained in much shorter time and eliminate the danger presented by the X-rays (DeGaspari 2005).

Finally, to speed the patient to full recovery, companies such as EBI, L.P. have developed implantable spinal fusion and bone growth stimulators. These stimulators can generate up to 60 μA of constant direct current for spinal fusions and up to 40 μA for bone healing, over a period of approximately 24 weeks, and have been shown to increase the probability of a successful fusion by 27% for spinal fusion (Kane 1988) and 38% for bone healing (EBI 2006). EBI, L.P. (Parsippany, NJ, USA) also offers external stimulators thereby eliminating the need for surgery to implant the device (**Figure 23**).

Figure 23 Spinal electrical stimulator. (Courtesy EBI Medical. Inc.)

3.14.1.3.4 Spinal and orthopedic solution on the horizon

Looking toward the future, it becomes apparent that the transition from a mechanical only based area of medicine to one of the integrated microsystems and advanced surgical navigation will continue to accelerate. The need to improve the design and materials of implants for longer prosthesis life and better therapeutic use comes clearly from the information gathered under real-world conditions, meaning real-time, *in vivo* data. This need is seen not only by commercial firms looking for the new untapped market, but also by governments. A project created under the Brite–Euram Program for the Commission of the European Community is chartered to develop smart orthopedic implants. This project will serve as a basis to advance the state of the materials, modeling, and data acquisition (Burny *et al.* 2000).

The use of microsystems in orthopedics continues to gain more attention as evidenced by the recent application of MEMS. Dr. Huikai Xie of the University of Florida (Gainsville, FL, USA) has proposed

using the AccuMicroMotion, a 1 mm × 1-mm sensor integrating a three-axes accelerometer and a single axis gyroscope MEMS device that "· · · could be implanted in bones during surgeries, giving orthopedic surgeons a unique way to monitor the progress of repairs" (Hoover 2006, Sadat *et al.* 2005) (**Figure 24**).

Theken Disc (Akron, OH, USA) is also expanding the use of microelectronics with the incorporation of a 2 cm^3 electronic circuitry into an artificial spinal disc. As of April 2005, the eDisc had been implanted into a primate for evaluation prior going to human clinicals. The eDisc "· · · redefines postoperative patient management through wireless data collection. This provides surgeons the unprecedented ability to assess and mange their patients by tracking the motions and loads on the lumbar spine" (Theken 2005) (**Figure 25**).

Amazing advances are also being made in orthotics, the development of electromechanical artificial limbs. One of the great limitations in this field has been the inability to control more than one joint movement at a time. This is now changing with the research being conducted at the Neural Engineering Center for Artificial Limbs, a program within the Rehabilitation Institute of Chicago (Chicago, IL, USA). This single degree of motion is now eliminated with the incorporation of new physiological advances using muscles as electrical amplifiers for the nerves that had operated the muscles of a severed limb, as myoelectrical sensors, and as controllers for the artificial limb. The new electronics improve the detection, amplification, and decoding of the electrical signals generated by the nerves, which in turn are translated into electromechanical instructions that operate the limb. The result is a much more natural control and simultaneous movement of multiple joints. In fact, two patients who have been outfitted with experimental devices are now able to throw a ball (Kuiken *et al.* 2005).

The future of surgical navigation is bright as well, with the use of robotics in the operating room being explored in limited applications (Sherman 2006). As advances in sensors, motors, imaging, and computing power continue forward, these assistants will do more and more of the delicate repair while minimizing the trauma further.

3.14.1.4 Obesity, Gastroenterology, and Urology Applications

3.14.1.4.1 Obesity

Obesity is the condition in which the energy stores of the body are too large (Canham 2003). Since the mid-1970s, the prevalence of those people who are classified as overweight or obese has increased dramatically in the United States, as well as in other parts of the world, with children and adolescents tripling and nearly two-thirds of adults now overweight or obese. This dramatic increase in weight is associated with an increase in the prevalence of associated comorbidities such as type-2 diabetes, hyperlipidemia, coronary heart disease, hypertension, stroke, asthma, and obstructive sleep apnea (Buchwald *et al.* 2004).

Metabolic syndrome describes a group of physical and metabolic conditions that are known health risks

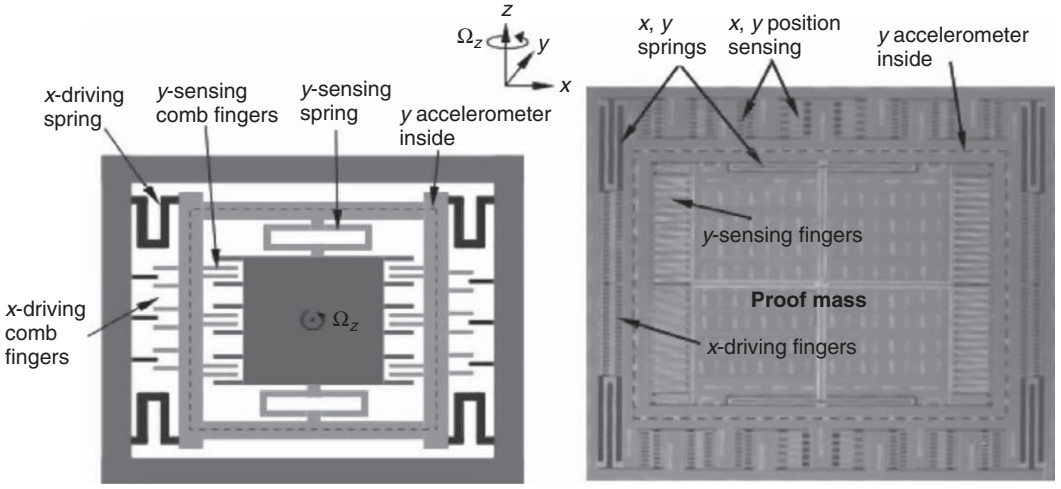

Figure 24 Diagram of AccuMicroMotion Sensor. (Source: Sadat A, Qu H, Yu C, Yuan J, Xie H 2005 Low-Power CMOS Wireless MEMS Motion Sensor for Physiological Activity Monitoring. *IEEE Transactions on Circuits and Systems.* v52, n12, pp. 2539–2551.)

Figure 25 Theken e-Disc (© 2004 Theken Disc.)

for patients, including conditions such as large waist circumference, insulin-resistant glucose metabolism, dyslipidemia, and hypertension. For example, patients with metabolic syndrome have 1.5–3.0 times increase in risk of coronary heart disease and stroke. But this condition is reversible. It has been shown that weight loss can improve all morbidities of metabolic syndrome (Klein *et al.* 2004), and therefore a means of reversing this obesity trend has become a major focus of research.

Following the first law of thermodynamics, the underlying cause of weight gain can be directly attributed to a long-term imbalance of energy consumption being greater than energy expenditure resulting in the excess energy stored as adipose (fatty) tissue. Other complications are caused by hunger and are also due to psychological factors such as taste, stress, and social reasons. On the consumptive side of the energy equation, expenditure is composed of the basal metabolic rate, thermic effect of food, and activity thermogenesis. While both energy consumption and expenditure appear to be controllable by an individual, uncontrollable factors such as hormones and genetics also play an influential role in determining the weight (Bouchard *et al.* 1990, Levine *et al.* 1999).

Obesity is often characterized in terms of body mass index (BMI) and obesity class. BMI is calculated by dividing the weight (in kilograms) by the square of the height (in meters), with an obesity class of I, II, and III having a BMI between 30 and 35, 35 and 40, and >40, respectively.

Therapy efficacy is quantified in terms of excess weight loss (EWL), defined as the amount lost divided by the excessive weight (amount above the ideal weight). Pharmacological treatments have shown a low EWL. Therefore the primary means of EWL is derived from surgical techniques. The surgical techniques employed for treating obesity today focus on reducing the body's ability to absorb calories. The more common techniques include gastric bypass, which relies on physical changes in the size and the intestinal pathway, and (more widely used) placing a band around the stomach. There are several gastric banding procedures such as laparoscopic gastric bypass, adjustable gastric band 'Lap Band' (Kuzmak), vertical banded gastroplasty (Mason), and silicone ring vertical gastroplasty. While these surgical procedures have demonstrated high EWL (40–60%), these procedures also present a mortality risk (Flum *et al.* 2005), as well as being difficult to reverse.

An alternative way to encourage weight loss is to create a sense of satiety, or reduction in appetite. Electrical stimulation of the stomach is an emerging therapy seeking to achieve this satiation (**Figure 26**). The stimulator consists of a chronically IPG and is known in the industry as an implantable gastric stimulation (IGS). The IGS contains a hermetically sealed microcircuitry and a power source with the electrical stimuli delivered by means of leads from the internal circuitry (using hermetic feedthroughs) to specific points on the stomach. Much of this technology is based on implantable cardiac pacemaker technology. Though the electrical pulses from the IGS influence the mechanical activity of the stomach as well as the gastric hormone levels, it is thought to primarily bias the satiety level in the brain through vagal afferent conduction.

3.14.1.4.2 Gastroenterology

The gastrointestinal (GI) system is composed of the alimentary canal (or tract), salivary glands, liver, pancreas, and gall bladder (Young and Austrin 1979), and the function of the GI is to ingest and absorb nutrients while also excreting unabsorbed nutrients and waste products. The branch of medicine concerned with functions and disorders of this system is called gastroenterology (Canham 2003).

There are many GI diseases (gastroenterology including ulcers, abnormal tissue growth, GI bleeding, and inflammation). Crohn's disease, in particular, is an inflammation of the lower part of the small intestine that can lead to severe intestinal blockage. Though it is critical to identify and diagnose these GI diseases as early as possible, small and hard to reach anatomy can make visual image identification

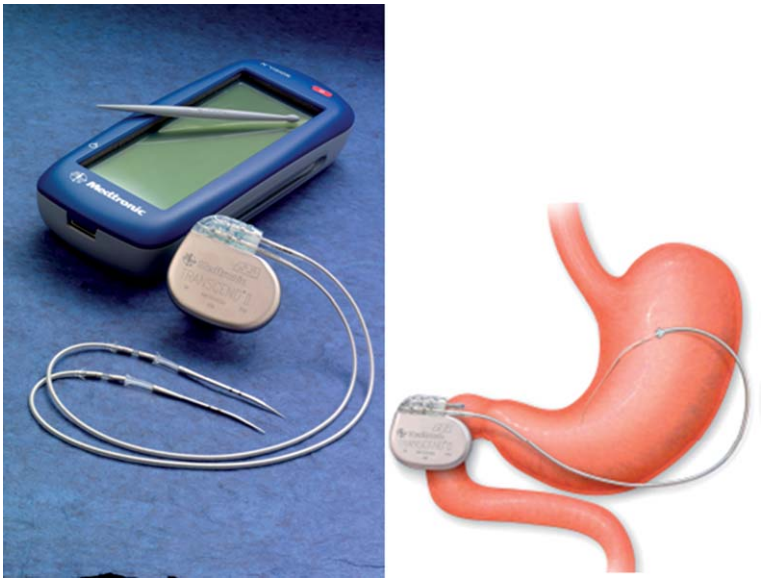

Figure 26 Physician programmer, gastric stimulator, and stimulation leads. (Courtesy: Medtronic.)

of anatomical and structural anomalies, as well as surgical procedures, very difficult.

Endoscopy is the key instrument for visualizing the interior of hollow organs (Merriam 1993) such as the upper GI tract (gastroscopy), the colon (colonoscopy), or the rectum (Yamada and Alpers 2006). GI scopes take up 37% of the total endoscopy market, which was estimated to be $324 million in the United States in 1999 (Technology for Industry 2005). Endoscopy has evolved from rigid tubes with fixed lenses in the 1970s to multicore fiber optics enabling flexible endoscopes in the 1980s (Wilkinson and Hitchings 2003). Further use of microsystems has led to the development of endoscopes with video cameras at the distal end (Panescu 2005). Other instances of microsystem technology enhancing the functionality of next generation endoscopes include Diagnostic Endo Laser Scanner's (DELAS, Laser and Medizin Technology GmbH, Germany) proposed use of a scanning imaging technique. The optical components consist of single fibers and microscanning mirrors to avoid the spectral limitations of conventional image guides (Schutz *et al.* 1997). More recently a team of researchers has developed a miniature confocal optical scanning microscope as an endoscopic application and has successfully obtained a real-time image. The confocal microscope can observe the longitudinal direction of a scanning head, including the electrostatic 2D MEMS scanner, and an aspherical objective lens. A scan angle of 12°, a mirror flatness of 80 nm, and a mirror reflectance of over 85% have been achieved. The diameter and the length of the scanning head are 3.3 and 8.0 mm, respectively, allowing it to be inserted into a channel of the endoscope. The lateral resolution is 0.5 μm, the depth resolution 2.9 μm, the field of view of 100 μm × 75 μm, and the frame rate is 20 frames per second (Murakami 2005).

Disadvantages of endoscopy are the pain it causes; the need for it to be done in the hospital, and it's inability to allow optimum view in difficult areas of the anatomy. More recent developments aimed at overcoming these limitations have resulted in the emergence of capsule endoscopy:

> The PillCam™ SB capsule endoscope is a naturally ingested device for use in the GI tract. Natural peristalsis moves the capsule smoothly and painlessly throughout the GI tract (**Figure 27**). The capsule contains an optical lens, complementary metal oxide semiconductor (CMOS) imager, white LED illumination, battery and radio transmitter to send color video images as it passes. Information is transmitted via an array of sensors secured to the patient to a DataRecorder worn around the patient's waist. The procedure is ambulatory, allowing patients to continue daily activities throughout the endoscopic examination. The effectiveness of this pill has been investigated for GI bleeding, Crohn's disease, small bowel tumors, pathology, esophageal mucosal pathology, and endoscopy (Given Imaging, Yoqneam, Israel) (Panescu 2005).

Figure 27 Inside the Pillcam™ (© Given Imaging).

An intracorporeal video probe (IVP) has been developed within the framework of a European Information Society Technologies (IST) project in both a catheter version (IVP1) and a stand-alone version (IVP2) for applications in video endoscopy and gastroenterology. It uses a CMOS camera and micromechanical tilting mechanism (Arena *et al.* 2005, Neidlinger *et al.* 2000, Sell 2005).

A failure in the normal physiological mechanism to prevent abnormal amounts of acid from entering the esophagus is known as gastroesophageal reflux disease (GERD) causing symptoms of heartburn and/or mucosal injury (esophagitis, peptic strictures, and Barrett's esophagus). The prevalence in the United States is 20%, while that based on injury is 7% and drives an annual cost for antacid medication in the United States estimated at $4 billion (gastroenterology).

The underlying mechanisms, therapeutic approaches, and potential complications are different for three unique groups (non-erosive reflux disease, erosive esophagitis, and Barrett's esophagus) of GERD (Fass 2002b). Current methodology for diagnosing entails passing a catheter, with a pH-sensitive ion-sensitive field effect transistor (ISFET) mounted on the tip, transnasally into the esophagus and leaving the catheter in place. This catheter is uncomfortable, cumbersome and conspicuous, leading most patients to modify their activity (Schepel *et al.* 1987, Smit *et al.* 1997).

Another diagnostic device, the Bravo pH capsule, is an oblong device (6.0 mm × 5.5 mm × 25.0 mm) (Wong *et al.* 2005) with an antimony pH and a reference electrode located at the tip, an internal battery, and a transmitter all encapsulated in epoxy (**Figure 28**). The Bravo sends data to an external receiver every 12 s via a 433-MHz RF signal while achieving data security via digital data transmission and a unique identification code. Prior to placement, the capsule is activated by a magnetic switch and is calibrated by immersing in pH buffer solutions of pH 7.01 and 1.07 (Medtronic, Shoreview, MN, USA).

The GI system is also used for drug delivery using oral tablets, capsules, solutions, rectal suppositories, and transmucosal (Technology for Industry 2005). Targeted delivery of chemotherapy for Crohn's disease and colorectal cancer has been achieved using nondigestible capsules containing a power source, a radio transmitter, and a medicament storage that can be opened remotely for delivery (GastroTarget Inc., Tonawanda, NY, USA). "The capsule signals a remote receiver as it progresses through the alimentary tract in a previously mapped route and upon reaching a specified site is remotely triggered to release a dosage of medicament" (Gastrotarget Corp. 1994).

A rise in CO_2 level of the gastric wall in critically ill patients can be an early warning for a reduction

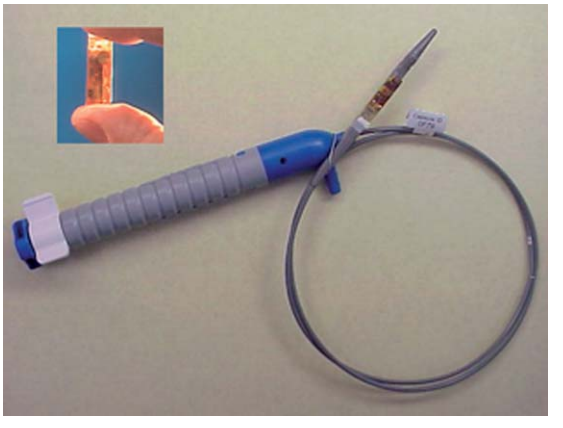

Figure 28 Bravo pH Monitor. (Courtesy: Medtronic.)

in peripheral blood flow, causing multiple organ failure. Companies such as Nihon Kohden (Tokyo, Japan) are investigating the measurement of this parameter using CO_2 ISFETs (Canham 2003). At the University of Twente (The Netherlands), a pH-sensitive hydrogel disk, which swells and deswells in response to pH changes clamped between a pressure sensor membrane and a porous metal screen together with a bicarbonate solution, is also being used as a CO_2 sensor. CO_2 reacts with the bicarbonate solution resulting in a pH change that is converted into pressure change by the enclosed hydrogel. The main advantage of this sensor is that a reference electrode required for potentiometric sensors is no longer needed (Herber *et al.* 2004b). The data collected showed that under isochoric conditions, the static and the dynamic stimulus-dependent behavior of hydrogels show fast reactions (Herber *et al.* 2004a).

3.14.1.4.3 Urology

Urology is the branch of medical science dealing with the study of the urinary tract in both sexes as well as the genital tract in males (Young and Austrin 1979). Urologists study and treat disorders of the urinary outlet of the kidney, urinary bladder, urethra, prostate, testicles, and penis diseases including obstructions from stones, tumors, inborn diseases, infections, impotence, sterilizations, and incontinence (Zeijlemaker *et al.* 2006). The renal system, pertaining to the kidneys, regulates water and electrolyte content; maintains the blood pH; excretes waste metabolic products, toxins, and drugs; retains vital nutrients; and regulates specific hormonal and metabolic functions (Canham 2003). The urological examination and diagnostic techniques include physical examination and urinalysis, instrumentation, and urinary tract imaging (Walsh *et al.* 2002).

Urinary incontinence is defined as involuntary loss of urine more than once a month at inappropriate places or times regardless of the amount that is lost (van Halteren 2003), which affects an individual's social interactions, self-esteem, and daily activities (O'Donnell 1997). Prevalence of urinary incontinence in the United States for the age group of 15–64 years is estimated at 10–20% for women and at 1.5–5.0% for men with an economic cost estimated to be $10.6 billion in 1987.

The urinary bladder is spherical in shape and is located at the end of both ureters in the abdomen behind the pubic bone with several blood vessels and a network of nerve bundles connected to it (Zeijlemaker *et al.* 2006). Incontinence, as a standalone disorder, is divided into stress incontinence caused by a weak sphincter, urge incontinence caused by a hyperactive bladder, or a combination of the two (mixed urinary incontinence). It can also be a part of more complex medical situations such as a neurological disorder, an obstruction, and mobility or cognitive limitations (van Halteren 2003).

Microsystems play a role in urodynamic investigations to diagnose urinary problems. This investigation, which takes about 30–60 min, involves artificial interventions in the bladder and simultaneous measurements. Cystometry is the study of the neuromuscular mechanism of the bladder by means of a cystometer that can measure pressure and capacity. A replacement device was proposed in 1984 for the catheter tip transducer used in cystometry. This telemetry pill enables pressure measurements under close to normal life circumstances for the patients and is introduced into the bladder using a cystoscope. A thick-film substrate serves as a carrier and as an interconnection for the components with the entire circuit protected in a micromachined ceramic package containing a removable container for the disposable battery. Using a dedicated receiver, developed with emphasis on noise reduction, the system is able to transmit pressure data over 4 m for up to 4 days per battery (Sansen *et al.* 1984, Puers *et al.* 1984). Micromachined piezo and capacitive pressure sensors for bladder pressure measurements are described in Puers (2005).

The wide range of therapies for various forms of urinary incontinence is classified as conservative treatments (physiotherapy, behavioral training, and physical stimulation), medicines, surgical, and external or internal assistance devices (van Halteren 2003) with the prescribed treatment depending on the cause of the disease (Zeijlemaker *et al.* 2006). For patients who are diagnosed with urinary urge incontinence (uncontrolled release of urine) or urinary urgency frequency (unstable bladder), electrical stimulation using an implantable stimulator may be a solution. This therapy is for those patients who have failed, or could not tolerate, more conservative treatments. Patients are contraindicated for implant if they have not demonstrated an appropriate response to test stimulation or are unable to operate the neurostimulators (Weil 2000). The implantable InterStim Therapy (Medtronic Inc., Minneapolis, MN, USA) system uses mild electrical stimulation of the sacral nerves that influence the behavior of the bladder, sphincter, and pelvic floor muscles (see

Figure 29 Implantable Interstim Therapy (Courtesy: Medtronic.)

Figure 29). In properly selected patients, InterStim therapy can dramatically reduce or eliminate symptoms.

In 1987, a closed-loop control of the unstable bladder was proposed. It relies on a biofeedback system that makes use of the bladder pressure as a parameter for functional stimulation. The key element is an implantable bladder pressure telemetry device, which relies on an RF power link that converts the pressure signal into a pulse position-modulated signal. To close the biofeedback system, an independent programmable stimulator has been developed, which is triggered by the pressure data (Sansen *et al.* 1987).

A urinary tract stimulator that is intended to restore normal bladder function in patients who have spinal cord injuries was proposed in 1993. The system is composed of two principal parts. The first part, which is external, consists of a handheld device based on an inductive-coupling technique. The second part, a fully programmable implantable device, includes a CMOS array IC that controls eight monopolar (or four bipolar) stimulation channels. In the experimental phase, the researchers investigated the effect of early electrical stimulation of the bladder during the spinal shock phase in paraplegic dogs. In addition, using the stimulator, they localized the parameters of stimulation that give best results in terms of effective bladder pressure and void a high volume of urine (Sawan *et al.* 1993). The combination of microfabricated sensors and actuators to form a closed-loop control system is currently still under investigation. An artificial sphincter and a sphincter sensor are actively being developed in the European project Healthy Aims (Tooley 2004).

Very small flexible endoscopes enabled by microsystem technology are used in urology to observe stones in the bladder (Technology for Industry 2005). Endoscopic optical coherence tomography (OCT) based on a microelectromechanical mirror has been used in thickness measurement and bladder tissue imaging. An endoscopic OCT system based on a microelectromechanical mirror to facilitate lateral light scanning is described. The front-view OCT scope, adapted to the instrument channel of a commercial endoscopic sheath, allows real-time cross-sectional imaging of living biological tissue via direct endoscopic visual guidance. The transverse and axial resolutions of the OCT scope are roughly 20.0 and 10.2 μm. Cross-sectional images of 500 × 1000 pixels covering an area of 2.9 mm × 2.8 mm can be acquired at five frames per second and with nearly 100 dB dynamic range (Pan *et al.* 2001).

The prostate is a relatively small chestnut-sized organ, which exists only in the male and is found right beneath the bladder at the beginning of the urethra. Current treatment of enlarged prostate involves surgical procedures via the urethra to physically remove or ablate the tissue using a heat source. Heat sources utilized today include laser treatment, microwaves, high-energy ultrasound waves, or heat. On the other hand, devices such as little plastic or metal tubes exist to be implanted in the prostate to keep the urethra open (Zeijlemaker *et al.* 2006).

3.14.1.5 Ophthalmic and Auditory Applications

3.14.1.5.1 Ophthalmic applications

3.14.1.5.1.(i) Introduction to ophthalmic applications The ophthalmic industry serves the medical needs of people with aberrations and diseases of the eye. Approximately 1 in 28 Americans 40 years of age and older is affected by loss of vision or blindness

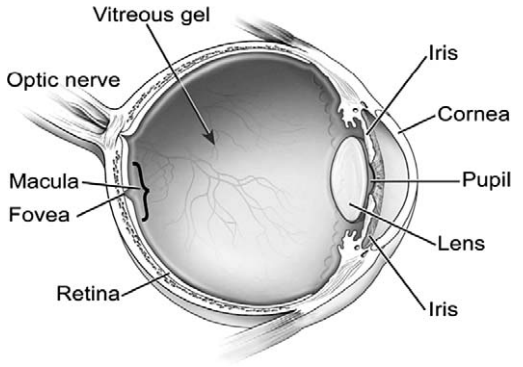

Figure 30 Schematic of the eye. (Source: National Eye Institute 2006 http://www.nei.nih.gov/)

(Gohdes *et al.* 2005). External medical devices to improve or correct vision range from prescription eyeglasses and contact lenses to nonprescription reading and sunglasses. Visual acuity, refraction, and intraocular pressure are some of the tests performed during eye examination. Ophthalmologists perform ophthalmic exams to check for diseases of the eye (American Academy of Ophthalmology 2006). Optometrists also perform many of these tests (American Optometrists Organization 2006). Laser-based corneal refractive procedures such as Lasik have made significant progress in providing long-term medical corrections for vision aberrations.

A schematic of the eye is shown in **Figure 30** (National Eye Institute 2006, National Institutes of Health 2006). Light enters the eye in a controlled manner through the pupil. Much like a camera, the light that enters this shutter-like structure is then focused by a lens. In the case of the eye, the lens focuses the light onto the retina. The macula is composed of photoreceptor cells. The macula is the part of the retina that receives and processes light and sends signals to the brain via the optic nerve. Degeneration of the macula photoreceptor cells, and optic nerve fiber damage, result in impaired or loss of vision. Further details on the anatomy and operation of the eye can be found in Eye Diseases and Conditions (2006), National Eye Institute (2006), and National Institutes of Health (2006).

An individual is defined as being legally blind when his or her best visual acuity is 20/200 or worse in their better eye or whose visual field, regardless of vision acuity, is restricted to 20° diameter. According to the American Foundation for the Blind (2006), approximately 1.3 million Americans are legally blind.

3.14.1.5.1.(ii) Ophthalmic diseases Some of the aberrations and diseases of the eye include myopia, hyperopia, presbyopia, astigmatism, cataracts, glaucoma, macular degeneration, and retina pigmentosa. Myopia or near-sightedness occurs when the eye's lens focuses incoming light in front of the retina. Hyperopia, or far-sightedness, occurs when the eye's lens focuses incoming light behind the retina. Eyeglasses or contact lenses typically correct for myopia and hyperopia, but do not slow their progression. The number of people in the United States estimated to suffer from myopia and hyperopia is currently 30.4 million and 11.7 million, respectively. Presbyopia results from the loss of the eye's ability to accommodate vision from near to far and is age related. People lose their ability to focus near vision and require reading glasses. The 119 million Americans 40 years and older are currently, or will soon, suffer from presbyopia (MedTech Insight 2005a, b). Astigmatism may result from an irregularly shaped cornea or lens and typically can be corrected with eyeglasses, contact lens, or refractive surgery. A comprehensive list can be found in Eye Conditions (2006).

A cataract is a clouding of the lens or the surrounding membrane that results in the obstruction of light (**Figure 31**) (National Eye Institute 2006, National Institutes of Health 2006). Cataracts are typically associated with older age and can be removed by surgery. Over the past 20 years, there has been widespread adoption of intraocular lens

Figure 31 A white congenital cataract. (Source: National Eye Institute 2006 http://www.nei.nih.gov/)

implants in conjunction with cataract surgery (MedTech Insight 2005a, b). Over 20 million people in the United States aged 40 and over have cataracts. This number is expected to increase to 30 million by 2020. Over half of the Americans aged 65 and over have cataracts. In 2005, cataract surgery-related products generated $3 billion in worldwide sales (MedTech Insight 2005a, b; National Eye Institute 2006, National Institutes of Health 2006).

Glaucoma is a condition where the optic nerve fibers die from lack of sufficient blood supply. Intraocular blood pressure is believed to play a role in this, as well as in lifestyle choices and comorbidities such as diabetes. External medical devices that measure intraocular pressure are used by ophthalmologists to diagnose and monitor glaucoma.

Retina pigmentosa and macular degeneration are retinal degenerative diseases. Macular degeneration is the most common cause of loss of vision in people over 55 years of age. Studies have found that both genetic and environmental factors influence this eye disease, but in cases of early onset of macular degeneration, the factors are primarily genetic. Retinitis pigmentosa is the name for a group of related eye diseases that affect the retina. All associated diseases are genetic in nature and cause a gradual degeneration of the rods and cones within the retina and gradual loss of vision, typically with the loss of peripheral vision preceding loss of central vision. Some retina pigmentosa syndromes include Usher syndrome, Bardet–Biedl (Laurence–Moon) syndrome, Best disease, choroideremia, cone–rod dystrophy, gyrate atrophy, and Leber's congenital amaurosis. There are at least 30 million people worldwide who suffer from retina pigmentosa and age-related macular degeneration. These are the two most common causes of as-yet untreatable blindness in developed countries (World Health Organization 2006). There are microsystems in development and in clinical trials studying the potential to provide therapy to patients suffering from age-related macular degeneration and retinitis pigmentosa. These are discussed below.

3.14.1.5.1.(iii) Ophthalmic current solutions Microsystems that include pressure and strain sensors, stimulating electrodes, microelectronics, and additional microsystems, such as Reichert Tonopen (Reichert Tonopen 2006), Keeler Pulsair Easy Eye (Pulsair 2006), Bausch and Lomb Proview Eyelid (Bausch and Lomb 2006), and Canon TX-F (Canon 2006), have been integrated into medical instruments to measure intraocular pressure. Medical

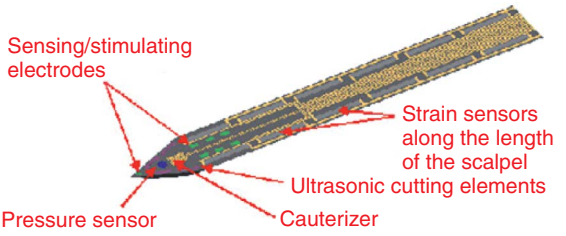

Figure 32 Verimetra's Data Knife, in development.

microsystems are also being integrated into medical instruments and tools to aid in ophthalmic surgery, such as Verimetra's Data Knife (Karoub 2003) (**Figure 32**). Significant progress has been made in the field of multivision intraocular lenses (IOLs) to replace lenses diseased with cataracts (**Figure 33**) (MedTech Insight 2005a, b).

3.14.1.5.1.(iv) Ophthalmic solutions on the horizon Shunts are currently implanted for patients with glaucoma to enable built-up fluid to exit. A feasibility study evaluating micromachined fluidics, sensors, and actuator valves integrated into drainage devices for glaucoma details potential applications of microsystems in this field (Howorth 2002) (**Figure 34**).

The major ophthalmic applications for medical microsystems are in prostheses that aid the near-blind or the blind to see. IOLs may become more widely used than just for the replacement for lenses diseased with cataracts. IOLs may be used as a pretreatment for precataracts. In addition, some companies are integrating microsystems with lenses for use in patients who require cataract surgery and who have glaucoma (Mesotec 2006).

Mesotec (Hanover, Germany) has developed a continuous intraocular pressure monitoring system that is powered externally by RF energy, reads the intraocular pressure, and delivers the data externally by RF telemetry (Mesotec 2006). An external antenna is required to deliver the RF signal and to receive the data from the implanted sensor, and can be integrated into special eyeglasses worn by the patient. The implanted device includes a foldable coil for coupling for the telemetry, a micromachined pressure sensor, and microelectronics. The sensor, microelectronics, and coil are integrated into a modified soft intraocular lens (**Figure 35**). This implantable medical device is intended to be used in patients that have both glaucoma and cataracts (Mesotec 2006).

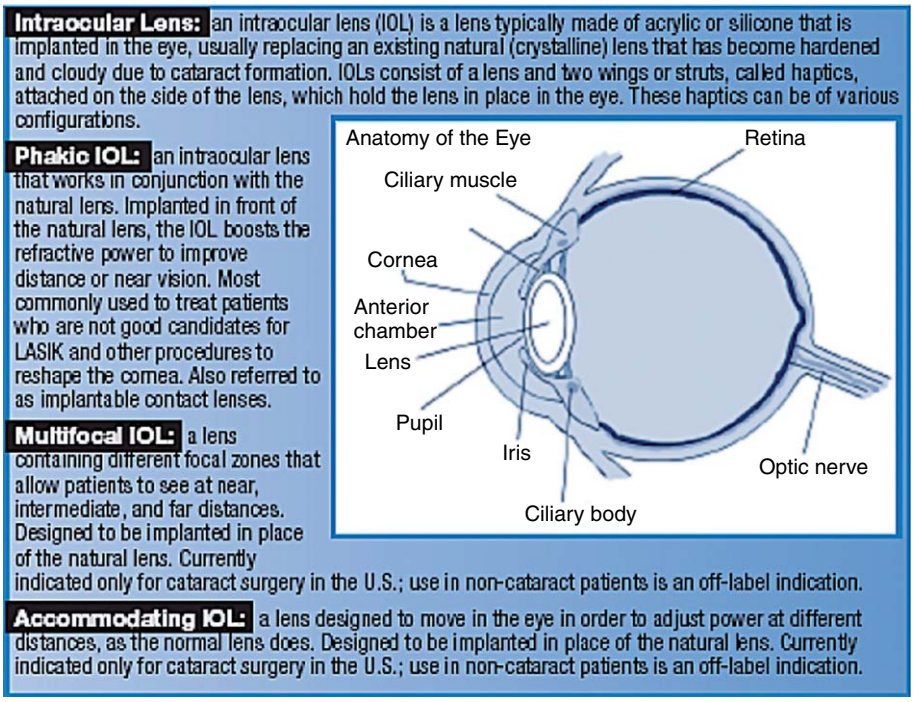

Figure 33 Intraocular lenses. (Source: MedTech Insight 2005 a *Novel Pain Products Address Growing Need* **7(2)**; MedTech Insight 2005b *Eyeing the Future of Ophthalmology* **7(11/12)**.)

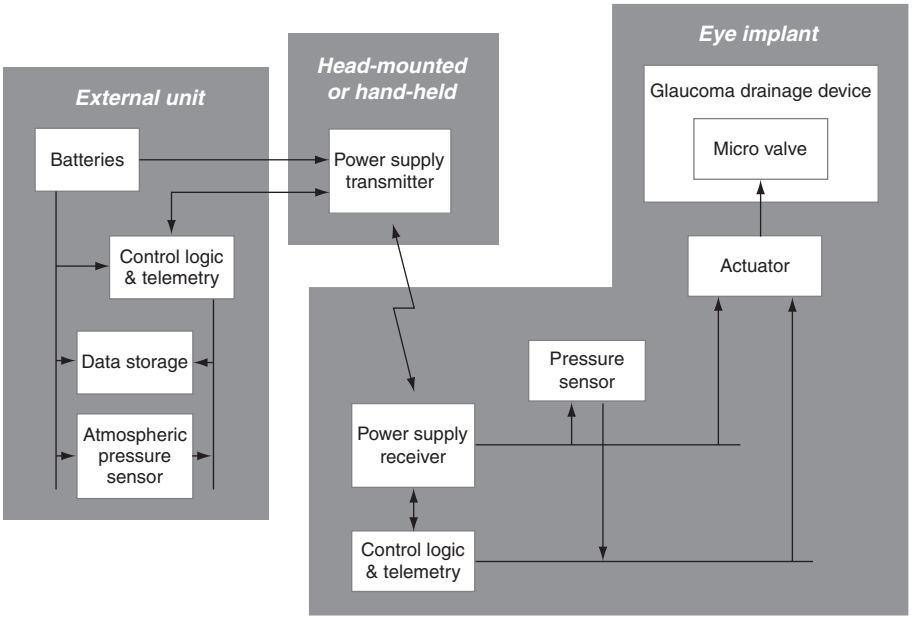

Figure 34 System design for active pressure-controlled glaucoma drainage device. (Source: Howorth D J 2002 Feasibility study for a micromachined glaucoma drainage device. M.Sc. thesis, Cranfield University.)

The most recent application of microsystems in ophthalmic applications is the design and manufacture of implantable medical devices to aid in vision improvement. Academic researchers active in this field include The Doheny Eye Institute and the Intraocular Retinal Prosthesis Group at the University of Southern California (The Doheny Eye Institute 2006), the Harvard–M.I.T. Retinal Implant Project

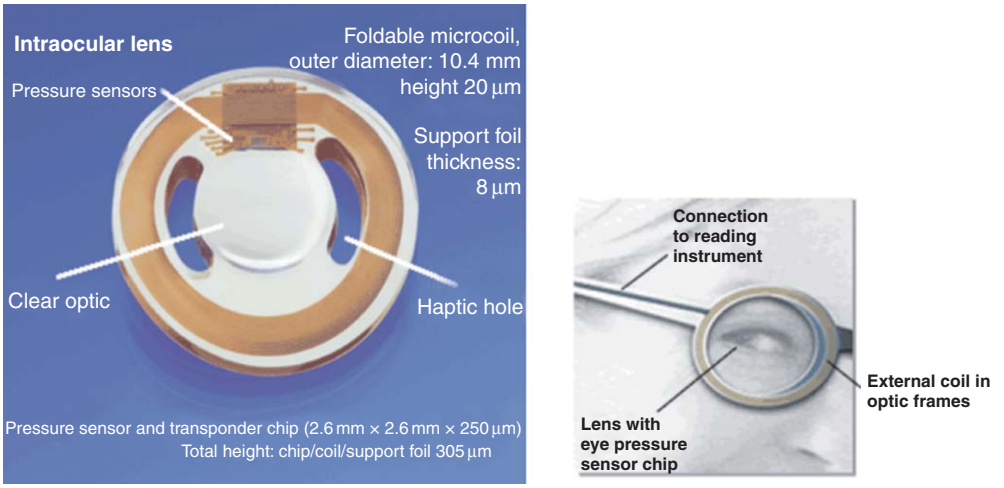

Figure 35 Mesotec-implanted device and external antenna. (Source: Mesotec 2006 http://www.mesotec.com/english/start.htm)

Group (The Retinal Implant Project 2006), Stanford University School of Medicine and the Kresge Eye Institute (Roberts 2006), University of Aachen and the Fraunhofer Institute in Germany (Fraunhofer 2006), the University of Uppsala in Sweden (Uppsala University 2006), and the Katholieke Universiteit in Leuven (Katholieke Universiteit Leuven 2006). Companies active in this field include Optobionics (Optobionics 2006), Second Sight (Second Sight 2006), and Mesotec (Mesotec 2006).

Medical microsystems are improving the lives of those with ophthalmic diseases and are bringing the hope of vision to the blind (About Vision 2006, All About Vision 2006, The Foundation Fighting Blindness 2006).

3.14.1.5.2 Auditory applications

3.14.1.5.2.(i) Introduction to auditory applications

The auditory industry serves the medical needs of people with aberrations and diseases of the ear. Otolaryngologists are head and neck surgeons who diagnose and treat disorders of the ears, the nose, the throat, and related structures of the head and the neck. Otolaryngologists and hearing health professionals perform auditory exams to check for diseases of the ear. External medical devices to improve or correct hearing range from behind-the-ear, in-the-ear, in-the-ear-canal, and on-the-body hearing aids to compact, portable listening devices (FDA 2006). Companies marketing hearing aids can be found (The Hearing Planet 2006). Implantable hearing devices include cochlear implants and partially implantable hearing systems.

A schematic of the ear is shown in **Figure 36** (Wikipedia 2006). Sound passes from the outer ear to the eardrum through the ear canal. The eardrum vibrates from the sound waves that are transmitted to the inner ear by the three bones termed the malleus, the incus, and the stapes. The inner ear contains the cochlea, the semicircular canals, and the vestibule. The vestibule is an oval cavity that contains the saccule and the utricle that communicate with the cochlea and the semicircular canals. The cochlear nerve, which is a part of the vestibular nerve, is associated with hearing. The vestibular nerve passes impulses from the inner ear to the brain and is associated with balance (Wikipedia 2006).

The market for medical devices to provide therapy for hearing loss is large. Twenty-eight million Americans suffer from some type of hearing loss. Age-related hearing loss affects 30% of adults 65 years of age and older and 1.7% of children under 18 years (National Institute on Deafness and Other Communication Disorders 2006). Hearing loss can result from exposure to damaging noise, certain medications, or from heredity, and can vary in severity from mild to total hearing loss.

3.14.1.5.2.(ii) Auditory diseases

The different types of hearing loss are termed conductive, sensorineural, and mixed hearing loss. Conductive hearing loss occurs when sound waves are not conducted to the inner ear and can be caused by the

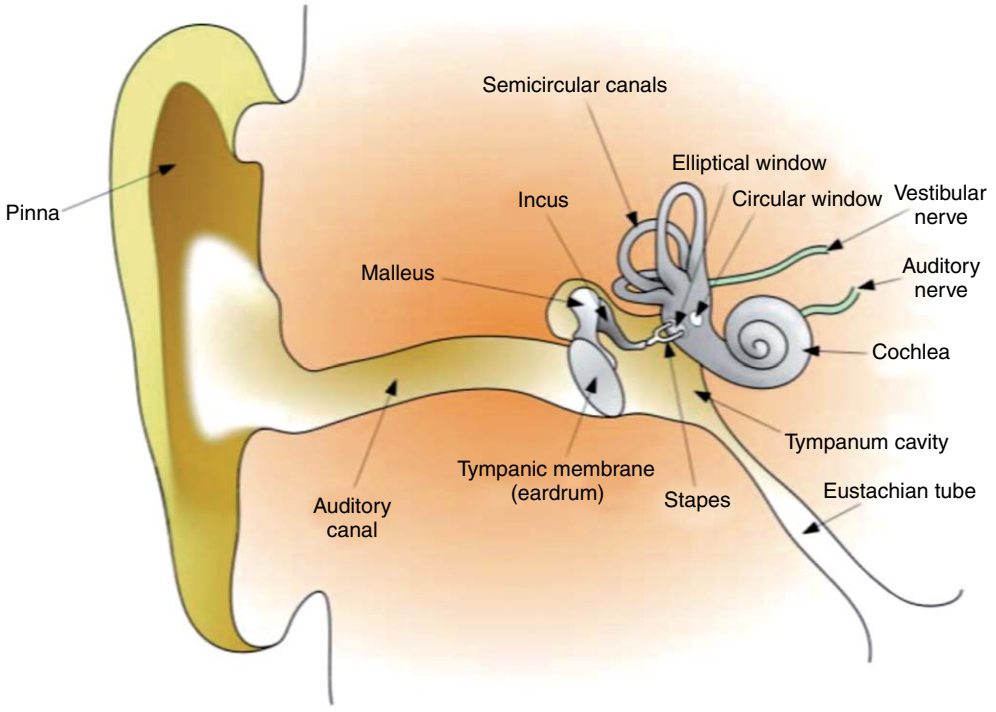

Figure 36 Schematic of the ear. (Source: Wikipedia 2006 http://en.wikipedia.org/wiki/Image:HumanEar.jpg).

buildup of earwax, an infection, fluid in the middle ear, or a punctured eardrum. Conductive hearing losses are typically corrected by medical or surgical therapies. Sensorineural hearing loss develops when the auditory nerve or hair cells in the inner ear are damaged by aging, noise, illness, injury, infection, head trauma, toxic medications, or an inherited condition. Sensorineural hearing loss usually cannot be reversed. Mixed hearing loss is a combination of both conductive and sensorineural hearing loss (Auditory and Vestibular Pathways 2006, Facts on Hearing Loss 2006, Hoversland 2006, National Institute on Deafness and Other Communication Disorders 2006).

3.14.1.5.2.(iii) Auditory current solutions

Microsystems integrated into external and implantable medical devices to aid in hearing aberrations include sensors and actuators such as microphones and implantable electrodes. Microphones pick up auditory signals from the environment and convert these to an electrical signal. Microphone technology and implantable electrode technology are discussed further in Section 3.14.2. Speech processes and microelectronics, such as amplifiers, digital signal processors (DSP), filters, transceivers, and receiv-ers, also play very critical roles in hearing aid and cochlear implant devices. The packaging of implantable systems must be biocompatible and biostable (Berkeley Sensors and Actuators Center 2006, Wireless Integrated Microsystems 2006).

There are a significant number of companies with hearing aid solutions (The Hearing Planet 2006). Three companies have FDA-approved medical implant devices such as cochlear implants that provide therapy for a chronic impairment or a chronic disease (University of Massachusetts Memorial Medical Center 2006): Med-El (Med-El 2006), Advanced Bionics (Advanced Bionics 2006), recently acquired by Boston Scientific (Boston Business Journal 2004), and Cochlear Corporation (Cochlear 2006). A diagram of an ear with a cochlear implant is shown in **Figure 37** (National Institute on Deafness and Other Communication Disorders 2006). The cochlear implant market growth is estimated to be between 15% and 20% per year. It is also expected that growth may accelerate due to the expanded implant eligibility criteria by the Medicare and Medicaid Services in April 2005 and due to the aging of the baby boomer

Figure 37 Diagram of ear with cochlear implant. (Source: National Institute on Deafness and Communication Disorders 2006 http://www.nidcd.nih.gov/health/hearing/hearingaid.asp).

generation (About Deafness 2006, American Academy of Otolaryngology Head and Neck Surgery 2006, Mishori 2006).

Research is continuing in the field of hearing improvement prosthesis. The University of Michigan at Ann Arbor, MI, has a focused research program on neural prostheses (Wireless Integrated Microsystems 2006). There is also significant research in the microsystem subcomponents, such as microphones, speech processors, and wireless telemetry (Berkeley Sensors and Actuators Center 2006, IEDW 2005, Loizou 1998, Wireless Integrated Microsystems 2006).

3.14.2 Emerging Technologies for Medical Applications

3.14.2.1 Novel Sensor, MEMS, and Microoptic Technologies for Medical Applications

3.14.2.1.1 Sensor technology for medicine and health care

Sensors are critical for the management of the patient's health, providing information to the managing physician as well as to therapy-providing devices. The accurate measurement of pressure is a key to the management of many conditions including hypertension, heart failure, hydrocephalous, glaucoma, and incontinence. Everyone is familiar with the sphygmomanometer as a method to obtain arterial blood pressure. Automated blood pressure systems from companies such as SpaceLabs Medical Inc. (Issaquah, Washington, DC, USA) and Sun Tech Medical Instruments (Raleigh, NC, USA) are now being used on ambulatory patients to manage hypertension.

Silicon pressure sensors are a key component in the monitoring of patients in a critical care unit. A cardiac catheter is placed in an artery or is wedged in a pulmonary capillary. The catheter has a lumen that is filled with a fluid. The pressure generated by the blood or the heart pushes on the fluid, which, in turn, pushes on the pressure sensor that is in a housing outside the body.

Silicon pressure sensors are also integrated directly into some catheters. Millar Instruments Inc. (Houston, TX, USA) has a broad product line of single and multiple sensors on catheters. The smallest of these catheters is approximately 0.67 mm in diameter. The PressureWire5 from Radi Medical System AB (Uppsala, Sweden) is even smaller, having a diameter of only 0.36 mm. In order to achieve these small sizes, ultraminiature silicon pressure sensors are required. **Figure 38** shows a number of pressure sensor dies manufactured by Silex Microsystems (Järfälla, Sweden). Each sensor is only 0.16 mm × 0.1 mm × 1.3 mm.

The silicon sensors on these acute catheters are coated with a polymer such as silicone rubber in order to protect the die from the effects of the blood as well as to insulate the electrical connection of the die. If the sensors are intended to be inserted into the body for years, however, a more robust approach is required. ISSYS (Ypsilanti, MI, USA) manufactures silicon sensors for chronic implantation using the dissolved wafer process (Gianchandani and Najafi 1992). In the dissolved wafer process, both a silicon wafer and

Figure 38 Ultraminiature (0.16 × 0.1 × 1.3 mm) silicon pressure sensor die manufactured by Silex Microsystems.

a glass or Pyrex wafer are processed simultaneously. In the process, a thin heavily boron (p^{++})-doped silicon layer forms one side of a capacitive pressure sensor and a metal pad on the glass forms the other side of the capacitive pressure sensor. Bonding of the silicon to the glass also forms a hermetically sealed pressure reference for the sensor. The p^{++} layer is far less affected by the corrosive nature of blood and, therefore, provides a reliable chronically implantable structure.

Mesotec has designed and built a fully integrated pressure/IC for the monitoring of glaucoma (Stangel *et al.* 2001). A photograph of the chip is shown in **Figure 39**. It contains a surface-micromachined pressure sensor, digital and analog circuitry, a circuit to harvest power from the RF, and communication circuitry. The chip is approximately 2.6 mm × 2.6 mm and is connected to an RF antenna that is incorporated into an artificial lens.

Figure 40 is a photograph of a chronically implanted pressure sensor manufactured by Remon Medical (Caesarea, Israel). The unique aspect of this design is that the power is delivered and the data are transmitted using ultrasound. The ultrasound signals from an external activator cause the acoustic transducer to flex, generating electrical energy that is stored in the capacitor. This stored energy is sufficient to activate the sensor for approximately 10 s, during which time it transmits the pressure values that are measured by the silicon pressure sensor.

Today, silicon accelerometers are designed into a number of implantable products. Because of the need

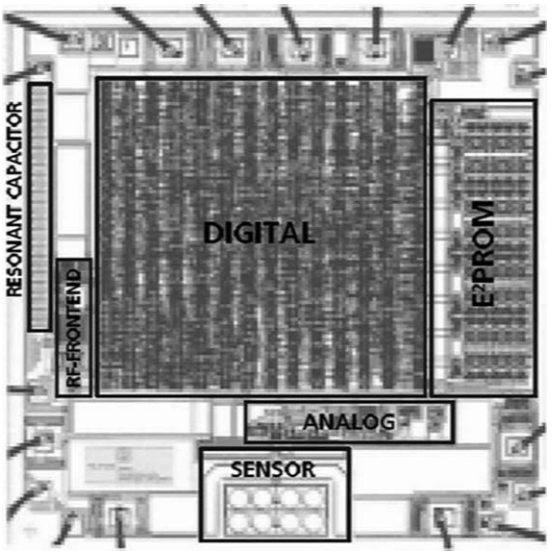

Figure 39 Integrated pressure sensor and IC from Mesotec for intraocular applications.

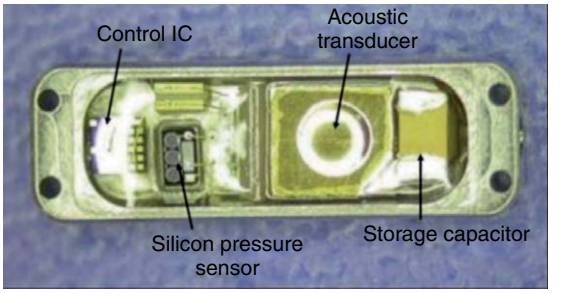

Figure 40 Photograph of the internal components of the initial design of an ultrasound-based chronically implanted pressure sensor. (Courtesy: Remon Medical.)

for extremely low power requirements for the sensor, the accelerometers are usually capacitive devices. **Figure 41** shows a diagram of the symmetric accelerometer structure from VTI Technologies.

This accelerometer is made by bonding three separate silicon wafers together to form a triple stack. The accelerometer has the advantage of being very rugged and immune to temperature effects. Other silicon accelerometers such as comb structures and three-axes accelerometers will be incorporated into products to lower the cost and increase the functionality.

The opticath catheter from Hospira (Lake Forest, IL, USA) is a device used in acute critical care to measure the oxygen saturation of venous blood. The system uses three wavelengths of light transmitted down an optical fiber into the blood to calculate oxygen saturation as well as hematocrit based on the reflection of the three lights.

Sensors for Medicine and Science Inc. (Germantown, MD, USA) is designing and testing an implantable sensor that relies on fluorescence to measure glucose concentration under the skin. A

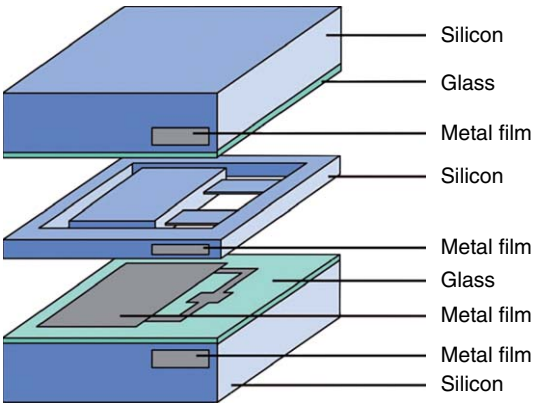

Figure 41 Drawing of the capacitive triple-stack silicon accelerometer from VTI Technologies.

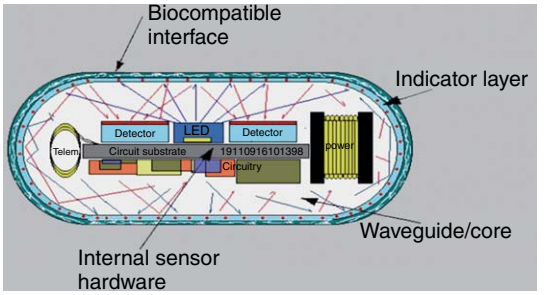

Figure 42 Diagram of a fluorescence-based implantable glucose sensor capsule. (Courtesy: Sensors for Medicine and Science.)

diagram of the sensor is shown in **Figure 42**. The sensor capsule contains an LED to excite the fluorophore in the indicator layer, optical detectors to measure fluorescence for both the signal and reference channels, and a circuitry to drive and control the optoelectronic components. The implanted capsule also has a circuitry to harvest energy from an external inductive power source.

3.14.2.2 Novel Electrode Technologies for Medical Applications

3.14.2.2.1 Introduction

A large portion of clinical applications of medical microsystem technologies deals with electrical stimulation and/or sensing. Section 3.14.1 mentions examples of IPGs such as cardiac pacemakers, cochlear stimulators, neurological stimulators for spinal and deep brain, sacral nerve stimulation, and gastric stimulation, and there are options to expand this into other clinical areas (Schneider and Stieglitz 2004).

Generally speaking, an electrical stimulus is generated in an IPG and electrically conducted to an electrode positioned at the optimum therapy delivery site. Although most of the electrodes currently appearing in medical products are made using conventional fabrication technology, numerous examples of microfabricated electrodes are currently being investigated for clinical applications. Microelectrodes offer the advantage of exact electrode positions, small size, multiple electrodes, and active circuitry (Kewley *et al.* 1997). Microsystems offer possibility for a higher degree of miniaturization and increased numbers of electrodes (Stieglitz 2002). This can lead to concepts featuring adaptable therapy and easy implant procedures (Receveur et al. 2005). We therefore feel that it is good to devote a part of this chapter to this subject.

This section has an emphasis on the technological aspects of microelectrodes. It can be seen as a cross-analysis of the information provided in the previous sections per clinical application area. The various electrodes are ordered in terms of shape, intelligence, materials, and biostability. At the end the information is summarized.

3.14.2.2.2 Electrode shapes, manufacturing process, and intelligence

We distinguish 1D electrodes, 2D electrodes, 3D electrodes, Smart Electrodes, and electrodes for external medical use. By 1D electrodes we mean that the general organization of electrodes is along a line, the shape of the electrode itself does not have to be 1D. One group describes 1D microelectrode arrays that are entirely flexible, made using a boron/EDP approach. It is 40 mm long and 4 μm thick (Bell *et al.* 1997).

2D electrodes are flat electrodes arranged in a 2D way. There are examples of planar fabrication processes that raise the electrodes somewhat in 3D or 2.5D. Electrodes of various materials can be made using photolithographic fabrication processes on a variety of substrates, such as the ones used for stimulation of the retina (Chow *et al.* 2002, Grumet *et al.* 2000, Hammerle *et al.* 2002, Weiland *et al.* 2002, Zrenner *et al.* 1997) and for brain research (Gosselin *et al.* 2004). The 2D arrays of electrodes with micrometer dimensions are also made using wires (Smit *et al.* 1999).

There are various ways reported to make 3D type of electrodes using microfabrication technologies. By making a 3D shape, there might be a gain in electrode surface area compared with 2D (Sachs *et al.* 2005). Generally speaking, 3D microelectrodes are being used to penetrate something. There are many examples of 3D microelectrodes (Birch 2004, Griss and Stemme 2003, Griss *et al.* 2001, Roxhed *et al.* 2005a, b, Schmidt *et al.* 1996, Thiebaud *et al.* 1997) and in the following only a couple of them are highlighted. One group uses probes that are entirely realized in a silicon technology and incorporates 10 recording sites each, with contact areas ranging from 100 to 2500 μm^2, spaced at 100 μm intervals. The probe substrate structure is obtained from a thinned silicon wafer by the application of a two-electrode electrochemical etch stop in potassium hydroxide (KOH) and a subsequent reactive ion etch (RIE) of silicon in sulfur hexafluoride (SF_6). (Peeters *et al.* 1991). Another 3D microfabricated structure is etched into a biocompatible polyimide insulation layer. The polymer layer is micropatterned

by electron beam lithography and etched in an oxygen plasma (Bauerdick *et al.* 2003, Sachs *et al.* 2005). A third group uses a combination of silicon and polymer material to achieve the desired properties. A 5–10-μm-thick silicon backbone layer is attached to the tip of the electrode to enhance the structural stiffness. This stiff segment is then followed by a 1-mm flexible segment without a silicon backbone layer. The fabricated implants have three shanks with five recording sites (20 μm × 20 μm) and two via holes (40 μm × 40 μm) to promote tissue attachment on each shank (Lee *et al.* 2004). Still another group uses a combination of dry and wet etching to form probes with 16 electrodes on each tip. Phase one: thin-film deposition to form the electrodes, bondpads, and insulation. Phase two: etches to define probe shape. Phase three: removes masking layers and package (Kewley *et al.* 1997). The following process yields probes of 1 mm long. A monolithic piece of silicon (6–20 ohm cm^{-1}) is micromachined and acid-etched to form the basic substrate of the electrode array – 100 needles of length 1 mm, each separated by a glass dielectric barrier and arranged in a 10 × 10 configuration with an interelectrode spacing of 400 μm. The silicon needles have electrodes on the first 50–100 μm of each tip. The unmetallized silicon electrode shafts and the substrate are insulated with a 2–3-μm layer of polyimide (Nordhausen *et al.* 1993, Rousche and Normann 1999). As a final example, we mention a 3D multielectrode array that is basically created using a sawing procedure. In 1″ (111) silicon wafers, approximately 4 mm thick, 600-μm-deep grooves are sawn, at distances of 120 μm apart. The walls of the silicon that result from this procedure are shortened in such a way that walls with three different heights result: 600, 400, and 200 μm. Perpendicular to the first sawing direction, new grooves of 600 μm depth are sawn, resulting in rows of silicon needles, with differing heights. The needles in a row have equal heights. The needles are 120 μm apart, and have a size of approximately 55 μm × 55 μm. They get their final size and shape from an RIE process, using an SF_6/O_2 plasma. A flip chip technique to connect the brush to (de)multiplexing circuitry, in which current sources and buffer amplifiers are also integrated, is being studied (Rutten *et al.* 1995).

Others assemble active 3D arrays out of 2D arrays of microfabricated electrodes. Gold beams on the probes are orthogonally bonded to pads on the platform using ultrasound. Active 3D probe arrays containing on-chip CMOS signal processing circuitry have also been made (Bai Qing *et al.* 2000). These arrays can be made in different sizes using programmable platform-based fused interconnects (Gingerich *et al.* 2001)

Microsystem technology provides options to add functionality directly on the electrodes. An 18 polar hybrid cuff electrode with miniaturized multiplexer reduces the number of cables to 4 by integrating this intelligence (Rodriguez *et al.* 2000, Stieglitz 2001). Another example is the actor component of a retina implant stimulator, which is a flexible active silicon multielectrode used for electrostimulation of the retinal ganglion cells (Schwarz *et al.* 2000) or electrodes integrated with CMOS circuits created using a dissolved wafer process (Najafi *et al.* 1985).

In most cases microelectrodes are also being used for external medical applications for biomedical research, not directly for diagnosis or therapy. Some examples are the use of neuronal networks on multielectrode arrays as biosensors (Gross *et al.* 1995); neurons coupled to transistors (Fromherz and Stett 1995, Fromherz *et al.* 1991); electrical or chemical neurotransducers (Bartic *et al.* 2003); 2D array of gold pads on CMOS for *in vitro* cell measurements (Berdondini *et al.* 2004); electrodes on polyimide to measure high density surface EMG (Lapatki *et al.* 2003) and hybrid biosensors: micromachined electrode arrays with living cells above then used for sensors (Kovacs 1998).

3.14.2.2.3 Electrode materials, performance, and biostability

Materials used for electrodes include platinum (Griss *et al.* 2001, Schneider and Stieglitz 2004), platinum black (Rizzo *et al.* 2003), iridium (Kewley *et al.* 1997; Najafi *et al.* 1985, Schneider and Stieglitz 2004), iridium oxide (Rizzo *et al.* 2003), gold (Chow *et al.* 2002, Najafi *et al.* 1985, Rutten *et al.* 1995), nickel chromium (Smit *et al.* 1999), TiW/Au (Peeters *et al.* 1991), copper, silver-coated, roughened, and chlorized (Lapatki *et al.* 2003), nanoporous titanium nitride (Bauerdick *et al.* 2003, Sachs *et al.* 2005), and four-part multilayer of Pt, Ti, W, and Pt (Rousche and Normann 1999). Gold, platinum, and silver are used for recording, and they can be chlorodized at the surface (Prohaska *et al.* 1986).

Important properties of microelectrodes are of course the electrical properties such as impedance, charge transfer capability, and stimulus thresholds. Threshold currents for phosphene generation in the cat's visual cortex with trains of biphasic pulses can be as low as 1.9 μA (Schmidt *et al.* 1996). Required electrode areas range from 1 μm^2 to normal of

$100\,\mu m^2$ to up to $5000\,\mu m^2$ (Peeters *et al.* 1991, Prohaska *et al.* 1986). Electrode–electrolyte impedance depends on the charge transfer processes at the interface (Prohaska *et al.* 1986). Researchers are investigating the use of microfabrication technologies to improve these properties. Examples are electrodes treated to lower the stimulation threshold. Sputtered iridium oxide films yielded the best performance, with a big influence of the oxygen concentration during sputtering (Mokwa 2004).

Arrays of microelectrodes with improved charge transfer capacity are realized by using a 3D micropattern. This yields a surface gain compared to non-3D electrodes resulting in a significant reduction of impedance by a factor of 0.3–0.2 (Bauerdick *et al.* 2003, Sachs *et al.* 2005). The structures in photoresist, pyrolize, become carbon structures mimicking fractals for application as electrode materials (Madou 2005).

The body presents one of the harshest environments since the immune system actively tries to deal with foreign materials. Biostability is therefore difficult to achieve, especially over longer periods of time. The literature contains numerous examples of issues with implantable microelectrodes. Gold is reported to dissolve after subretinal implantation (Chow *et al.* 2002). Photodiode arrays that were implanted for 18 months in the subretina of the rat showed pit corrosion in silicon and silicon dioxide. Titanium nitride is stable (Hammerle *et al.* 2002, Zrenner *et al.* 1997). Silicon dioxide can be used as an insulating layer. It has good adherence to conducting layers and no pinholes but Na^+ and K^+ diffuse through it, creating impurity conduction bands and lowering the insulating properties. Silicon nitride layer can be added to block ion diffusion (Prohaska *et al.* 1986). The other side of biostability is biocompatibility, i.e., the implanted material not causing harm to the body. Extensive work is being performed but is not reviewed here.

3.14.2.2.4 Summary

Electrodes are made on a flat substrate with thin-film techniques (2D array), plating (electroplating or electroless) creating 2.5D, or with combinations of various processing steps to create poles with the possibility to have multiple electrodes along the length of each pole (3D array). The electrode materials are Pt/Au/Ir/Ir oxide/Ag/TiNi/C. There are several concepts in which the electrodes are made on top of electronic circuitry providing some form of intelligence (multiplexing/current sources). The substrates can be thinned or processed to the extent that they become flexible or can be made of a flexible material from the start. Corrosion of silicon and silicon dioxide after implantation in the retina has been reported.

3.14.2.3 Microelectronics Technologies for Medical Applications

3.14.2.3.1 Introduction

We are all familiar with microelectronics and microsystems. We use products that include them everyday. We have become so accustomed to the functionality they provide that we take for granted their capabilities and the speed with which new products expand these capabilities. In addition, we have all seen many articles that describe various technical and nontechnical aspects of microelectronics. This brief overview of microelectronics for medical applications does not duplicate that wealth of information. Instead we focus on the role of microelectronics in medical equipment, instruments, and implantable medical devices, as well as on the requirements of medical applications. We also briefly discuss some of the key differentiators between microelectronics for consumer and medical applications.

Medical applications require the highest levels of quality and reliability. In addition, minimizing size and power consumption is essential for implantable medical devices. Clearly these are the attributes that we desire in almost all of our electronic products. Advances in reliability, size, and power drain have helped drive widespread acceptance of electronic products. This has been a major factor in the global spread of television, personal computers, cell phones, laptops, and personal music players. The key difference is that, as in all high-reliability applications, requirements for medical applications are more stringent, and much more thoroughly tested, than for many commercial products. Likewise, expectations on the quality, reliability, and performance of medical equipments, instruments, and devices are also much higher than for consumer products.

3.14.2.3.2 Microelectronic components and technologies

One place to begin this overview of medical applications of microelectronics and microsystems is a brief discussion of what is included in the broad term microelectronics. Although we all are aware that microelectronics is a key element in many products we use everyday, it is still a very complex subject

encompassing many disciplines, components, and processes. It may help to set the stage for this overview by listing some basic components and processes used to develop and manufacture microelectronics for medical equipment and devices. Within medical products, ICs include many elementary circuits and functional blocks including the following:

- Digital logic circuits
- Analog circuits
- Memories, including flash memory
- Microprocessors (μP)
- Analog-to-digital converters (ADC)
- DSP
- Digital-to-analog converters (DAC)
- RF circuits

and many other types of circuits. In addition, electronic devices include discrete semiconductor and passive components such as the following:

- Capacitors
- Resistors
- Inductors
- Transformers
- Substrates
- Connectors

and many variations of these components, as well as many other components.

ICs for medical products can be developed in several ways. These include the following:

- Commercial off-the-shelf ICs (COTS)
- Programmable logic arrays (PLA), field programmable logic arrays (FPLA), complex programmable logic devices (CPLD)
- Application-specific off-the-shelf ICs (ASSP)
- Full-custom application-specific ICs (ASIC)

Of these four approaches, COTS are viewed as the lowest risk and the lowest cost approach. Using them is also the quickest way to develop electronics for a product. Programmable arrays and logic devices share many of the same characteristics, but can be modified electrically if the original programming of the logic array needs to be updated. They can also be modified at the end of the production line if required to support changes in the product mix. Application-specific standard products are intended to provide some of the optimization of full-custom ICs and some of the advantages of off-the-shelf products. These ICs may also include some sections that are electrically alterable to incorporate some of the advantages of PLA as well. Development of full-custom ICs is the most expensive, involves highest risk, and often takes the longest to achieve the required functionality. But they have the advantage of enabling the most optimized design. For a given level of complexity this minimizes the size of the IC and its power drain. It also enables the development of custom circuits to improve the performance and the reliability of the final product. Clearly all of these approaches offer specific advantages and many medical products incorporate a mix of them, although full-custom ICs are more likely to be used in implantable medical devices than in other medical products.

Development and manufacture of integrated and discrete components require a large number of more fundamental technologies. Examples of these fundamental technologies include the following:

- Semiconductor and wafer fabrication technologies, technologies for packaging silicon die such as die bonding, wire bonding, chip-and-wire, flip-chip, ball grid array (BGA) and micro ball grid array, chip scale packaging (CSP), stacked die packaging, and system-in-package (SIP) packaging
- Printed wiring board (PWB), flex tape, and hybrid technologies
- Electronic materials

This is only a sample of some fundamental circuit blocks, components, and technologies required to develop and manufacture electronic products. But it does suggest the breadth of disciplines, components, and processes required.

3.14.2.3.3 Microelectronics in medical applications

Given the complexity of microelectronic circuits, components, and technologies, a high-level overview of the requirements of medical applications might be in order. Medical instruments and devices must achieve several things. First and foremost, they must be safe and reliable. They must also benefit patients either by providing valuable diagnostic and monitoring data or by delivering effective therapies. Also, in the case of implantable medical devices, they must be small and safe to implant. Clearly they must be useable by physicians, healthcare workers, and caregivers. User interfaces must be adequate to assure that medical instruments and devices are controllable enough to consistently perform the required functions. Requirements like these help to define criteria that drive the selection of microelectronic designs, components, technologies, and test methods.

3.14.2.3.3.(i) Complexity and quality Advances in the capability and sophistication of new medical products can drive the increases in the complexity of the microelectronics. In terms of medical applications, advances in product capabilities include the following:

- Collecting more data
- Analyzing it more accurately
- Responding to it more rapidly
- Performing more sophisticated actions
- Accomplishing all this while being easier to use

In addition to collecting data and responding appropriately, medical devices must process, store, and communicate the data to physicians. This can provide useful information as they perform their analyses of patients' conditions and medical needs. As worldwide information infrastructures have continued to become more tightly interconnected, communicating this information may also include interfacing with computers and other equipments, as well as connecting to physicians and healthcare workers through public communication infrastructures such as telephone systems, cell phones, and the Internet.

3.14.2.3.3.(ii) Patient safety Although no product will gain long-term acceptance unless it is of value to users, without question the first priority for any medical product is patients' safety. It is absolutely imperative that medical products must safely deliver the highest quality performance, and do so reliably. Microelectronics has proven, throughout many decades, that with proper design and thorough testing, very high levels of quality can be achieved. Second, medical products must continue to function correctly throughout the entire life of the product. Thus the reliability of medical products is as important as quality.

3.14.2.3.3.(iii) Cost vs. quality In some technologies, there may appear to be trade-offs between cost and quality. Microelectronics is one area where this is definitely not true. Increasing the level of integration within microelectronic circuitry reduces the number of individual components as well as the number of interconnections required to connect these circuits to inputs and outputs of the finished product. This decreases the number of potential points of failure and increases the intrinsic level of reliability the product is capable of achieving. Therefore, higher levels of integration tend to produce correspondingly higher levels of reliability for a given technology. We are all familiar with the growth in the complexity of electronic products. One example of this is the growth in the complexity levels of leading-edge ICs over the past 40 years. If we take the number of transistors on a silicon die as an indicator of complexity, the complexity level of leading-edge ICs has grown by a factor of approximately 100 million over that time. Also, over these four decades, the cost per transistor has dropped to approximately a ten-millionth of its initial cost. This has been achieved while continuously improving quality and reliability levels attainable with microelectronic circuits.

Since the early 1990s the picture has become a bit more complicated. Some data suggest that failure-in-time (FIT) rates and the rate of failures in the first couple of years have increased for individual chips. In the worst case, they may have increased at approximately the same rate as the growth in the complexity of the die. The usual recommendation for counteracting this trend is to derate operating voltages and temperature. This, and the fact that higher levels of integration will reduce the number of separate components, can improve the attainable level of quality and reliability to historical levels, or better, on a function-by-function basis. Other measures that can augment these efforts to assure the highest levels of quality and reliability are mentioned in some of the following paragraphs.

3.14.2.3.3.(iv) Complexity vs. quality To successfully increase the level of complexity of ICs by 100 000 000 times, the levels of predictability and consistency of wafer fabrication and microelectronics design, processing, and testing have to be raised to extremely high levels. This requires correspondingly high levels of process control throughout these operations. This progress would not have been possible without major advances in process control technologies and methodologies. This includes advances in quality metrics and methodologies, such as six sigma. It also includes advances in hardware and software design tools, as well as in wafer processing, manufacturing, and test equipments. Obviously, much of the progress in computers used for circuit design and in equipments used for processing, manufacturing, and testing electronic products was possible only because of advances in microelectronics. This combination of advances in microelectronic technologies, computers, and equipments has continued to raise the predictability and consistency of processes and technologies used to develop, fabricate, and test microelectronics. This in turn has raised the quality level of microelectronics while reducing both the size and the cost of electronic

products on a function-by-function basis. These advances are part of the mainstream of wafer fabrication processing, microelectronic manufacturing, and state-of-the-art testing. Developers and manufacturers of medical products take full advantage of these advances in quality and reliability, but in themselves they may not be enough. In the next few paragraphs we deal with additional requirements to assure the highest quality and reliability in medical applications.

In some cases, advances in microelectronic technologies have been used to grow the complexity of products as rapidly as possible. Electronic games and Flash memories are examples of how quickly microelectronics can enable the expansion of the complexity and the capability of electronic products. In other cases, advances in microelectronic technologies and processes have not been pushed to the complexity limit, but rather have been used to produce products that are simultaneously both more reliable and more sophisticated. Implantable medical device is an example of this type of product evolution.

Products that become more reliable as their complexity grows may seem inconsistent with some personal experiences with computers and cell phones. This highlights a key difference between consumer electronics and microelectronics for medical applications. As in high-reliability products, medical applications require far more stringent quality, reliability criteria, and testing.

3.14.2.3.3.(v) Design for quality Quality must be designed-in. Good designs can be compromised by inadequate manufacturing and test processes, but these processes cannot increase the levels of quality and reliability above the constraints imposed by the design of a product. This includes design of both the circuits themselves and processes used for fabrication and testing.

3.14.2.3.3.(vi) Wafer yields and quality Design and integration of wafer fabrication processes is extremely important to wafer fab management teams. The financial consequences of poor yields are very real and visible. Whenever wafer fabs run at full capacity, higher yields translate into shipping more wafers. Whenever wafer fabs run at less than full capacity, higher yields reduce the cost of operations and work in process. This may help to reduce adverse impacts of the idle capacity. Yields have significant financial impact on both of these situations. This is especially critical as the cost of constructing wafer fabs is now in the multi-billion-dollar range. Therefore wafer fab management teams focus on achieving the best wafer yields possible.

One consequence of higher wafer yields is that quality and reliability tend to be directly proportional to yield. Therefore medical product manufacturers, even when they rely on full-custom ICs, leverage higher-yielding processes for their products. They match their designs to available wafer fabrication processes that are proven to yield the highest-quality and -reliability ICs. For implantable medical devices, they may also use design methodologies optimized for high reliability as well as for extremely low power drain. Proprietary circuitry may also be added to assure reliable long-term performance of microelectronic circuits. In this way, complex and sophisticated functions are incorporated into medical products without compromising quality or reliability.

3.14.2.3.3.(vii) Design and test for reliability There are also well-established methods for identifying potential reliability and performance factors. These can be analyzed and effective countermeasures are designed into the electronics and manufacturing processes before a product is released to production. Adding additional functionality to assure reliable performance of the end product also increases its complexity. These increases in complexity are almost always transparent to users of high-reliability products. Although invisible, this one-way growth in product complexity can be used to simultaneously increase the functionality of a product and its reliability. This is one more aspect of microelectronics that contributes to making reliable, high-quality medical products available to physicians and patients.

3.14.2.3.3.(viii) Reliability In addition to high-quality components, processes, and fundamental technologies, there are many other factors that must be considered to assure the highest levels of quality and reliability in medical instruments and devices. It is essential that new technologies not only produce products of highest quality, but also wearing out, and other failure mechanisms must be analyzed in depth. This is not trivial. Semiconductor technology has reached the level of extreme miniaturization where critical layers on a die can be less than 10 molecules thick. Analysis of wear-out and other failure mechanisms at these dimensions requires extensive knowledge of metrology and advanced laboratory instruments and skills. At these dimensions even defects that are much smaller than the wavelength of light can be catastrophic.

3.14.2.3.3.(ix) Environmental factors and reliability Besides physical defects within microelectronic circuits, many external factors can also affect the performance and reliability of advanced products. These external factors include robustness to:

- Electrical charge and interference
- Magnetic and electromagnetic fields
- Other sources of radiation
- Subatomic particles
- Temperature extremes
- Mechanical shock

All of these must be analyzed and appropriate steps must be taken to assure the quality and reliability of products. These measures may include redundancy and other electrical and mechanical design approaches. Also, they may include the addition of various forms of stress testing as well as self-test capabilities built into the product itself during manufacturing process. All of these measures are well known within the disciplines that create microelectronic circuits, processes, and testing. While well understood by experienced design, manufacturing, test, quality, and reliability engineers, these measures are applied extensively and meticulously in the development and production of implantable medical devices. In some cases they may add to manufacturing cost and cycle time. But this may be offset, on a total life cycle cost basis, by improvement in the performance and longer lifetimes of medical products.

3.14.2.3.3.(x) Technologies vs. quality In addition to assessing the performance of new technologies against all the factors described in the preceding paragraphs, microelectronic technologies for medical applications must be thoroughly proven with millions of hours of product experience in other applications. Therefore medical products are seldom based on technologies just at the beginning of their use in commercial products. But this does not mean that technology in medical applications lags behind the state of the art. As the global electronics industry approaches the two-trillion-dollar level, it routinely drives very rapid learning curves for new technologies. By intelligently monitoring the learning curves of these technologies, developers of medical equipment and devices can determine which technologies have proven their quality and reliability enough to be incorporated into applications that require the highest levels of quality and reliability.

3.14.2.3.3.(xi) Size Size is also an important consideration in implantable medical devices. In these applications, smaller devices tend to be associated with greater patient safety and comfort. Microelectronics is essential for miniaturizing implantable medical devices. Ongoing advances in microelectronic components, processes, and technologies enable development of sophisticated products that perform many complicated functions in small devices without compromising quality or reliability.

Another key factor in the size of implantable medical devices is power consumption. Clearly this is closely related to advances in the energy density of power sources. Even with the most advanced power sources, it is still important to use power as efficiently as possible. Although some implantable devices can be recharged, most depend on a single primary battery for power. Therefore lifetimes of implanted devices are heavily dependent on the power drain of microelectronic circuits. Many design and processing techniques have been developed to maximize the power efficiency of microelectronics in these devices. These power management techniques, while well understood by experienced circuit designers, are applied extensively and meticulously in the development of implantable medical devices – so much so that even though power management is an increasingly important consideration in consumer electronics, the power drain of many medical devices is still a small fraction of the power drain of typical cell phones and other handheld devices.

3.14.2.3.4 Future

There is little reason to conclude that the progress of microelectronic technologies will end any time soon. In fact, it appears that progress may well continue at roughly the same rate as it has for decades. There are major challenges ahead in some fundamental technologies, but this more likely indicates that the form of some future progress may be different, not that the pace of progress will slow. At the same time, with the present interest in nanotechnology, and other alternatives to silicon-based technologies, there are many interesting potential substitutes, or extensions, of present microelectronic technologies. Ongoing advances in MEMS and MEMS packaging may also enable additional functionality for microelectronic circuits, especially in the areas of sensors and communications. This could reduce the size of future products while enabling them to be more connected with their environment as well as other electronic devices in their vicinity.

3.14.2.3.4.(i) Disruptive breakthroughs vs. rapid evolution It is important to remember that disruptive breakthroughs have been few and far between in IC technology. One of the reasons is that the rate of evolutionary change in silicon-based technologies has been so fast that it often progresses at a faster rate than do new technologies. Furthermore, this rate is likely to continue for the foreseeable future. This is unlike examples of new technologies that are inferior to established technologies when they are first implemented, but improve faster than mature technologies. In those cases, there are many examples of new technologies overtaking and ultimately displacing older, more established technologies. Unlike this scenario, whenever a new technology is both inferior to a mature technology and improving at the same rate or slower, the existing technology is unlikely to be displaced.

The historical rate of progress in silicon-based microelectronic circuits is likely to continue for at least another decade. Therefore, it is likely that the next 10 years will be dominated by a continuation of rapid evolutionary advances, not disruptive breakthroughs by totally new technologies or circuit architectures. Evolutionary advances are likely to occur in many areas of microelectronics, including component sizes and integration, die and circuit packaging, wafer processing and photolithography, semiconductor device design, and power management. The combination of these advances will continue the historical rate of progress in microelectronics, or may even accelerate it (Tummala 2006).

Even if the likelihood of disruptive breakthroughs in fundamental microelectronic technologies is low, this is not an indication that the rate of advances in medical applications will slow. Quite the opposite, the rate of progression may even accelerate in the future. Many factors may indicate that the next few decades will be more exciting than ever. Safety, quality, reliability, and sophistication of medical instruments and devices will continue to advance. At the same time, medical devices will continue to incorporate more functions within the devices of same size, or smaller, as energy sources advance and circuits become both more complex and more efficient. These medical products will communicate with each other, as well as with physicians and caregivers to help them improve effectiveness of diagnoses and treatment.

Can this truly be achieved without disruptive breakthroughs in technology? Yes, continuation of trends currently dominating advances in electronic products is fully capable of achieving progress in medical applications just as in many other products. Two fundamental trends will continue to drive these advances: convergence and the rapid evolution of fundamental technologies. These trends are powerful drivers of progress in both consumer and high-reliability applications, including medical applications. With expanding research and support of developments in biotechnology, nanotechnology, bioinformatics, and the convergence of these technologies, many new and exciting opportunities for advances in medical diagnostics, prevention, and therapies are already emerging. The continued evolution of microelectronics will provide a platform to integrate these and enable reduction to practice of great numbers of opportunities that will benefit patients and their families. Advances in global communication and computing infrastructures, as well as continuing advances in the complexity, quality, and reliability of medical products, may enable systems and capabilities that have the promise of providing patients with access to these benefits anywhere, anytime.

3.14.2.3.4.(ii) Convergence The size of many products will continue to shrink as well. This combination of networked medical applications, integrated with expanding applications of biotechnology and nanotechnology, will make possible creation of medical equipment, instruments, and devices that bring new and more sophisticated diagnostic and therapeutic capabilities to physicians and healthcare workers. These advances, coupled with advances in the informatics capabilities of networked systems that integrate personal health, history, and environmental data, will provide physicians and caregivers with access to information and resources they have never had before. This can enable simultaneous advances in both personal medicine and global health. Clearly, we stand at the threshold of many life-changing advances in healthcare.

3.14.2.4 Communication Technologies for Medical Applications

Wireless biomedical telemetry is used in hospitals, clinics, homes, ambulances, and other healthcare institutions. This telemetry is typically part of an external biomedical monitoring and diagnostic system, a body-worn device, or an implantable medical device designed to gather data, administer therapy,

and possibly provide therapy adjustment for the patient. These devices exchange data with a system designed for medical professional use, or with the patient. Typically, biomedical telemetry is administered, or prescribed for use by a healthcare professional.

Originally the term wireless telemetry was defined as the transmission and measurement of data from remote sources by radio. This definition has expanded to include telecommand that involves the control/reprogramming of devices, and additionally, has expanded beyond radio to include infrared and ultrasonic communications.

Current wireless biomedical telemetry systems can be very sophisticated, are primarily radio-based, and can be divided into the following three general classes of devices:

- Healthcare facility-based wireless (i.e., EKG and pulse oximetry transmitters that allow a patient's mobility about most of one hospital floor while being continuously monitored).
- Implanted and body-worn telemetry systems that are part of portable therapeutic and monitoring systems can be controlled and read by both healthcare professionals with physician-programming devices and by patients with handheld devices. These can be used both in health care facilities and in home use environments.
- Personal health assistant devices. These can be blood glucose monitors, pulse rate, blood pressure monitors, or weight scales. These can be nonprescribed consumer electronics. Use of these types of devices in healthcare management systems is becoming more prevalent.

Wired biomedical telemetry systems, typically hospital-based and connected to the hospital computer network, are quite common. While not covered here, it is worth noting that these systems can automatically measure blood pressure, heart rate, arterial oxygen saturation levels, respiration rate, and allow manual data input for managing hospitalized patients. Wireless systems allow patient mobility to the bathroom, exercise, and allow for general patient case of mobility and comfort. They can also provide increased patient safety due to the continuous monitoring aspect of wireless telemetry.

Wireless biomedical telemetry systems are regulated by both the United States of America Federal Communications Commission (FCC) and the FDA. The FCC defines the RFs allowed for use in transmitting biomedical data, and the power levels allowed. The FDA defines electromagnetic interference (EMI) immunity and safety requirements of therapeutic devices and the associated telemetry interaction at the system level. The frequencies and power levels are important parameters when designing a biomedical telemetry system. The number of users and their power levels, along with man-made noise, can cause significant interference to certain frequency bands. This is one reason why the FCC has created protected frequency bands specifically for biomedical telemetry. These include the wireless medical telemetry system (WMTS) for in-hospital use and the medical implant communications service (MICS) for implantable use. Nonlife critical telemetry often uses the nonprotected industrial, scientific and medical (ISM) bands. The medical portion of the ISM band is related to radio diathermy and other noncommunications use of RF. There are many industrial, commercial, scientific, and home uses of the ISM band, which can lead to significant noise and interference levels on the bands (i.e., cordless phones, WiFi, Bluetooth).

Hospital-based wireless EKG telemetry systems are ubiquitous. Currently manufactured systems utilize the WMTS frequency band. The following paragraph is an excerpt from the FCC WMTS website that describes the creation of this frequency band quite well:

> Prior to the establishment of the WMTS, medical telemetry devices generally could be operated on an unlicensed basis on vacant television channels 7–13 (174–216 MHz) and 14–46 (470–668 MHz) or on a licensed but secondary basis to private land mobile radio operations in the 450- to 470-MHz frequency band. This meant that wireless medical telemetry operations had to accept interference from the primary users of these frequency bands, i.e., the television broadcasters and private land mobile radio licensees. Further, if a wireless medical telemetry operation caused interference to television or private land mobile radio transmissions, the user of the wireless medical telemetry equipment would be responsible for rectifying the problem, even if that meant shutting down the medical telemetry operation.

The FCC was concerned that certain regulatory developments, including the advent of digital television (DTV) service, would result in more intensive use of these frequencies by the primary services, subjecting wireless medical telemetry operations to greater interference than before and perhaps precluding such operations entirely in many instances. To ensure that wireless medical telemetry devices can operate free of harmful interference, the FCC

decided to establish the WMTS, in a Report and Order released on June 12, 2000 (FCC 2006).

The impetus for change occurred in mid-2000, following an incident at Baylor University Medical Center where a HDTV broadcast interrupted medical telemetry in part of the hospital for a short time (Baker 2002). This incident led to WMTS being created by the FCC, and older systems being phased out via attrition. Frequency assignment to channels in the WMTS band are still handled by a frequency coordinator to ensure that multiple uses of the frequency band within the hospital do not interfere with each other.

On the implantable side of wireless biomedical telemetry óne of the earliest uses of implantable telemetry involved the control of the pacing rate of implantable cardiac pacemakers. Originally, the control of the first pacemakers involved piercing the skin of the patient with a custom-sharpened screwdriver to adjust a small potentiometer encased in a waterproof silicone rubber seal. Much to the patients' delight, a simple inductively coupled 160–190-kHz two-way telemetry system replaced the screwdriver and allowed painless adjustment of the pacemaker's pacing rate. This telemetry system, which operates over a short range of just a few inches, was originally used by Medtronic Inc., beginning in the 1960s. Many medical implant manufacturers are still using these short-range inductively coupled systems.

Implantable telemetry systems currently in use today are evolving into longer-range telemetry, which includes the use of the MICS band from 402 to 405 MHz (nearly worldwide allocation), the 902–928-MHz ISM bands in the United States, and the 433 and 868 MHz bands in Europe.

The MICS band is an ultra-low-power band designed to be shared between weather balloons (Meteorological Aids) and medical implantable devices. This band provides licensing by rule, and protection against interference from nonlicensed interferers. The ISM bands allow the use of higher power levels, but must share the use of the frequency bands with other devices operating with much more efficient antennas and much higher power than implanted battery-operated systems. Due to body losses and limited battery power, implanted transmitters are typically the weakest link in the telemetry link and require a quiet, protected frequency band to operate consistently and effectively. The FCC created MICS to provide this.

For external to external and body-worn to external medical telemetry communications that are intended to operate outside healthcare facilities, the options are more limited. Primarily FCC Part 15 and the ISM bands provide the frequency solutions. Using these frequency bands is complicated by the different international radio regulations that have different frequencies and power levels between the United States and Europe. This makes a common worldwide solution very difficult. Different products often need to be designed for different countries.

The future of wireless biomedical telemetry will require systems that operate on common worldwide frequency bands to accommodate travelers. Better use of frequency spectrum and avoidance of interferers will also be necessary as wireless devices proliferate. Clear channel access protocol, and listen-before-talk protocols along with cognitive radio concepts and automatic frequency agility can be utilized to mitigate interference and channel-loading concerns.

3.14.2.5 Enabling Power Technologies for Medical Applications

Medical devices, particularly implanted devices, have highly specialized power source requirements. These include small size, appropriate shape factor, long service life (longevity), and predictable end-of-service characteristics. Small size and shape factor are directly related to the biocompatibility and comfort of the device. A long service life enables reduction of the negative consequences of device replacement, namely the necessity of a surgical procedure, and the associated risk and expense. A predictable end-of-service characteristic allows for some type of warning to be issued by the device (such as by RF telemetry), when the power source is approaching depletion.

Figure 43 shows a comparison of power and current needs for several families of implanted devices. The needs vary by several orders of magnitude, depending on the application.

For any given power drain, the characteristics of high longevity and small size of the power source are directly opposed to each other. This is because both the amount of stored energy of a battery and its rate of release (i.e., power) scale with its size. Therefore, any implanted power source represents a balance between the two. It is always desirable to employ a power source design that maximizes energy density, to help reduce the impact of this compromise.

Until recently, and with a few exceptions, the industry standard power sources for implanted devices over the past three decades have been primary (i.e., single use) batteries using lithium (Li) metal anodes. Different versions of these Li-based cells have been widely

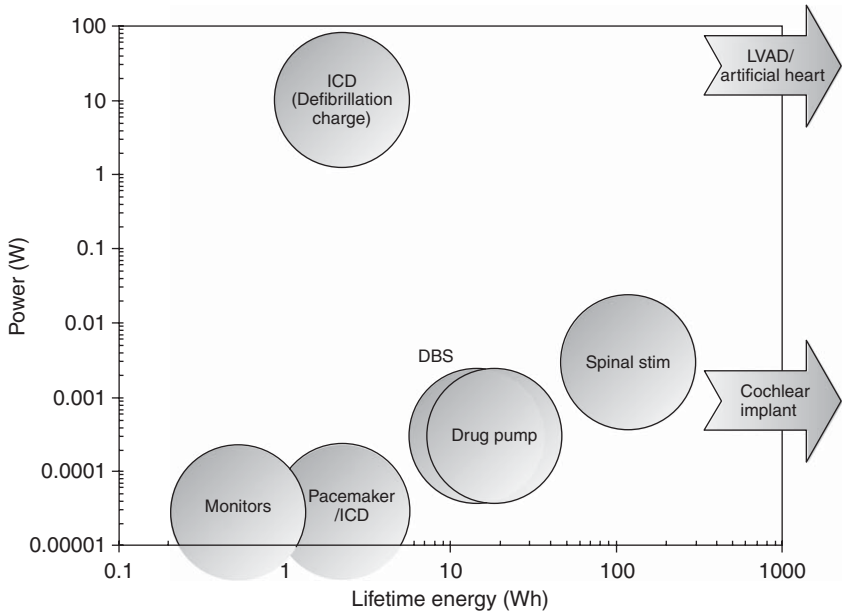

Figure 43 Power and energy map for several implantable device classes: monitors (e.g., heart rate), pacemakers and implantable cardioverter/defibrillators, deep brain stimulators (DBS), drug pumps, spinal stimulators, cochlear implants, left-ventricular-assist devices (LVAD), and artificial hearts. Values are approximate. The artificial heart/LVAD and cochlear implants are shown as arrows to the right, indicating that at present these devices are powered essentially in a continuous fashion by transmitted energy from an external source. (Courtesy: Medtronic.)

deployed (e.g., lithium/iodine, lithium/thionyl chloride, lithium/silver vanadium oxide) (Greatbatch and Holmes 1992, Takeuchi *et al.* 1998). Li is the preferred anode material due to its strong electropositive character (leading to high-voltage cells), high capacity density, and its stability in a variety of electrolyte systems. With a state-of-the-art cathode (a hybrid combination of silver vanadium oxide and carbon monofluoride), and in medium-rate configurations, lithium primary batteries can achieve a packaged energy density of $1\,\mathrm{W\,h\,cm^{-3}}$ (Chen *et al.* 2005), which is as high as any battery currently available.

Since about the year 2000, another type of lithium-based battery, the lithium-ion rechargeable cell, has been used for implanted applications (MacLean *et al.* 1995, Okamoto *et al.* 2002). Initial use was in the field of artificial hearts and LVAD, but more recently an even broader application has emerged in the form of neurostimulators (e.g., the Restore™ device by Medtronic Inc., the Precision™ by Advanced Bionics, and the EON™ by Advanced Neuromodulation Systems). Lithium-ion batteries offer a variety of advantageous characteristics, including high lifetime energy density, relatively high power capability, absence of memory effect, and a low rate of wear-out (also known as capacity fade) (Okamoto *et al.* 2002).

For a detailed description of batteries and general, as well as implanted power sources, along with historical perspective, the reader is referred to Linden and Reddy (2002), Untereker *et al.* (2000), and Scott *et al.* (2004).

The use of microtechnology in battery components includes engineered particulate active materials and conductive additives that range from tens of micrometers to nanometers, as well as microporous polymer separators that permit ion flow while preventing electrical contact between the anode and the cathode.

In terms of high miniaturization at the full battery level, perhaps the broadest use of batteries in very small devices is that of the zinc–air hearing batteries, which are button cells in the size range of a few millimeters in diameter and thickness (e.g., Rayovac size LZ10A). Recent rechargeable batteries that have potential applications in small medical devices include the pin-type BION battery from Quallion (Sylmar, CA, USA) and thin-film-type lithium-based batteries being pursued by a number of start-up companies (Bates *et al.* 2000, Schmidt 2001).

Power sources other than electrochemical batteries have also been considered, but not commercialized. These include thermoelectric generators (MacDonald 2002, Mano *et al.* 2002), β-electric generators, and

biofuel cells. If successful, all are likely to use some aspects of microtechnology in their design. However, at this point it is too early to speculate on the likelihood of commercial adaptation of these technologies.

3.14.2.6 Biocompatible Packaging Technologies for Medical Applications

The electrical systems of implantable devices are not generally biostable or biocompatible. To protect both patient and device, coatings or hermetic packaging are employed. The most common case material for hermetically sealed devices such as pacemakers and implantable defibrillators is titanium. It is biocompatible, formable, weldable, and has a good strength-to-weight ratio. These titanium cases are typically designed with feedthroughs for transmission of electrical signals for sensing and therapy delivery. These feedthroughs are similar to commercial versions except that the materials are selected specifically for biocompatibility. The ferrules are usually titanium or a titanium alloy. The feedthrough wires may be niobium or other suitable material and the insulator is typically glass ceramic or sapphire (**Figure 44**).

Implantable devices may also use glass to provide hermetic protection and allow easy RF communication or power transfer. Glass packages could use wafer bonding techniques from the semiconductor or MEMS industries to form a cover to a package base and enclose the electronics. Other embodiments include glass tubes with sealed ends. Laser joining

Figure 45 Trovan ID100A human implantable transponders. (Courtesy: Trovan®)

and other methods have been developed to allow glass–glass and glass–silicon sealing with minimal heating of nearby sensitive components. If electrical connections need to be made through the glass package, standard MEMS techniques can be used to create metal contacts through vias (**Figure 45**).

Acute sensors or therapy devices may not require complete hermeticity. Polymers such as liquid crystal polymer (LCP) with very low gas and water permeability are employed in near-hermetic packages in commercial products and could provide short- to medium-term protection for medical devices (SBIR 2006). This could allow greater shape flexibility including unique features for securing the devices in the body. Research is continuing on methods to improve the performance of polymers in the body by surface modification and coatings (**Figure 46**).

Future developments in materials and biosciences are likely to advance the function of medical device packages from being simply biotolerable to

Figure 46 Bravo™ pH monitoring system. (Courtesy: Medtronic.)

bioneutral – where the device is practically invisible to the body, and eventually make the packages biofunctional with the ability to respond to changes in chemistry, mechanical loading, and other stimuli.

Biographies

Sarah Audet received her Bachelor of Science degree from the State University of New York at Upstate Medical Center in the field of Medical Technology, her Master's of Science Degree in Electrical Engineering from Boston University, and her Ph.D. in Electrical Engineering from the Technical University of Delft, The Netherlands. Sarah has worked in the field of sensor design, development, and manufacture since 1990 at several companies including AT&T, Princeton Gamma-Tech, Motorola, and Medtronic. Sarah is currently the Director of Technology Planning at Medtronic.

In addition to her direct responsibilities, Sarah is involved with mentoring local high school students, mentoring women in science fields, and volunteering to assist with external programs to educate students in the field of science.

James Carney is a Medtronic Technical Fellow and serves as Senior Principal System Engineer working in Medtronic's Cardiac Rhythm Disease Management Division in Minneapolis, MN. At Medtronic, he has led the development of sensors and diagnostic monitors that are placed in the human body to enable the management of chronic diseases or to provide input to therapy-giving devices. His responsibilities also include identifying and assessing new technologies that might be incorporated into implantable medical products. Jim studied Electrical Engineering at the University of Notre Dame and then obtained a Ph.D. in Electrical Engineering from the Massachusetts Institute of Technology. Prior to joining Medtronic, Dr. Carney worked at Honeywell's Sensors and System Development Center where he led research teams in a number of high-technology programs including semiconductor lasers, GaAs ICs, and silicon MEMS.

Greg Haubrich is a Medtronic Technical Fellow and serves as a Senior Principal RF Engineer in Medtronic's Cardiac Rhythm Disease Management Division in Minneapolis, MN. At Medtronic, he has led the design and development of RF Communication Systems and Circuits. Greg has a Bachelor's degree in Electrical Engineering from the University of Minnesota Institute of Technology, and is a licensed Professional Engineer. Prior to joining Medtronic, Greg worked at Honeywell's Military Avionics Division where he designed microwave radar altimeters and at Motorola, Schaumburg, IL, designing cellular mobile and portable cell phone RF circuitry. Greg is also a member of the executive board of the Minnesota Astronomical Society, and regularly volunteers for the Boy Scouts of America as a merit badge councilor.

Erik Herrmann received his BA degree in Physics and Physics-Microcomputing from Ithaca College, Ithaca, NY, in 1990, MBA degree in Technology Management from the University of Phoenix, Phoenix, AZ, in 2001, and MS in Electrical Engineering from Arizona Statue University, Tempe, AZ, in 2003.

Prior to joining Medtronic in 2002, he held positions in product engineering and engineering management with responsibilities for the design and manufacture of electronic products involving analog signal processing, power amplification, embedded digital systems, and RF communications. Since joining Medtronic, he has worked in product development as IC Product Engineer and as a manager in the Technology Group.

Vincent C.M.H. Larik was born in Vaals, The Netherlands, on September 2, 1954 and received his BSEE degree from the HTS, Heerlen, The Netherlands, in 1976. His responsibilities at the Medtronic Bakken Research Center, Maastricht, The Netherlands, include the management of the Advanced Concepts group, and research in the novel technologies and methodologies applicable to invasive medical devices for therapy and diagnosis.

Rogier A.M. Receveur was born in Capelle aan den IJssel, The Netherlands, on February 9, 1969 and holds a Master's degree in Applied Physics from Delft University of Technol-ogy, Delft, The Nether-lands, in 1993. He has worked at Océ Tech-nologies and is now a Senior R&D Engineer at Medtronic Bakken Research Center, Maastricht, The Netherlands. His research interests include microfabrication technology, and sensors for biomedical applications. Ir. Receveur is a member of The Netherlands' Physical Society and the Royal Dutch Society of Engineers.

Erik Scott is Senior Manager of Battery Research and Technology at the Medtronic Energy and Component Center (MECC). He has spent eight years developing battery technology for implantable medical devices, and he has also worked for six years at ALZA Corporation, developing techniques for delivering medicines across skin using iontophoresis. Erik received his Ph.D. in Materials Science and Engineering from the University of Minnesota.

Glen Vaughn holds Bachelor's and Master's Degrees in Electrical Engineering from Arizona State University, along with a Doctorate in Economics and Finance. Glen has held a wide variety of positions in semiconductor and information technology over the last 40 years, first with Motorola and now with Medtronic. In addition to these responsibilities, Glen also serves on the Board of Directors of the Arizona Bioindustry Association and is a member of the Dean's Advisory Council at the Ira A. Fulton School of Engineering at Arizona State University.

3.15.1 Introduction

Until the advent of advanced microfabrication techniques and microelectromechanical systems (MEMS), combustion at small size scales was largely an academic topic revolving around the question of quenching diameter. However, as the MEMS field grew, subdisciplines such as power MEMS, micropropulsion, and microreactor technologies were spawned. Devices in each of these areas require a heat source, typically a combustor due to the high energy density of liquid hydrocarbon fuels. Thus, combustion in small volumes has become an important area of research.

Because of various microcombustion applications, several types of combustors have been studied. They can be divided into two major categories: (1) homogeneous gas-phase microcombustors and (2) heterogeneous catalytic microcombustors. The first type is similar to the combustion systems that are found in larger-scale gas turbines, whereas the second type is more characteristic of a chemical reactor with a surface catalyst to promote reaction rates. The type of combustor chosen for a given application will depend on the required fuel, materials constraints, the thermodynamic cycle, and available fabrication techniques; however, the fundamental physics, limitations, and constraints for all of these combustors are the same.

This chapter provides a general understanding of microcombustion fundamentals and challenges, shows some microcombustor operational data, and provides some design guidelines. First, an introduction to basic combustion principles and definitions is presented, followed by a discussion of fundamental issues unique to combustion systems at the microscale. Next, a detailed presentation of homogeneous gas-phase microcombustors is provided, including operational data and guidelines for microcombustor designers. This is followed by a detailed discussion of heterogeneous catalytic microcombustors with data and design suggestions. Finally, this chapter concludes with a discussion of micrcombustor applications ranging from micro heat engines to microscale methanol reformers and some perspectives on microcombustor research needs.

3.15.2 Basic Combustion Concepts

Before discussing issues pertaining specifically to microcombustors, the reader should be familiar with some basic combustion concepts. These include the fundamental chemical equations of combustion reactions, the concept of equivalence ratio (normalized fuel–air ratio), reaction rate and Arrhenius expressions, and various definitions of efficiency.

3.15.2.1 Combustion Chemistry

Combustion consists of a chemical reaction between a fuel (typically hydrogen or a hydrocarbon species) and an oxidizer leading to heat release. In general, the overall chemical equation for complete combustion of hydrocarbons with air can be written as

$$C_xH_y + \left(x + \frac{y}{4}\right)(O_2 + 3.76N_2) \rightarrow xCO_2 + \frac{y}{2}H_2O + 3.76\left(x + \frac{y}{4}\right)N_2 \quad [I]$$

Typical fuels include hydrogen, propane, and gasoline. Choice of fuel often depends on fuel storage constraints, reaction rates, and emissions requirements. The combustion chemistries for hydrogen and propane with air, respectively, are

$$H_2 + \frac{1}{2}O_2 + 1.88N_2 \rightarrow H_2O + 1.88N_2 \quad [II]$$

$$C_3H_8 + 5O_2 + 18.8N_2 \rightarrow 3CO_2 + 4H_2O + 18.8N_2 \quad [III]$$

The only products of complete combustion are water and carbon dioxide (in the ideal case nitrogen is inert); however, in reality this is not the case. Trace quantities of pollutants such as oxides of nitrogen (NO_x) and carbon monoxide (CO), as well as some unburned hydrocarbons, are usually present. Incomplete combustion may occur if the reactants are not well mixed or if there is insufficient residence time (as is often the case with microcombustors). In these scenarios, there will be significant quantities of reactants in the exit gas stream.

Although combustion chemistries can generally be written as single chemical equations, in reality there are many individual subreactions that combine to give the overall reaction. These sets of chemical equations are referred to as the reaction mechanism.

3.15.2.2 Equivalence Ratio

If propane and air, for example, are provided to a combustion system in a 23.8:1 molar ratio, the mixture is considered stoichiometric. In this case, all fuel and air are consumed in the reaction. If there is excess oxidizer, the mixture is lean, whereas with excess fuel, it is rich. This ratio is referred to as the fuel–air ratio and is usually given on a mass basis, which can be obtained by scaling the molar ratio by the molecular weights of the constituents. In a real combustor, the mass-based fuel–air ratio can be found directly from measurements of the fuel and air mass flow rates.

$$fa = \frac{\dot{m}_f}{\dot{m}_a} \quad [1]$$

The fuel–air ratio can be normalized by the stoichiometric ratio to yield a quantity known as equivalence ratio.

$$\phi = \frac{fa_{actual}}{fa_{stoichiometric}} \quad [2]$$

This is a more commonly used measure of mixture ratio. If $\phi = 1$, the fuel–air mixture is stoichiometric. When $\phi < 1$, the mixture is lean, and if $\phi > 1$, it is rich. Combustion reactions typically peak in temperature around an equivalence ratio of unity and are reduced the more lean or rich the mixture. This is primarily due to the unreacted constituents absorbing some of the heat released from the reaction. The theoretical temperature achieved with an adiabatic boundary condition (all released heat is used to heat the products) is known as the adiabatic flame temperature and is a useful reference point.

3.15.2.3 Kinetics

Chemical kinetics is the study of the rate at which a reaction occurs. Generally, the conditions that can impact the reaction rate include reactant concentration, temperature, and the presence of a catalyst. The reaction rate is expressed as the rate of change in concentration of the reacting substances (a decrease for reactants and an increase for products) per unit time. The rate of change can also be equated to a rate constant multiplied by the concentrations of the reactant species raised to the power of their respective stoichiometric coefficients. For example, an arbitrary reaction may be written as

$$A + 2B \rightarrow C + D \quad [IV]$$

where the reaction rate is

$$-R = \frac{d[A]}{dt} = -k[A][B]^2 \quad [3]$$

with brackets denoting concentration and k the rate constant.

The temperature dependence of reaction rate is contained within the rate constant k. This is embodied in the Arrhenius expression for the rate constant that is generally given as

$$k = A\exp\left(\frac{-E_a}{RT}\right) \quad [4]$$

where E_a is the activation energy for the reaction, R the gas constant, T the temperature, and A the kinetic preexponential factor. The pre-exponential factor accounts for molecular collisions and the steric factor, and along with the activation energy, it is usually obtained empirically. Typically, the constants are extracted from a linear fit to data on $\ln(k)$ versus $(1/T)$ plots where the slope of the fit is $(-E_a/R)$. Collision theory and more advanced techniques such as transition state theory can be used to calculate pre-exponentials and rate constants; however, these methods tend to overpredict reaction rates.

The activation energy represents an energy barrier that must be overcome in order to convert from reactants to products. This energy is typically provided in the form of thermal energy, and once it is provided, the reaction rapidly proceeds to completion. Figure 1 shows energy as a function of reaction coordinate for a typical exothermic combustion reaction. In the presence of a catalyst, the activation energy is reduced while all other aspects of the reaction remain unchanged.

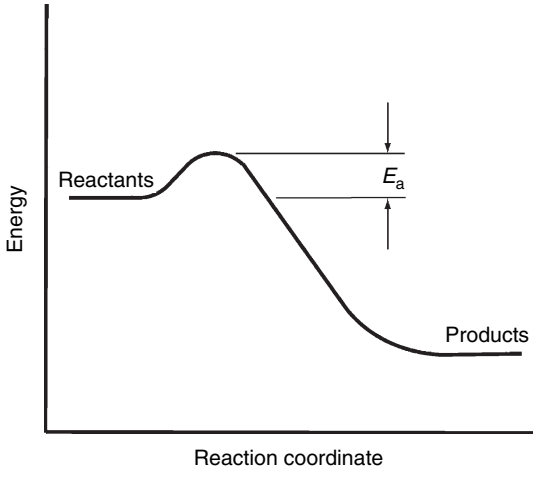

Figure 1 Energy as a function of reaction coordinate for a typical exothermic reaction.

3.15.2.4 Microcombustor Efficiency Definitions

For the purpose of this discussion, overall combustor efficiency will be based on an enthalpy balance across the combustor and is defined as

$$\eta_c = \frac{(\dot{m}_a + \dot{m}_f)h_2 - \dot{m}_a h_1}{\dot{m}_f h_f} \quad [5]$$

where subscript (1) refers to the combustor inlet and subscript (2) refers to the combustor exit. The combustor efficiency can be written as the product of two subefficiencies: a chemical efficiency and a thermal efficiency. These two parameters can be written as

$$\eta_{chem} = \frac{[(\dot{m}_a + \dot{m}_f)h_2 - \dot{m}_a h_1] + \dot{Q}_{loss}}{\dot{m}_f h_f} = \frac{\text{total enthalpy released}}{\text{maximum enthalpy release possible}} \quad [6]$$

$$\eta_{therm} = \frac{(\dot{m}_a + \dot{m}_f)h_2 - \dot{m}_a h_1}{[(\dot{m}_a + \dot{m}_f)h_2 - \dot{m}_a h_1] + \dot{Q}_{loss}} = \frac{\text{enthalpy rise of fluid}}{\text{total enthalpy released}} \quad [7]$$

where $\dot{Q}_{loss}$ is the heat lost to the wall. It is worth noting that alternate definitions of efficiency may be more suitable depending on the application for which a microcombustor is being designed. The above definitions assume that it is desirable to retain enthalpy in the gas stream as opposed to losing heat through the structure. For some applications, a hot wall may be the desired outcome.

3.15.3 Microcombustor Fundamentals and Challenges

There are fundamental concepts and challenges that are unique to microcombustion systems. These include timescale and material constraints as well as heat transfer and fluid–structure thermal coupling. These concepts are outlined below.

3.15.3.1 Timescale Constraints

For many energy conversion applications, power density is the most important metric. Using the gas turbine combustor as a model system, the differences in power density spanning length scales become evident. As summarized in Table 1, the high power density of a microcombustor directly results from high mass flow per unit volume. Because chemical reaction times do not scale with mass flow rate or combustor volume, the

Table 1 Comparison of operating parameters and requirements for a micro gas turbine engine combustor with those estimated for a conventional GE90 gas turbine combustor

	Conventional combustor	*Microcombustor*
Length (m)	0.2	0.001
Volume (m^3)	0.073	6.6×10^{-8}
Cross-sectional area (m^2)	0.36	6×10^{-5}
Inlet total pressure (atm)	37.5	4
Inlet total temperature (K)	870	500
Mass flow rate ($kg\,s^{-1}$)	140	1.8×10^{-4}
Residence time (ms)	~7	~0.5
Efficiency (%)	>99	>90
Pressure ratio	>0.95	>0.95
Exit temperature (K)	1800	1600
Power density ($MW\,m^{-3}$)	1960	3000

Note: Residence time is calculated using inlet pressure and an average flow temperature of 1000 K.

realization of this high power density is contingent upon completion of the combustion process within a shorter combustor through-flow time.

This fundamental time constraint can be quantified in terms of a homogeneous Damköhler number – the ratio of the residence time to the characteristic chemical reaction time.

$$Da_{\mathrm{h}} = \frac{\tau_{\mathrm{residence}}}{\tau_{\mathrm{reaction}}} \qquad [8]$$

To ensure a Da_{h} greater than unity (and complete combustion), a designer of a microcombustor can either increase the flow residence time or decrease the chemical reaction time. The characteristic combustor residence time is given by estimating the bulk flow rate through the combustor volume.

$$\tau_{\mathrm{residence}} \approx \frac{\text{volume}}{\text{volumetric flow rate}} = \frac{VP}{\dot{m}RT} \qquad [9]$$

Residence time can be increased by increasing the size of the combustion chamber, reducing the mass flow rate, or increasing the operating pressure. A chemical reaction time can be approximated using an Arrhenius-type expression.

$$\tau_{\mathrm{reaction}} \approx \frac{[\mathrm{fuel}]_0}{A[\mathrm{fuel}]^a[\mathrm{O_2}]^b \exp(-E_{\mathrm{a}}/RT_0)} \qquad [10]$$

Eqn [10] indicates that reaction time is primarily a function of fuel properties and the mixture temperature.

Because high power density requirements mandate high mass flow rates through small chamber volumes, the mass flow rate per unit volume cannot be reduced without compromising device power density. Hence, there is a basic trade-off between power density and flow residence time.

$$\text{Power density} \propto \frac{\dot{m}}{V} \propto \frac{\dot{m}_{\mathrm{f}}\mathrm{LHV}}{V} \propto \frac{\rho}{\tau_{\mathrm{residence}}} \qquad [11]$$

For a given operating pressure (and thus density), and assuming a Da_{h} of unity, reducing the chemical reaction time, and thus required residence time, is the only means of ensuring complete combustion without compromising the high power density of the device.

For a catalytic combustor, there is an additional timescale to consider. The reaction time and residence time are still important parameters; however, diffusion time must also be accounted for. The time required for a fuel and oxidizer molecule to come into contact with the active catalytic surface can govern the operation of the device.

As a result, there are several nondimensional parameters that can be examined to determine which process governs performance. Combustor residence time and reaction time can be estimated in the same fashion as done in the gas-phase case. Reaction mechanisms for many catalytic reactions can be found in the literature. The homogeneous Damköhler number is the ratio of these two quantities and indicates their relative importance. With the additional diffusion timescale, a second Damköhler number can be defined. This parameter is the ratio of the diffusion time to the reaction time and indicates the relative rates of these two processes.

$$Da_2 = \frac{\tau_{\mathrm{diffusion}}}{\tau_{\mathrm{reaction}}} \qquad [12]$$

Finally, there is a third ratio of timescales. The ratio of diffusion time to residence time is known as the Péclet number. For high Péclet numbers (>>1), reactants do not have time to diffuse to the active surface and simply pass through the combustor unreacted. A device operating under these conditions is said to be mass transfer controlled or diffusion limited.

$$Pe = \frac{\tau_{\mathrm{diffusion}}}{\tau_{\mathrm{residence}}} \qquad [13]$$

For low Péclet numbers (<<1), the chemical reaction may be controlling the combustion process and the two Damköhler numbers must be examined. If they are both <<1, then the device is kinetically limited or reaction controlled.

For the microscale devices of interest here, power density is the primary performance metric. As discussed previously, high power density requires high mass flow rates through small chamber volumes resulting in relation [11]. At the small volumes of interest, residence time will be correspondingly low while catalytic reaction rates are generally fast. As a result, these devices will likely be diffusion limited. Péclet number must then be considered the governing nondimensional parameter; thus, power density can be rewritten as

$$\text{Power density} \propto \frac{\rho Pe}{\tau_{\text{diffusion}}} \qquad [14]$$

Hence, there is a basic trade-off between power density and diffusion time. Noting that Péclet number can also be written as

$$Pe = \frac{Lv}{D} \qquad [15]$$

where L is reactor length and v velocity, power density can be rewritten as

$$\text{Power density} \propto \frac{\rho Lv}{D\tau_{\text{diffusion}}} \qquad [16]$$

For a given operating pressure and temperature (thus density), and reactant species, reducing diffusion times will increase the power density of the device and improve performance. Diffusion timescales for a given fuel–air mixture generally can be reduced by increasing catalyst surface area-to-volume ratio.

3.15.3.2 Heat Transfer and Fluid–Structure Coupling

Energy loss due to heat transfer at the walls of the combustion chamber in a large-scale flame combustor is typically neglected. However, for a microcombustor, this is an important factor. The surface area-to-volume ratio for a microscale combustor is approximately $500\,\text{m}^{-1}$, or two orders of magnitude greater than that of a typical combustor.

Waitz *et al.* (1998) have shown that the ratio of heat lost to that generated scales with the hydraulic diameter as follows:

$$\frac{Q_{\text{loss}}}{Q} \propto \frac{1}{d_{\text{h}}^{1.2}} \qquad [17]$$

The hydraulic diameter of a microcombustor is on the order of millimeters or less, hundreds of times smaller than that of a typical combustor. Therefore, the ratio of heat lost to that generated may be as much as two orders of magnitude greater than that of a large-scale combustor.

The effect of this large surface heat loss on combustion is twofold. First, large thermal losses have a direct impact on overall combustor efficiency. Therefore, typical large-scale combustor efficiencies greater than 99% are not feasible. Second, the heat loss leads to lower reaction temperatures that can increase kinetic times and narrow flammability limits. This can exacerbate the constraints of short residence time.

In a catalytic device, the heat loss problem becomes worse. The reaction and heat release process occur on the solid surface of the catalyst, so there is a direct conduction path through the structure and out of the device. In the case of a gas-phase microcombustor, there is a thermal boundary layer between the hot reacting gases and the wall, helping to limit heat loss. In a catalytic device, the thermal boundary layer acts to isolate the hot wall from the relatively cooler free-stream flow. In addition, surface area-to-volume ratio is likely to be even higher in a catalytic combustor because of the need to fill the chamber with a monolith or porous substance coated with an active catalytic material.

However, it is important to note that for some applications such as a heat source for a solid-state power generator (e.g., thermoelectric or thermophotovoltaic devices), or for an endothermic reactor (e.g., a methanol reformer for a fuel cell), heat loss through the structure to some other device is desirable.

3.15.3.3 Material Constraints

Choice of materials for microcombustors is often limited due to the available fabrication techniques. Typically, deep reactive ion etching (DRIE) in silicon wafers and aligned fusion bonding are used to generate 2D extruded geometries that serve as combustion chambers, fuel–air mixers, fuel injectors, and other associated components. Consequently, many microcombustion systems are silicon based.

There are several material constraints imposed upon a silicon microcombustion system. The most critical requirement is a wall temperature limit of less than 950 K. At temperatures above this level, silicon begins to soften and lose its structural integrity. However, high surface heat transfer and the high thermal conductivity of silicon are beneficial in this case. Combustor wall temperatures can be kept below the 950 K requirement by conduction of heat through the structure to the ambient.

It is also important to note that silicon-based microcombustors are typically isothermal. This is a result of the combination of the high thermal conductivity of silicon and the short conduction paths inherent in a microsystem. This can be quantified by the heat transfer Biot number

$$Bi = \frac{hL}{k} = \frac{\text{resistance to conductive heat transfer}}{\text{resistance to convective heat transfer}} \quad [18]$$

which is typically <<1 for these systems.

There are several material and fabrication issues that are specific to developing a catalytic microcombustor. First, the catalyst material itself can be problematic. For noble metals such as platinum (a typical hydrocarbon–air catalyst), agglomeration of thin layers can occur at elevated temperatures. This phenomenon has been shown to occur at temperatures on the order of 1000 K (Maskell *et al.* 1987, Wang *et al.* 2003). This is a potential problem not only during the combustion process but also during any high-temperature fabrication steps such as silicon wafer bonding and glass seal packaging processes, both of which occur at temperatures approaching 1350 K. Agglomeration will reduce the active surface area and negatively impact the performance.

The substrate material on which the active catalyst is deposited must also be chosen with care. It should be a material with a temperature limit at least as high as that of the catalyst itself and be inert with respect to the catalyst. Diffusion of the catalyst layer or reaction with its substrate would also further reduce the surface area and the performance. Finally, thermal shock of the catalyst and substrate material must be considered, especially if ceramic substrates are used.

3.15.4 Homogeneous Gas-Phase Microcombustion

For the purpose of the following detailed discussion, a baseline microcombustor will be used as a reference. It should be noted, however, that the conclusions drawn from data generated in this device are generally applicable to other microcombustors.

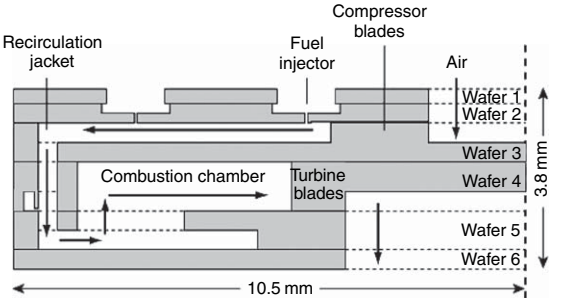

Figure 2 Schematic of a six-wafer microcombustor. (Source: Mehra A 2000 Development of a high power density combustion system for a silicon micro gas turbine engine. Ph.D. thesis, Massachusetts Institute of Technology.)

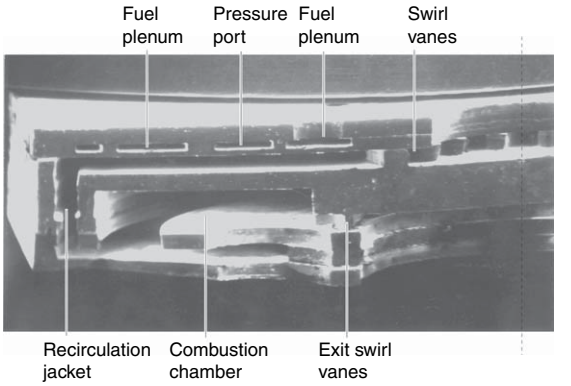

Figure 3 Scanning electron micrograph (SEM) of a six-wafer microcombustor. (Source: Mehra A 2000 Development of a high power density combustion system for a silicon micro gas turbine engine. Ph.D. thesis, Massachusetts Institute of Technology.)

An axisymmetric microcombustor fabricated from six silicon wafers using DRIE and aligned fusion wafer bonding is shown in **Figures 2** and **3**. It consists of a 191-mm^3 radial inflow combustion chamber, various flame holding chamber inlet geometries, a recirculation jacket that serves as both a thermal management system and a fuel–air mixer, and several sets of fuel injectors.

3.15.4.1 Performance of a Baseline Gas-Phase Microcombustor

Tests were performed with premixed hydrogen–air in the radial inflow microcombustor. Plots of combustor exit gas temperature and overall combustor efficiency for constant equivalence ratio are shown in **Figures 4** and **5**, respectively. Mass flow rate was

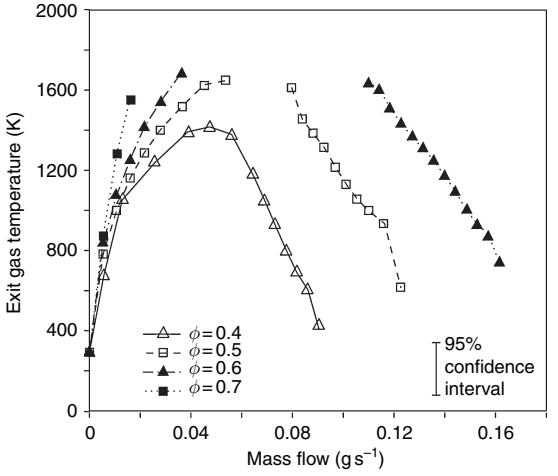

Figure 4 Exit gas temperature versus mass flow rate for an annular six-wafer microcombustor. (Source: Mehra A 2000 Development of a high power density combustion system for a silicon micro gas turbine engine. Ph.D. thesis, Massachusetts Institute of Technology.)

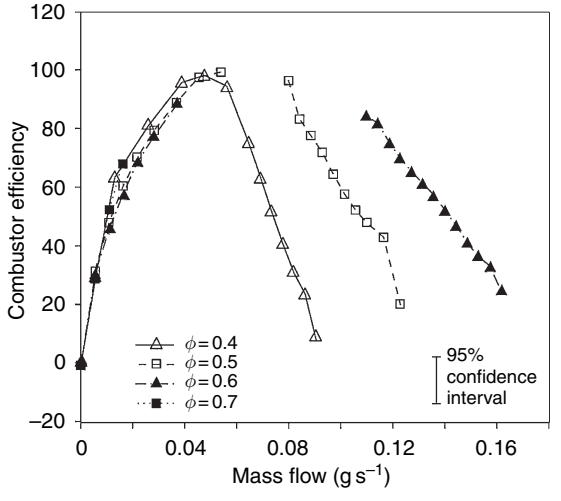

Figure 5 Overall efficiency for an annular six-wafer microcombustor. (Source: Mehra A 2000 Development of a high power density combustion system for a silicon micro gas turbine engine. Ph.D. thesis, Massachusetts Institute of Technology.)

varied by increasing the inlet pressure with a fixed exit area to atmosphere.

The combustor produced exit gas temperatures in excess of 1600 K for a mass flow rate of 0.11 g s^{-1} and an operating pressure of 1.13 atm. The overall efficiency in this case exceeded 90%, and the power density was approximately 1100 MW m^{-3}. The break in the $\phi = 0.5$ and $\phi = 0.6$ exit temperature and efficiency curves is due to a lack of measurement

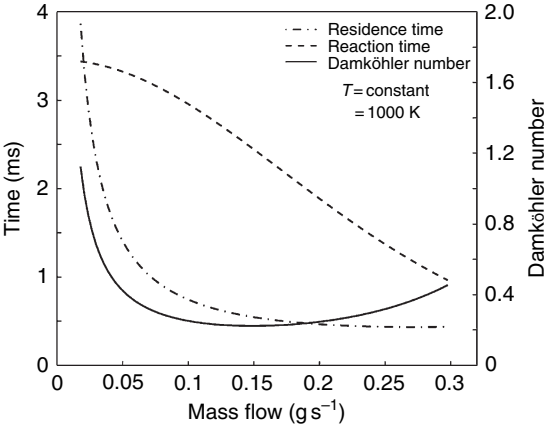

Figure 6 Reaction time, residence time, and Damköhler number (Da_h). (Source: Mehra A 2000 Development of a high power density combustion system for a silicon micro gas turbine engine. Ph.D. thesis, Massachusetts Institute of Technology.)

capabilities for gas temperatures over 1600 K. The $\phi = 0.7$ curve terminates at a mass flow rate of 0.015 g s^{-1} due to upstream burning in the recirculation jacket, which can result in overheating and destruction of the device (Mehra 2000, Mehra *et al.* 2000, Spadaccini *et al.* 2003).

The flame blowout characteristics of the combustor can be explained by examining the change in Da_h over a constant equivalence ratio operating line. Using eqn [9] for residence time, and a simple one-step mechanism for hydrogen–air combustion,

$$\tau_{\text{reaction}} = \frac{[H_2]_0}{A[H_2]^2[O_2]\exp(-E_a/RT)} \qquad [19]$$

with $E_a = 10\,950$ cal mol^{-1} and $A = 1.62 \times 10^{18}$ (cm^3 mol^{-1})^2 s, an estimate of Da_h can be obtained (Mehra 2000). **Figure 6** shows a plot of reaction time and residence time along with Da_h versus mass flow rate. Residence time decreases more rapidly than reaction time, resulting in a Da_h less than one. This leads to chemical inefficiency at high mass flow rates and flame blowout.

3.15.4.2 Recirculation Zones and Flame Stability

Two types of combustion chamber inlets were utilized in this device to understand the impact of different flame holding recirculation zones. The first is a simple annular inlet 1.2 mm wide. The second is an array of 60 slots 2.2 mm long intended to create multiple small recirculation zones for more

rapid and uniform ignition of the incoming flow. Scanning electron micrographs (SEMs) of both inlets are shown in **Figure 7** (Mehra 2000).

Combustor efficiency for premixed hydrogen–air tests in the slotted-inlet geometry is plotted in **Figure 8**. Performance is similar to that of the annular-inlet combustor. However, the slotted-inlet device produced higher exit temperatures and efficiencies in the high mass flow, kinetically limited regime of the operating line. This is attributed to the presence of multiple recirculation zones at the inlet, which more rapidly and uniformly ignite the incoming mixture. The sharp drop in performance for the slotted combustor is due to the rapid extinction of the ignition zones. In the annular case shown in **Figures 5** and **6**, the single large recirculation zone stays lit over a wider range of mass flow rates. However, it also results in lower chemical efficiency (Mehra 2000).

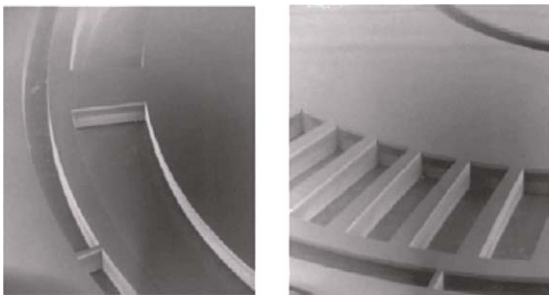

Figure 7 Scanning electron micrographs (SEMs) of inlet geometries. (Source: Mehra A 2000 Development of a high power density combustion system for a silicon micro gas turbine engine. Ph.D. thesis, Massachusetts Institute of Technology.)

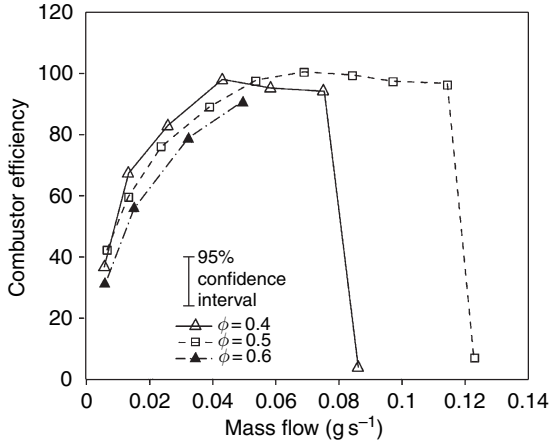

Figure 8 Overall efficiency for a slotted-inlet six-wafer microcombustor. (Source: Mehra A 2000 Development of a high power density combustion system for a silicon micro gas turbine engine. Ph.D. thesis, Massachusetts Institute of Technology.)

Without internal measurements or flow visualization, numerical simulations can be used to understand this performance difference. **Figure 9(a)** shows temperature contours generated from computational fluid dynamics (CFD) software, for the combustor with an annular inlet. In **Figure 9(b)**, contours of temperature are plotted for a 2D cut through the combustor inlet in the $\theta - z$ plane. These contours show a temperature gradient from the bottom of the combustion chamber to the top and indicate the primary ignition zone is in the upper right corner of the combustor. **Figure 10(a)** and **10(b)** show the same contour plots for a combustor with a slotted inlet. The temperature contour in the $\theta - z$ plane shows significantly higher temperatures in the lower regions of the combustion chamber and a higher overall temperature. The shape of the contours indicates that there are small, hot ignition zones near the slotted inlet (Spadaccini 2004, Spadaccini *et al.* 2003).

3.15.4.3 Fuel Injection and Fuel–Air Mixing

Fuel injection and mixing were evaluated in these devices by testing three sets of fuel injectors at different locations within the recirculation jacket and comparing overall combustor efficiencies to a premixed case. The premixed operation consisted of fuel–air injection through the primary air inlet only. **Figure 11** plots efficiency for different equivalence ratios at a mass flow rate of 0.045 g s^{-1}. The injectors were located at radii of 4.8 and 8.0 mm into the recirculation jacket while a set of sidewall injectors were at the base of the recirculation jacket just upstream from the combustion chamber. The figure indicates that performance decreases as the injectors get closer to the combustion chamber due to the decreased mixing length and time (Mehra 2000).

3.15.4.4 Primary and Secondary Zones

Typical large-scale combustors utilize a multizonal combustion strategy. An initial primary zone consists of a high-temperature, near-stoichiometric combustion zone followed by dilution jets of air to form a secondary zone with a leaner mixture and lower temperature. Ultimately, most of the fuel is consumed and a more uniform and controlled exit temperature can be achieved.

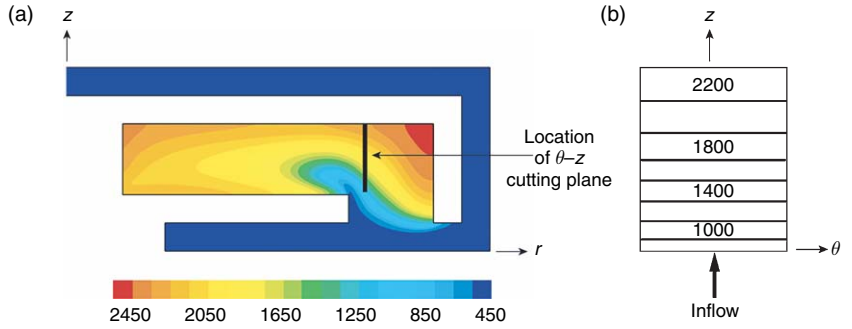

Figure 9 Temperature (K) contours for an annular-inlet microcombustor. Note: FLUENT v. 5.1 with a nine-species, 20-step, hydrogen–air reaction mechanism for the chemical model and an adiabatic wall boundary condition were used in these simulations. (Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

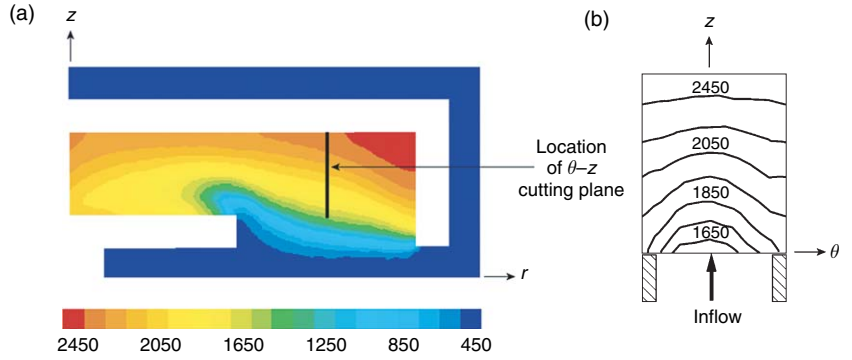

Figure 10 Temperature (K) contours for a slotted-inlet microcombustor. Note: FLUENT v. 5.1 with a nine-species, 20-step, hydrogen–air reaction mechanism for the chemical model and an adiabatic wall boundary condition were used in these simulations. (Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

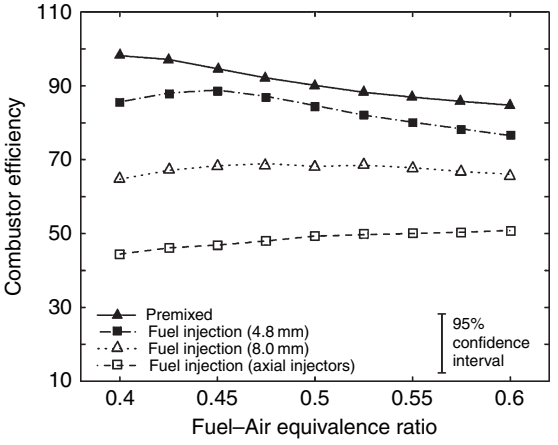

Figure 11 Overall efficiency for fuel injection schemes. (Source: Mehra A 2000 Development of a high power density combustion system for a silicon micro gas turbine engine. Ph.D. thesis, Massachusetts Institute of Technology.)

A multizone microcombustor that operates in a similar fashion may be beneficial for overall performance. This was fabricated by modifying the geometry shown in **Figures 2** and **3**. A series of holes through the inner wall were created to connect the upper recirculation jacket to the combustion chamber. These holes allowed inlet air to bleed into the combustion chamber. This dilution air serves two purposes: (1) it splits the combustion chamber into the two zones and (2) it dilutes the hot combustion products reducing their temperature to the required outlet temperature. In the primary zone, the fuel–air mixture is burned near stoichiometric conditions. By burning at higher temperature, kinetic rates increase and reaction time decreases, effectively increasing Da_h. The dilution jets also serve to strengthen recirculation zones and improve flame stability. Due to the nature of this mode of operation, premixed combustion is not feasible and fuel injection occurs just

downstream of the dilution holes in the cooling jacket. A 3D, adiabatic, reacting flow CFD solution shows the effect of the two zones in **Figure 12**.

The dual-zone combustor exhibited slightly lower exit gas temperatures and efficiencies than the baseline microcombustor. However, its operating range was much wider for hydrogen–air operation. Combustion was stabilized at equivalence ratios as low as 0.2 and mass flow rates as high as 0.2 g s^{-1}. **Figure 13** compares the dual-zone combustor efficiency with the baseline for similar conditions (Spadaccini 2004, Spadaccini *et al.* 2003).

The significant extension in operating range is largely due to strengthened recirculation zones and the hot, stable primary zone. For the same overall efficiency, the dual-zone combustor achieved a 100% increase in mass flow rate before blowout. The ability to operate at low overall equivalence ratio is a result of a higher local equivalence ratio in the primary zone. **Table 2** summarizes the maximum power densities achieved for both devices with various fuels (hydrocarbon fuel data have not been presented here) (Spadaccini 2004).

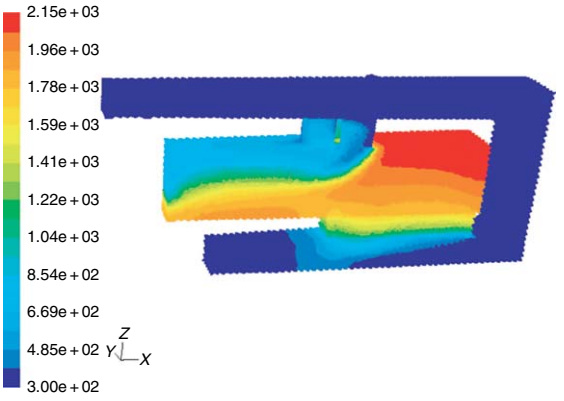

Figure 12 Temperature (K) profile from 3D, reacting flow computational fluid dynamics (CFD) solution for dual-zone microcombustor. (Source: Lee J-W 2000 Numerical simulation of a hydrogen microcombustor. M.S. thesis, Massachusetts Institute of Technology.)

3.15.4.5 Operating Space

Microcombustor performance is a function of both chemical and thermal losses. Performance can be quantified in terms of nondimensional power density, defined as power density normalized by the maximum possible power density at a given operating condition (the latter being a function of mass flow rate and fuel type). If it is assumed that there is adequate fuel–air mixing and rapid, uniform ignition, this quantity is a function of only two parameters – Damköhler number and nondimensional heat loss. Damköhler number can be estimated as previously described using exit gas temperature for residence time calculations and Chemkin III (a reaction kinetics software package) with detailed reaction mechanisms from the literature for chemical time approximations. Heat loss can be quantified in nondimensional terms by normalizing the heat lost from the device by the maximum possible heat that can be generated at a given operating condition. The heat lost was estimated using a 1D heat transfer model (which is a good approximation in this case due to the low Biot number and isothermal nature of the structure).

Figure 14 plots this nondimensional power density for several microcombustors in three-parameter space. This plot includes multiple fuels as well (hydrogen, ethylene, and propane). The heat loss parameter and homogeneous Damköhler number are on the x- and y-axes, respectively. A second-order, least squares surface fit was used to generate contours of nondimensional power density (the fit explains 65% of the variance in the data) (Spadaccini 2004, Spadaccini *et al.* 2003).

Thermal efficiency in these devices is inversely proportional to heat loss, whereas chemical efficiency is directly proportional to Damköhler number. Hence, optimum performance is achieved at low levels of heat loss and high Damköhler number as indicated in **Figure 14**.

Table 2 Maximum power densities and efficiencies for microcombustors

	Baseline microcombustor		*Dual-zone microcombustor*	
Fuel	*Power density (MW m^{-3})*	*Efficiency (%)*	*Power density (MW m^{-3})*	*Efficiency (%)*
H_2	1150	>99	1400	92
C_2H_4	500	85	100	38
C_3H_8	140	50	75	29

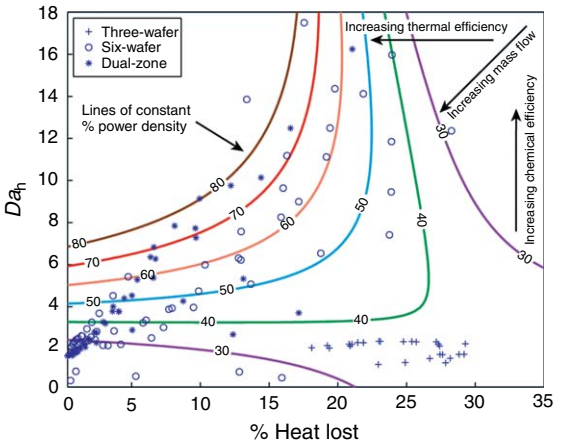

Figure 14 Nondimensional operating space. (Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

This nondimensional operating space further explains the operating line considerations of a microcombustor. Conditions of increasing mass flow for constant equivalence ratio move from the upper right side of the operating space to the lower left. In the low mass flow region of the operating space, performance is limited by heat loss, whereas at high mass flow, Damköhler number falls and performance is limited by chemical inefficiency. In the area of moderate mass flow, the center of the operating space, the highest power densities are achieved.

3.15.4.6 Suggested Design Methodology and Recommendations

The nondimensional operating space of Figure 14 can also be useful in the design process. For example, a good estimate of the volume required for a propane–air microcombustor suitable for a given application can be obtained. If operating conditions such as a 1600 K exit gas temperature, 1 atm pressure, a mass flow rate of 0.15 g s^{-1}, and an equivalence ratio of $\phi = 0.8$ are required, the nondimensional power density can be computed and is found to be approximately 60%. The heat loss from the device can be assumed to be approximately 5% based on data for similar devices or can be estimated using a heat transfer model. From Figure 14, the desired Damköhler number can be found and is approximately 5.5. The chemical time can be computed using Chemkin III or any other suitable technique and the desired residence time found from the Damköhler number. This results in a residence time of 1.44 ms and a volume of 950 mm^3, or about a fivefold increase in volume compared with the gas-phase microcombustors presented here.

It is important to note that these results are for design point operation only and operating line issues must be kept in mind. Namely, the combustors will likely reach a minimum Damköhler number at which blowout may occur, before reaching the design mass flow rate. To account for this, a gas-phase microcombustor volume should be sized for this off-design operating condition.

The following design trade-offs and recommendations for homogeneous gas-phase microcombustion systems should be considered:

1. The high power density requirements of a microcombustor mandate high mass flow rates per unit volume. However, this results in low residence time and Damköhler numbers of order unity or less. Microcombustion systems are fundamentally limited by this trade-off between high power density and efficient combustion.
2. The large surface area-to-volume ratio of a microcombustor makes nonadiabatic operation intrinsic to its design. The coupling between heat transfer and chemical kinetics is a critical element of the design process. Thermal management strategies such as the recirculation jacket shown in Figure 2 are effective solutions. While keeping

the inner wall cool, it acts as a fuel–air preheater to improve kinetic rates, mitigating the effect of lower wall temperatures.

3. Recirculation zones are critical for rapid and uniform ignition of incoming reactants. However, if these ignition zones are too large, the effective volume of the combustion chamber will be significantly reduced, resulting in decreased residence time and Da_h.
4. Fuel injection for non-premixed operation should occur as far upstream of the combustion chamber as possible to provide adequate mixing length.
5. It is not sufficient to design a microcombustor exclusively for design point operation. Operating line issues need to be considered.

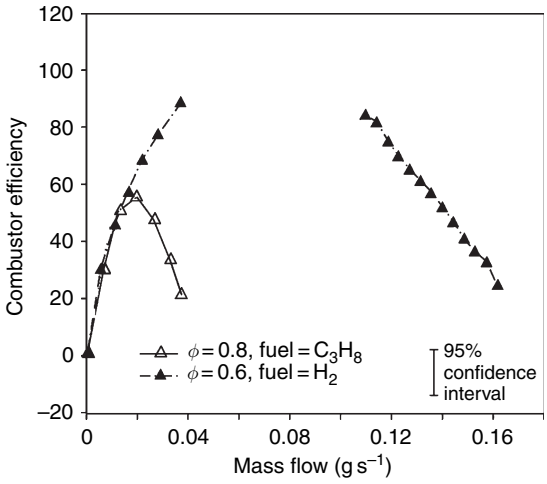

Figure 15 Performance comparison for different fuel types in a gas-phase microcombustor. (Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

3.15.5 Heterogeneous Catalytic Microcombustion

Thus far, this chapter has focused predominantly on homogeneous gas-phase combustion. We have an understanding of the combustor volume required for a practical device, given the requirements for mass flow, exit gas temperature, and fuel type. This has also provided an understanding of the operating behavior and performance of a microcombustor with homogeneous gas-phase hydrocarbon–air mixtures. Experimental results described by Mehra *et al.* and Spadaccini *et al.*, and those from the performance estimation method presented in Section 3.15.5.6 suggest that a microcombustor operating with a more practical hydrocarbon fuel such as propane will need to be at least five times larger than a device operating with hydrogen. A sample of experimental results is shown in **Figure 15** for both hydrogen–air and propane–air combustion to underscore this point. The factor of five difference in mass flow range for the two fuels is attributable to the difference in chemical kinetic rates.

Ultimately, for most practical applications of microcombustors, the goal is to operate with storable liquid hydrocarbon fuels such as propane or ethylene. To utilize these fuels without increasing combustor volume or temperature, chemical conversion rates must be increased significantly. Surface catalysis is a means of increasing reaction rates. Heterogeneous reactions of hydrocarbon–air mixtures over noble metal catalysts are known to be faster than those occurring in the gas phase. For this basic reason, the development of catalytic microcombustors has been pursued.

A typical large-scale catalytic combustor would consist of a monolithic structure (a set of parallel channels) coated with an active catalyst material. Common catalyst materials include noble metals such platinum and palladium as well as more exotic and proprietary metal oxides. The fuel and air flow through the channels and diffuse to the active surface. When a fuel molecule and an oxygen molecule reach the surface, they are adsorbed and they react, releasing heat. The products of the reaction are then desorbed and they flow out of the channel. The heat that has been liberated from the reaction is transferred both conductively through the solid and convectively to the fluid. Eventually, the remaining fuel–air mixture can get hot enough to ignite in the gas phase. **Figure 16** shows a schematic of a typical catalytic combustor.

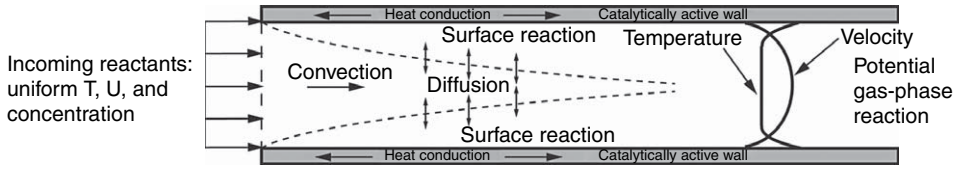

Figure 16 Schematic of a typical catalytic combustor.

For the purpose of illustrating key points and showing operational data, a model catalytic microcombustor, based on the gas-phase device previously presented, will be used. **Figure 2** shows the gas-phase geometry; however in the catalytic case, the combustion chamber is filled with a porous substrate coated with platinum that will act as the active catalytic surface. Although a porous catalyst material was chosen for this application, another common catalyst geometry is the monolithic channel-type structure with catalytically active walls, as previously described.

3.15.5.1 Ignition Techniques and Characteristics

To achieve autothermal operation of a catalytic microcombustor, the catalyst has to be heated to a suitable ignition temperature. This can be accomplished by one of the following three methods:

1. Begin with hydrogen–air operation (which will catalytically ignite at lower temperatures) and preheat the catalyst. The fuel can then be converted to a hydrocarbon fuel once the catalyst has reached adequate temperature (typically >500 K).
2. Externally heat the entire microcombustor with a heater and begin flow of the hydrocarbon–air mixture when the desired preheating temperature is achieved.
3. Heat the catalytic element directly by resistive heating followed by flowing of the fuel–air mixture. This requires that the catalyst itself be fabricated with electrical contacts.

Typically, a catalytic combustor will exhibit an ignition/extinction hysteresis similar to that shown by Schmidt and co-workers (Goralski and Schmidt 1996, Veser and Schmidt 1996, Williams *et al.* 1991). For the test device used as the model here, this is shown in **Figure 17** with two different porous catalyst materials. The entire combustor was heated via an external electrical heater while a hydrogen–air mixture was flowing through the device. Wall temperature is plotted against heater power and ignition occurs at a heater power of approximately 20–30% (around 80–100°C). Upon removal of the external heater, the combustor continues to operate autothermally, resulting in the hysteresis.

3.15.5.2 Performance of a Baseline Catalytic Microcombustor

The baseline catalytic device contained a 95% porous foam material coated with platinum as the active surface. Porosity can be defined as the open volume divided by the total volume.

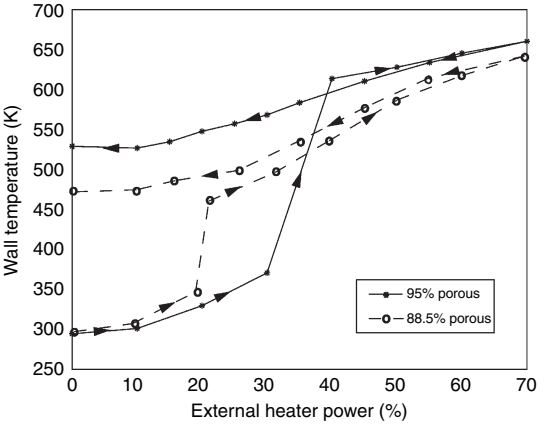

Figure 17 Ignition characteristics for a catalytic microcombustor. (Source: Spadaccini CM 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

$$\alpha = \frac{V_{\text{open}}}{V_{\text{total}}} \qquad [20]$$

Plots of exit gas temperature and overall combustor efficiency for a range of mixture ratios are shown in **Figures 18 and 19**, respectively. The maximum exit gas temperature achieved was approximately 850–900 K over a wide range of flow rates, and efficiencies were up to 30%. The sharp drop in performance at $0.35\,\text{g}\,\text{s}^{-1}$ was a result of transients from the experimental setup that was operating at

maximum flow levels. Although these temperatures and efficiencies are quite low, the mass flow rates achieved were in excess of $0.4\,\mathrm{g\,s^{-1}}$, well beyond those measured for the baseline gas-phase device. The maximum power density achieved was approximately $1050\,\mathrm{MW\,m^{-3}}$, which is a 7.5-fold increase over gas-phase propane–air power densities, and about 95% of that for gas-phase hydrogen–air mixtures (Spadaccini 2004, Spadaccini *et al.* 2007).

The overall combustor efficiency can be divided into its thermal and chemical components. A wall temperature measurement combined with a 1D heat transfer model reveals that heat loss is greater than in the gas-phase case; the losses are dominated by chemical inefficiency, indicating that most of the reactants pass through the device without contacting the active surface. **Figure 20** shows an estimate of the efficiencies in the device for a stoichiometric mixture ratio.

3.15.5.3 Diffusion Characteristics and Timescale Analysis

To determine which phenomena control the combustion process in a catalytic microcombustor, relevant physical timescales can be evaluated. These include reaction time, residence time, diffusion time of the fuel species, and diffusion time of the oxidizer. Residence time can be estimated from the volume, mass flow rate, pressure, and bulk gas temperature as in the gas-phase case (eqn [9]). Reaction rate can be obtained from an Arrhenius-type rate expression. For a propane–air reaction on a platinum catalyst, the following mechanism can be used (Hayes and Kolaczkowski 1997)

$$-R_{C_8H_8} = -k_S[C_3H_8] \qquad [21]$$

where the rate constant is

$$k_S = 2.4 \times 10^5 \exp\left(\frac{-1.08 \times 10^4}{T}\right) \qquad [22]$$

More complex reaction mechanisms can be found in the literature.

Molecular diffusion coefficients for propane and oxygen diffusion through air can be obtained from the Fuller correlation (Hayes and Kolaczkowski 1997):

$$D_{AB} = \frac{1.013 \times 10^{-2} T^{1.75} \left(\frac{1}{M_A} + \frac{1}{M_B}\right)^{1/2}}{P\left[\left(\sum v_i\right)_A^{1/3} + \left(\sum v_i\right)_B^{1/3}\right]^2} \qquad [23]$$

A and B represent the diffusing species and the medium, respectively while M_A and M_B are the molecular weights of the species and v_i is the diffusion volume of each atom in the molecule. Diffusion volumes for carbon, hydrogen, and oxygen are 16.5, 1.98, and 5.48, respectively. A table of diffusion volumes can be found in Hayes and Kolaczkowski or elsewhere in the literature. This correlation is based on collision theory and D_{AB} is in units of square meter per second.

Using estimates of these various timescales, nondimensional parameters can be calculated and used to determine the governing physical phenomena. These parameters and their approximate values for

a catalytic microcombustor are summarized in Table 3. From this simplified timescale analysis, it is clear that the diffusion of reactants to the surface is the controlling parameter. The second Damköhler number indicates that the surface reaction rate is much faster than the rate of diffusion to the surface. The high Péclet number indicates that reactants can flow through the device without coming into contact with the active catalytic surface. The longest timescale in the system is the diffusion time.

If a tubular plug flow reactor is assumed, the Péclet number can be estimated and shown to be a strong function of geometry. For a given set of flow conditions (pressure, temperature, and mass flow rate), the Péclet number can be calculated for a range of diameters (or pore sizes). Figure 21 shows this parameter for $P = 2$ atm, $T = 1000$ K, and a mass flow rate = $0.3\,\mathrm{g\,s^{-1}}$ for both propane and oxygen. For the diameters greater than ~100 μm, the Péclet number is greater than unity. It is also important to note that propane diffuses more slowly than oxygen due to its larger molecular size. This results in a higher Péclet number and indicates that propane diffusion to the active surface is the governing phenomenon.

Table 3 Summary of nondimensional parameters

	Nondimensional parameter	*Range*
Damköhler number for residence time	$Da_h = \frac{\tau_{residence}}{\tau_{reaction}}$	0.5–5
Damköhler number for diffusion time	$Da_2 = \frac{\tau_{diffusion}}{\tau_{reaction}}$	30–500
Péclet number	$Pe = \frac{\tau_{diffusion}}{\tau_{residence}}$	50–130

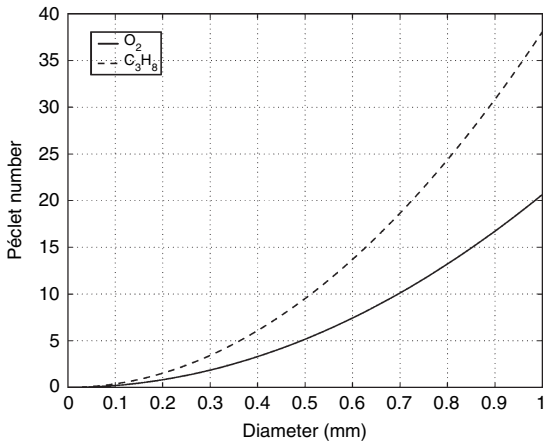

Figure 21 Péclet number versus diameter. (Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

3.15.5.4 Pressure Loss

For many microcombustor applications, minimizing pressure loss through the device is critical. The addition of a porous catalyst material or a monolithic catalyst support can significantly increase the pressure loss of the system.

Pressure loss through a porous substrate can be estimated from the Ergun equation for Reynolds numbers less than 300 (based on the thickness of a fiber or diameter of a catalyst particle) (Hayes and Kolaczkowski 1997):

$$-\frac{dP}{dz} = \frac{v}{L}\frac{(1-\alpha)}{\alpha^3}\left[\frac{150\mu(1-\alpha)}{L} + 1.75\rho v\right] \quad [24]$$

where μ is the viscosity, v velocity through the porous media, and L a characteristic length scale, usually the width of a foam fiber or diameter of a particle in a packed bed. For a monolithic catalyst support, pressure loss through a single channel can be estimated using a Darcy friction factor (Fay 1994)

$$f = \frac{64}{Re_d} \quad [25]$$

and

$$-\frac{dP}{dz} = f\left(\frac{L}{d_h}\right)\left(\frac{1}{2}\rho v^2\right) \quad [26]$$

3.15.5.5 Isothermal Plug Flow Reactor Model

In most cases catalytic microcombustors can be modeled as isothermal plug flow reactors. The equations developed here have been derived from a control volume analysis of a fluid element in a plug flow reactor. These equations, coupled with an isothermal assumption, yield trends in fuel conversion and bulk gas temperature rise through a reactor as a function of flow conditions and geometry.

The Péclet number analysis indicated that the diffusion of fuel species is the governing phenomenon; therefore, only the mass transport and consumption of

the fuel species is taken into account in subsequent derivations. Homogeneous gas-phase reactions will be neglected, and the catalytic reaction mechanism shown in eqn [21] and [22] will be utilized (propane–air over platinum will be used as a model reaction and for comparison to experiment).

A steady-state gas-phase mole balance across the control volume results in

$$C_b v \frac{dY_{f,b}}{dz} + a_v k_m C_b \left(Y_{f,b} - Y_{f,s}\right) = 0 \quad [27]$$

The surface area-to-volume ratio can be written in terms of porosity and foam fiber thickness as

$$a_v = \frac{4(1-\alpha)}{w} \quad [28]$$

A mole balance performed at the catalyst surface yields

$$k_m C_b \left(Y_{f,b} - Y_{f,s}\right) = (-R_f)_S (1-\alpha) \quad [29]$$

whereas an energy balance across the fluid element provides the final equation

$$-\rho C_p v \frac{dT_b}{dz} + a_v b (T_S - T_b) = 0 \quad [30]$$

Analytical solutions to these equations can be found or an appropriate numerical method can be applied to solve the system. In the case of a non-isothermal structure, a fourth energy balance equation across a differential element in the wall, accounting for conduction in the solid, would be required. Also, a similar set of equations can be obtained for a monolithic channel-type system by modifying eqn [28].

Correlations for gases in packed bed reactors can be used to approximate the heat and mass transfer coefficients in porous substrates. These transport coefficients are given in terms of nondimensional j factors – j_D for mass transfer and j_H for heat transfer (Hayes and Kolaczkowski 1997).

$$j_D = \frac{k_m}{v} Sc^{2/3} \quad [31]$$

$$j_H = \frac{h}{C_p \rho v} Pr^{2/3} \quad [32]$$

These j factors can be estimated using the following correlations (Hayes and Kolaczkowski 1997).

$$j_D = j_H = 0.91 Re_j^{-0.51} S_f \quad Re_j < 50 \quad [33]$$

$$j_D = j_H = 0.91 Re_j^{-0.41} S_f \quad Re_j > 50 \quad [34]$$

S_f is the shape factor, and for this analysis, a value of 0.79 was used (shape factor for ring-type structures) (Hayes and Kolaczkowski 1997). The Reynolds number used here can be found from

$$Re = \frac{\rho v w}{6(1-\alpha)\mu S_f} \quad [35]$$

The boundary conditions required to execute this simplified model include the inlet bulk gas temperature, the inlet bulk gas fuel mole fraction (obtained from equivalence ratio), and the inlet surface mole fraction. The catalyst surface temperature also must be specified, which due to the isothermal condition is constant throughout the reactor. A typical set of boundary and flow conditions is summarized in **Table 4**.

Figures 22 and **23** show temperature and fuel concentration profiles, respectively. Along with substrate porosity of 95% and an average foam fiber

Table 4 Typical boundary and flow conditions for reactor inlet in 1D isothermal plug flow model

Parameter	*Value*
T_b (K)	500
T_S (K)	1000
$Y_{f,b}$ (from ϕ)	0.04 ($\phi = 1.0$)
$Y_{f,S}$	0.00
Pressure (atm)	2
Mass flow (g s^{-1})	0.3

Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.

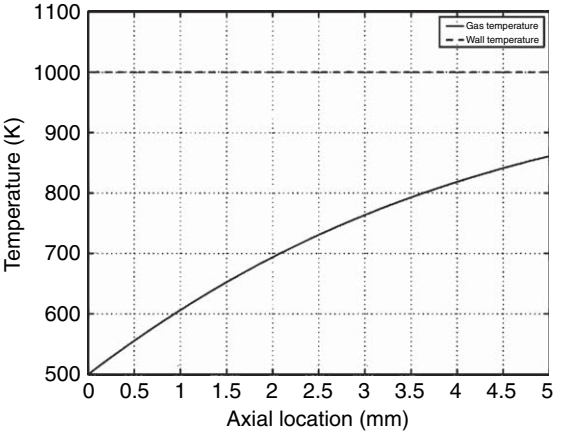

Figure 22 Axial temperature profile in a porous media plug flow reactor. (Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

thickness of 90 μm, the conditions listed in **Table 4** were used to generate these results.

With this model, the effect of key design variables such as porosity and surface area can be further examined. For constant flow conditions, the model can produce fuel conversion profiles for various porosity and surface area materials. **Figure 24** shows trends in fuel conversion for increasing surface area-to-volume ratios using the conditions listed in **Table 4**. The profiles indicate that higher surface area-to-volume ratios (usually a result of lower porosity for a constant fiber thickness) will significantly improve fuel conversion.

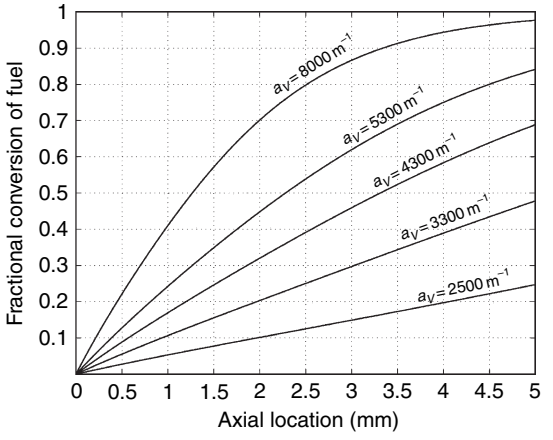

Figure 24 Fuel conversion profiles for various porosities in a porous media plug flow reactor. (Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

3.15.5.6 Operating Space

The 1D isothermal plug flow model can also be used to visualize the operating space of a catalytic microcombustor. **Figure 25** shows lines of constant power density on a plot of total pressure loss through the device versus catalyst temperature for an equivalence ratio of unity. The maximum power density is obtained from the exit gas temperature predicted by the model. **Figure 25** indicates that at higher pressure loss (higher surface area-to-volume ratio) and higher catalyst temperatures, combustor performance improves. It is also clear that by relaxing a given pressure loss constraint and utilizing a catalyst that can survive at higher temperatures, the available operating space will broaden. A representative constraint of less than 5% total pressure loss is indicated by the black line and gray shaded area. The shaded area above a 1400 K catalyst temperature represents an approximate failure temperature for a catalyst layer.

The catalytic microcombustor operating space can be viewed more generally by plotting nondimensional parameters. **Figure 26** shows lines of constant combustor efficiency on a plot of Péclet number versus thermal efficiency. As Péclet number decreases, combustor efficiency increases due to the time available for diffusion of the reactant species to the active surface. However, as heat is lost from the system (lower thermal efficiency), the overall efficiency decreases.

3.15.5.7 Design Recommendations

Design recommendations for heterogeneous catalytic microcombustion systems include the following:

1. High power density catalytic microcombustors are typically diffusion controlled. A designer should seek to approach the high-temperature reaction-controlled regime to maximize performance. This can be achieved by implementing the following:
   a. Utilize the most thermally durable catalytic materials to achieve high-temperature operation.
   b. Utilize the highest surface area-to-volume ratio substrate material available that does not violate the system pressure loss constraint.
   c. Relax the total pressure loss constraint as far as the device performance will permit.
2. Searching for a more active catalytic material is not required unless
   a. the ignition transient is of concern or
   b. the overall design lies in the reaction-controlled regime.
3. High surface area-to-volume ratio catalyst materials result in increased heat loss from the system. As a result, thermal management is more critical than in the gas-phase case. A materials solution such as a thermal barrier combined with a concept similar to the recirculation jacket may mitigate these losses.

3.15.6 Applications – Microcombustors in Practice

There are a large set of applications for microcombustors, most of which involve small-scale power systems or propulsion. These systems can range from microscale heat engines to solid-state power systems and fuel cells. This section will provide a brief review of these applications.

3.15.6.1 Micro Heat Engines

A heat engine can be defined as a device that converts thermal energy into work. The thermal energy results from a temperature difference that is provided by a hot and a cold reservoir. The heat engine utilizes this difference in a thermodynamic cycle. Consequently, there are many types of cycles and heat engines such as a Brayton cycle (gas turbine engine) and an Otto cycle (a spark ignition piston engine). Many heat engines use a combustor as the source for the hot reservoir, and recently, there have been efforts to miniaturize these systems for portable power applications. Combustors for heat engines will be required to provide high-enthalpy gas to the system rather than lose heat through the structure.

The Brayton cycle, or the gas turbine engine, if miniaturized could be used both for portable power by integrating a generator with the system or as a turbojet propulsion device for a small aircraft (Epstein *et al.* 1997, Groshenry 1995). This type of device would require a microcombustor to be integrated with a rotating microscale compressor and turbine. This combustor would need to accept high-pressure air from the compressor and mix and burn fuel, resulting in a high-enthalpy fluid provided to the turbine for work extraction. It is important to note that a combustor for this system should provide this high-enthalpy gas with minimal thermal loss to the structure. An example of a micro gas turbine design is shown in **Figure 27**.

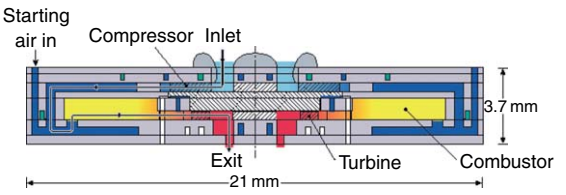

Figure 27 Baseline micro gas turbine engine schematic. (Source: Spadaccini C M 2004 Combustion systems for power-MEMS applications. Ph.D. thesis, Massachusetts Institute of Technology.)

Other microcombustor geometries for Brayton cycles, besides the radial layout shown in **Figure 27**, have been tested as well. These include conventionally machined, small-scale canister geometries. In these designs, combustion efficiencies over 99% have been obtained with hydrogen fuel in a 2-cm^3 chamber and with methane in a 15-cm^3 chamber. The canister devices were also shown to have reduced heat loss when compared with a similarly sized radial design (Isomura *et al.* 2002, Takahashi *et al.* 2002).

Microscale Otto cycle devices have also been studied. Early attempts at implementing these systems typically involved a free piston structure with a spark ignition system at either end of a cylinder. When ignition occurs, hot combustion gases expand, moving the piston to the other end of the cylinder, thus resulting in mechanical work. Again, this type of combustion system would require that enthalpy be retained in the gas and converted to work rather than lost through the structure (Lee *et al.* 2002, Park *et al.* 2002).

Another Otto cycle micro heat engine that has been under development is the micro rotary engine or the micro Wankel engine. In this type of device, there is no reciprocating component, but rather a rotating set of three combustion chambers. Typically, the rotor is triangular in shape and spins in an oval-shaped housing, forming three distinct volumes of gas. Due to the geometry of the rotor and housing, the volume of each chamber changes as the rotor spins. One of these chambers will have a minimum volume and a compressed gas. Fuel is then injected into this volume and ignited. The gas volume expands, causing the rotor to spin. Similar to the piston engine and the gas turbine, the combustor for the rotary engine provides high-enthalpy fluid to drive the system, with the thermal losses through the structure being the primary loss mechanism (Fernandez-Pello *et al.* 2002).

3.15.6.2 Heat Sources for Solid-State Power Generators and Endothermic Reactors

A microcombustor can provide heat for other types of power and chemical systems. Some of these solid-state devices include thermoelectric generators and thermophotovoltaic systems. Thermoelectrics (TEs) are solid-state devices that converts thermal energy into electrical energy by utilizing the Seebeck effect. TEs consist of a p- and n-type semiconductor material connected electrically in series and thermally in parallel. Carriers (electrons in n-type, holes in p-type) transport heat from the hot side of the device to the cold side, which can be used to drive an electrical load. A microcombustor for this type of system would have fundamentally different requirements than those for the fluid power systems discussed in Section 3.15.7.1. A TE device requires that heat be provided through the structure rather than being delivered via a high-enthalpy fluid. The primary loss mechanism is a hot exit gas. For this reason, a catalytic microcombustor that generates heat on the solid and can have a high rate of conduction through the structure is the ideal system (Arana 2003, Schaevitz 2000, Yoshida *et al.* 2006).

A thermophotovoltaic power system uses thermal radiation emitted from a hot structure and converts it to electrical energy with a photocell that is designed to absorb the infrared portion of the spectrum. Like the TE, this solid-state device requires a hot wall rather than a high-enthalpy fluid. Again, the most suitable combustor for this type of system is a catalytic combustor where heat is generated on a surface and conducted through the structure (DiMatteo *et al.* 2001, Wernsman *et al.* 2004).

One other type of system that benefits from heat conduction through the structure is an endothermic microreactor such as a methanol reformer for a fuel cell system. This type of device requires heat to be provided to its walls in order to drive an endothermic chemical reaction (often a heterogeneous catalytic reaction itself). A microcombustor is an ideal heat source for this application. The structures of a catalytic microcombustor and an endothermic microreactor can be thermally coupled. Heat will flow through the wall of the combustor and into the structure of the endothermic system (Park *et al.* 2006).

3.15.6.3 Micro Thrusters

Microscale rockets and thrusters for satellite attitude control, microsatellite repositioning, and even small-scale launch vehicles also may require microcombustors. These devices consist of a high-pressure combustion chamber connected to a nozzle for generating thrust. Fuels can range from liquid hydrocarbons to monopropellants such as hydrazine or hydrogen peroxide and even solid rocket propellants. These combustors do not utilize air as the oxidizer, but instead use stored oxygen. Liquid fueled rockets typically carry liquid oxygen to be injected with the fuel. Monopropellants have oxygen bound within the propellant molecule, and a catalytic reaction is used to break down and burn the propellant species. In solid fuels, the oxidizer is mixed with the fuel grain. In all

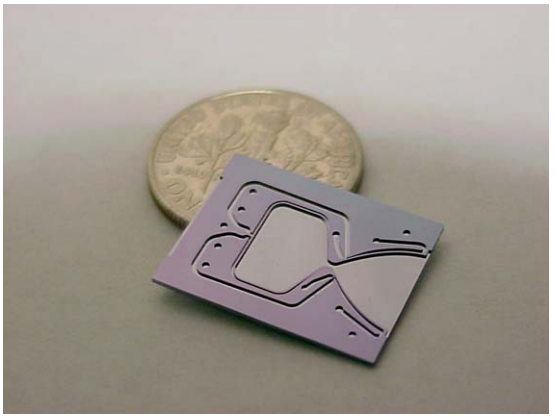

Figure 28 A silicon micromachined regeneratively cooled liquid bipropellant microrocket. (Source: London A P 2000 Development and test of a microfabricated bipropellant rocket engine. Ph.D. thesis, Massachusetts Institute of Technology.)

cases, the combustion process occurs at extremely high temperatures and pressures, resulting in unique requirements for the microcombustion chamber. Usually, a complex active cooling architecture in the structure is required. An example of a regeneratively cooled, liquid bipropellant microrocket is shown in Figure 28. Like the heat engine application, a microcombustor should provide high-enthalpy fluid, in this case to the nozzle for thrust (London 2000).

3.15.7 Future Perspectives

Microcombustors may have broad applications in power MEMS, micropropulsion, and microreactors as these fields mature. Although significant progress has been made in understanding combustion at the microscale, there is still work to be done. Microcombustors must become smaller and more efficient, providing high-enthalpy flow for heat engines and propulsion systems or hot surfaces for solid-state power generators and reactors. In order that these systems be practical, the combustor and its fuel reservoir must not be the limiting component.

To achieve the high power densities required by many applications, a hybrid gas-phase/catalytic microcombustor may be the optimal solution. In this embodiment, the combustor would consist of an initial low-temperature catalytic section that ignites the mixture and raises the temperature to some moderate level. The catalytic reaction would consume some of the fuel and air species but leave enough reactants for a subsequent gas-phase flame-based reaction. It would also raise the temperature to a level at which a gas-phase flame would autoignite, quickly burning the remaining fuel–air mixture and providing a high-enthalpy fluid in a minimum volume.

Other future areas of work will include developing microcombustors that operate with liquid hydrocarbon fuels such as gasoline, JP-8, and kerosene. This will require either injectors that atomize and mix the fuel or prevaporizors that convert the liquid fuel to the gas phase before injection into the combustion chamber. It also will likely require the use of a catalyst to increase reaction rates. Operating at high efficiency and power density with these more commonly used logistics fuels will result in broader applications of micropower systems with combustors.

Another advancement that would result in more practical combustion-based micropower systems is fuel flexibility. A microcombustor that can operate without significant performance change using various fuels could be deployed in scenarios where conventional fuel sources may be limited.

Microcombustors will likely be a part of many small-scale power systems in the future. Similarly, they will play a major role in providing heat to microchemical processors that may have an important industrial impact. Regardless of application, the principles presented here will provide a foundation for the design of microcombustors.

Christopher M. Spadaccini received a Bachelor of Science and Masters of Science from the Department of Aeronautics and Astronautics at the Massachusetts Institute of Technology (MIT) in 1997 and 1999, respectively. In 2004 he received a Ph.D. from the Department of Aeronautics and Astronautics at MIT for his work on "Combustion Systems for Power-MEMS Applications." Dr. Spadaccini is currently a staff research engineer at the US Department of Energy's Lawrence Livermore National Laboratory (LLNL). As a member of the Center for Micro- and Nanotechnology at LLNL, he pursues research in the areas of micro- and nanoscale power systems, microcombustion, fluid mechanics and microfluidics, heat transfer and thermodynamics, as well as new nanostructured materials and novel microfabrication techniques. He has written over a dozen conference and journal publications and is a part-time faculty member in the Chemical and Materials Engineering Department at the San Jose State University. Dr. Spadaccini's work is applied to a broad range of problems including national security, energy, and environmental issues.

Ian A. Waitz received a Bachelor of Science in Aerospace Engineering from the Pennsylvania State University in 1986. In 1988 he received a Masters of Science in Aeronautics from George Washington University, and in 1991 he completed his Ph.D. in Aeronautics at the California Institute of Technology. Currently he is a professor in the MIT Department of Aeronautics and Astronautics and Director of the Partnership for AiR Transportation Noise and Emissions Reduction (PARTNER), an FAA/NASA/Transport Canada-sponsored Center of Excellence. His principal fields of interest include propulsion, fluid mechanics, thermodynamics, reacting flows, aeroacoustics, and, in particular, aspects of the above that relate to environmental issues associated with aircraft design and operation. Professor Waitz pursues experimental and computational research in these areas. He has written approximately 60 technical publications including a report to the US Congress on aviation and the environment, holds three patents, and has consulted for many organizations. During 2002–2005 he was Deputy Head of the Department of Aeronautics and Astronautics. He was an associate editor of the AIAA *Journal of Propulsion and Power*. In 2003 Professor Waitz received a NASA Turning Goals Into Reality Award for Noise Reduction. He is a fellow of the AIAA, and an ASME and ASEE member. He teaches graduate and undergraduate courses in the fields of thermodynamics and energy conversion, propulsion, fluid mechanics, and environmental effects of aircraft. He was honored with the 2002 Class of 1960 Innovation in Education Award and appointment as a MacVicar Faculty Fellow in 2003.

3.16 Micro-Coolers

Junghoon Yeom and Mark A. Shannon, Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Nomenclature

A	surface area where heat transfer occurs
A_{eff}	cross-sectional area of an MHP
A_{surf}	project geometrical area where boiling occurs
c_p	intensive heat capacity or specific heat
d	fan diameter
h	overall heat transfer coefficient
h_{boil}	boiling heat transfer coefficient
k_{eff}	effective thermal conductivity of an MHP
L_{eff}	effective length between the evaporator and the condenser in an MHP
q	heat flux removed
q_{CHF}	critical heat flux – maximum heat flux in the nucleate boiling regime
R_{th}	effective thermal resistance
S	Seebeck coefficient
T	absolute temperature
ΔT	temperature difference between the surface to be cooled and the ambient

ΔT_{sat}	wall superheat ($=T_{wall}-T_{sat}$)	ρc_p	mass specific capacity
ZT	nondimensional figure of merit	σ	electrical conductivity of thermoelectric material
λ	thermal conductivity of thermoelectric material

3.16.1 Introduction

Small to microscale cooling systems exploit an extraordinary number of cooling modalities, ranging from passive to active cooling, air to liquid to solid-state media. These systems are manufactured with an array of technologies including traditional copper machining as well as silicon micromachining for integrated cooling. To begin our discussion of microscale cooling, we need to start with a working definition of a microcooler, which encompasses most of, but not all, the cooling modalities encountered. Miniature systems typically consist of both microscale and mesoscale systems. Mesoscale systems are somewhat larger, on the order of centimeters, with a maximum dimension not to exceed, say, 5 cm. For this chapter, we define microcoolers as devices where the critical heat transfer through the system being cooled occurs at dimensions less than a few hundred microns and where the overall dimension of the system does not exceed a few square centimeters of a planform area. While one may note that the former constraint does not limit the number of devices much, since the heat energy transferred is often limited at interfaces and boundary layers that are less than hundreds of microns, when combined with the second constraint, the task of defining a microcooler becomes easier. The second constraint simply limits the total number of systems considered to a manageable number, while keeping the dimensions small enough that adapting normal or even mesoscale cooling systems to work at the scale becomes a significant technical challenge and is consistent with the definition of microscale cooling by Phelan *et al.* (2001, 2002) as those whose maximum dimensions are on the order of millimeters, such that in principle, they can be incorporated directly at chip level in electronic heat transfer applications to provide localized cooling.

Most microcooling technologies deal with heat transfer from a hotter to a cooler body, and fewer deal with moving heat energy up a temperature gradient or cooling below ambient temperature. Our intent is to review the current state-of-the-art mechanical microscale cooling fundamentals and devices and to discuss the strengths and shortcomings of each. Out of the huge number of cooling technologies, we will also focus on microcooler systems that can be miniaturized and incorporated into packaging at the chip, substrate, or board level, which can be integrated into systems for electronic cooling, and/or lightweight and portable systems used in military or medical applications. We should also note that there are a tremendous number of articles on numerical simulation of microcoolers to better understand and optimize the systems. However, a review of analytical and computation modeling related to microcooling technologies is beyond the scope of this chapter.

The objectives of this chapter are to

(1) critically review available small-scale microcoolers to discuss the potentials and challenges of both conventional and emerging cooling technologies;
(2) assess and suggest future microcooling technologies for two major applications of electronics cooling and portable coolers for military/medical uses;
(3) address the question of whether we can apply some of the well-developed technologies for electronics cooling to less developed portable applications.

We will also discuss how the development of MEMS technology relates to microcooler technology via (McGlen 2004, Munkejord *et al.* 2002, Perret *et al.* 2002, Punch 2005)

(1) integration of microcoolers into silicon chips and the thermomechanical issues that arise when different materials with different CTEs are used at the interface;
(2) advancements that microfluidic devices such as pumps, valves, and microchannels have on microcooler technologies, and some of the remaining outstanding issues.

3.16.1.1 Applications of Microcoolers

Microcooling technologies for electronics cooling have been actively researched and developed in both industry and university research. More than 95% of the papers, proceedings, and proposals address the issues related to electronics cooling. Much less written work has been publicized about portable microcoolers for military and medical purposes, which indicate that most of the ideas and research are still formative and ongoing for other applications.

3.16.1.1.1 Electronics cooling

One might wonder why so much effort has been, and continues to be, expended on developing microcoolers for electronics heat transfer. Current methods of heat removal involving extended surfaces and fan arrays that are frequently used in electronics become insufficient as more powerful electronic components dissipate more heat while the space around these components continues to be reduced due to miniaturization trends of electronic systems (Garimella *et al.* 2002). Exacerbating these macroscopic trends, at the level of the electronic chip, the ever-higher densities of transistors and dissipative elements fabricated on silicon are being interconnected with multiple layers of thin-film structures of dielectrics and conductors, which act to trap heat and slow heat transfer from the active elements. The thermal conductivity of thin films can be one or two orders of magnitude lower than that of the bulk material, so even small increases in power dissipation in a thin-film region may cause serious local heating in microelectronic devices. Many of the important parameters governing the operation of active elements, such as electron and hole mobility, dopant migration, and Schottky barrier, are strongly temperature dependent, and even a few degrees increase can cause errors or premature device failure. In addition, the trend to reduce operating voltages in digital systems reduces the total voltage differential separating a "1" from a "0." Thus, thermal voltage fluctuations are becoming more significant for proper digital system operation. In many instances the standard techniques used today cannot achieve the required cooling performance due to physical limitations in heat transfer capabilities. These limitations are principally related to the low thermal conductivity of air for convection, and the maximum amount of heat that can be conducted by the materials used in the electronic systems.

Figure 1 shows a comparison of various cooling techniques as a function of the attainable heat transfer in terms of the heat transfer coefficient. The heat transfer coefficient of natural cooling in air, relying on both free convection and radiation, is around $10\,\mathrm{W\,m^{-2}\,K}$ ($10^{-3}\,\mathrm{W\,cm^{-2}\,K}$), which limits heat flux removed to air below $0.05\,\mathrm{W\,cm^{-2}}$ at the cooler–air interface. In order to successfully remove heat fluxes at the chip–cooler interface that are expected to be in excess of $120\,\mathrm{W\,cm^{-2}}$ by 2010, and $180\,\mathrm{W\,cm^{-2}}$ by 2018, according to the International Electronics Manufacturing Initiative (iNEMI Report 2005), a very large heat sink or an unacceptably large chip-to-ambient temperature difference would be needed. To accommodate a heat flux of more than $100\,\mathrm{W\,cm^{-2}}$, at a temperature difference of 50 K, requires an effective heat transfer coefficient of $2\,\mathrm{W\,cm^{-2}\,K}$, which is more than three orders of magnitude higher than natural convection to the chip itself can supply. Moreover, it is becoming higher than even forced convection over an enlarged area of an aluminum or copper heat sink can potentially provide. For instance, even with a 100 to 1 area increase and $150\,\mathrm{W\,m^{-2}\,K^{-1}}$ forced heat transfer

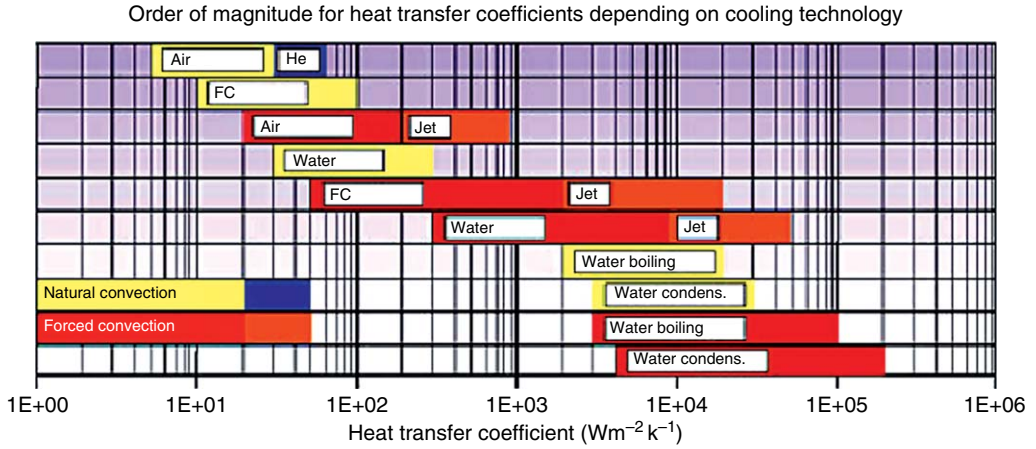

Figure 1 Heat transfer coefficient attainable with natural convection, single-phase liquid forced convection and boiling for different coolants. (Source: Lasance C 1997 Technical data column. *Electronics Cooling* **3(1)**, http://www.electronics-cooling.com/articles/).

coefficient from **Figure 1**, an isothermal (infinite thermal conductivity) heat sink does not quite reach what is needed. From **Figure 1**, it appears that there will be a need for liquid cooling or other heat transfer enhancement, such as microcoolers, in the future of thermal management. The majority of this review will be dedicated to discussing a number of promising thermal management technologies that are emerging for electronics applications. A particular emphasis is placed on so-called on-chip cooling, a result of the integration of a microcooler into the electronic devices to be cooled. Recently, optoelectronic devices that generate significant amounts of heat (100–1000 W cm^{-2}) and often require an operating temperature below the room temperature for better performance need active cooling, which has led to the use of compact refrigeration systems (Burger 2001, Little 1984). Nascent active microcooling system research will also be touched on in this review to meet these subambient temperature cooling applications.

3.16.1.1.2 Microclimate cooling

Protective garments have been proposed to cool military personnel on active duty in hot desert climates or other hazardous environments where personal microclimate control is required. Sealing off military personnel from the surrounding environment with a protective suit made of impermeable layers of material is the only effective barrier to many nuclear, biological, and chemical weapons. However, sealing off the body from transfer of gases and perspiration for any substantial time raises potentially life-threatening problems of heat stroke that needs enhanced cooling. A number of other nonmilitary applications also offer potential application for the microclimate controller fabric, such as use by firefighters, astronauts, surgeons operating in elevated temperature rooms, and users in private sector chemical and industrial hazardous operating environments. There are many nonpersonal cooling applications such as temperature-sensitive package shipping, individual beverage cooling, glove box and car seat cooling, and even thermal signature management. There has been limited research and development of lightweight portable microclimate cooling, which will be discussed briefly in this chapter.

3.16.1.1.3 Drinking water cooler

Maintaining adequate hydration levels for combat soldiers during field operation in hot climates is critical to an individual's performance and even their lives. Under exertion, 1–3 liter of water per hour is lost through evaporation that needs to be replenished. Similarly, outdoor enthusiasts, e.g., hiking, biking, and engaged in sports face similar water demands. Soldiers carry their water supplies on their backs in an ergonomically designed bladder-type reservoir commonly referred to as the On-the-Move Hydration System, and similar systems are available for civilian uses. Although some of the commercial products are designed to provide a means for soldier hydration during operation in extreme cold environments, no system is yet built to offer an active cooling to drinking water warmer

than body temperature in the hot desert environments. Supplying cooled water to soldiers and people under high exertion in hot climates is important for two main reasons. First, drinking cool water lowers body temperature, preventing heat-related injuries, such as heat stroke. Second, people have difficulty consuming large quantities of hot water, which can reach 50°C in desert climates. Therefore, a lightweight, portable, active water cooler unit needs to be developed to cool drinking water below body temperature.

3.16.2 Challenges Related to Microcooling Technologies

In electronics cooling, several challenges exist: (1) remove ever-increasing heat fluxes approaching the flux at the surface of the sun; (2) scale down the overall system to be compact and compatible with the existing electronics; (3) transfer heat to air (ultimately), which has low heat capacity; (4) spot removal of heat energy where the Biot number of the system is small; (5) nonlinear heat removal due to the addition of energy at the junction to be cooled; and (6) low enough cost and high enough reliability to be successful in the marketplace.

For military and medical applications, the issues are tightly related to whether or not the device to be cooled is portable and/or needs to be lightweight and small in volume. The challenges include (1) cooling energy density and power density, providing an overall cooler system (including unit, coolant, and battery if required) that is lightweight and small enough to be portable, which is related to scaling; (2) a cooler that has the desired cooling rate at the temperature that it needs to operate at; (3) energy consumption that does not need high-voltage source or complex electronics; (4) robust operation; and (5) cost.

Microcooler technologies can, in a broader sense, be categorized into two areas: refrigeration cooling and nonrefrigeration cooling (Phelan *et al.* 2001). Refrigeration cooling refers to a system that can lower the target temperature (e.g., the junction temperature in the electronic chip) below the ambient temperature or at least below the temperature that a nonrefrigeration system can accomplish. Since nonrefrigeration cooling uses natural/forced convection to air or liquid and/or the phase change of a liquid, the lowest possible temperature will be limited by the temperature of the medium (air or liquid) used for the low-temperature reservoir, i.e., the ambient temperature. Therefore, nonrefrigeration cooling is useful only for cooling devices hotter than the ambient. It will not, however, be effective to lower the temperature of human bodies or drinking water exposed to hot ambient conditions.

Central to our discussion of microcoolers for the above applications is the ability to remove excess heat from the device. The heat flux carried away from the device being cooled, given simply by $q = hA\Delta T$, is proportional to the heat conductance term (hA), a product of the heat transfer coefficient and the surface area where heat transfer occurs, and the temperature difference between the surface of the device and the environment to which the heat is being rejected. Often, the temperature of the low-temperature reservoir is higher than the surrounding ambient temperature, such as a device rejecting heat within a computer case, in which numerous other heat-producing devices heat up the air within the case. Another example is within tanks and personnel carriers, where significant amounts of heat are generated by weapons, communications, and control systems, which often exceed the ability of air conditioning systems to remove, particularly in hot ambient desert environments. Similarly, for new high-performance military aircraft, the design is being driven more and more by the need to remove heat energy produced by increasing high-powered avionics packages.

In electronics cooling, the surrounding low-temperature rejection reservoir is typically lower than the chip heat rejection surface temperature, allowing heat to be spontaneously transferred out of the chip without supplying active refrigeration cooling. Due to the specification of the electrical components, there is often a maximum allowable temperature at which the device should be operated, capping the maximum attainable ΔT (a typical allowable temperature difference of 60°C between the component surface and the ambient). For consumer electronics such as computer processors, often an 85°C maximum chip case temperature is specified, with the intent of holding the silicon device temperature to less than 125°C. Above this device temperature, significant degradation in performance is often noted for silicon devices. Military and special device specifications often exceed 125°C, and newer high-temperature transistors are being actively developed to significantly raise the maximum operating temperature in order to lessen the relatively stringent absolute temperature cooling systems must maintain. However, the trend toward higher device densities

combined with a higher-frequency operation well into radio and microwave frequencies both act to increase the heat flux that must be removed, regardless of the specific maximum operating temperature. In addition, since electronic devices themselves are being packed with higher densities within the overall system, higher rejection temperatures available due to higher permissible device temperature operation act to increase the overall temperature reservoir to which the system's devices reject to. Therefore, the goals in designing the thermal management systems have been to (1) increase the heat exchange surface area as large as possible and/or (2) increase the overall heat transfer coefficient.

As will be discussed, increasing the surface exchange area is limited by the thermal conductance of the heat sink/exchange system being employed and the total size and weight permitted. Thus, increasing the surface area using normal-scale electronic cooling systems is rapidly reaching practical limits. Similarly, increasing the overall heat transfer coefficient, which is typically proportional to the air velocity raised to a power less than one, by increasing cooling air speed is limited by fan power consumption, which is proportional to the velocity squared. From a system perspective, at some point for any given system, adding more power, even if it is available (which is decidedly not true for portable systems), will potentially generate more heat than is removed. However, both the heat exchange area and the heat transfer coefficient are also coupled together through characteristic length scales of the heat transfer and system. As will be discussed, when the phenomenological length scale associated with the heat transfer, such as the fluid boundary layer and the thermal diffusion length, are on the same order as the physical length scale, enhancements in the total heat transferred are possible. Importantly for microcoolers, several key phenomenological length scales are in the submilliter range, or well within the microscale. Therefore, microscale passive cooling technologies have sprung out of research to address both the goals of thermal management systems.

While nonrefrigeration microscale cooling enhancement has dominated microcooler research and development thus far, there has also been significant, but nascent research in microscale refrigeration cooling. Advances in microscale passive cooling can certainly be helpful but is not sufficient when the ambient temperature is hotter than the target temperature of the system, such as with many optoelectronic applications, and microclimate or drinking water cooling. Active cooling capacity by the addition of energy is needed. Many different types of active cooling technologies have been proposed, both solid-state and mechanical. Solid-state thermoelectric coolers have received the bulk of the research, since the method has been well known and actively developed over several decades, and many thermoelectric coolers have been commercialized for cooling numerous electronic systems, including sensitive low-temperature optical sensors. Since the active heat pumping mechanism is the transport of hot charge carriers across a semiconductor junction, solid-state coolers have the potential to be scaled down to the microscale. Similar thermoionic coolers also have this potential. Integrating solid-state coolers with microfluidic heat exchangers that are being developed for nonrefrigeration microcoolers offers the potential to provide the subambient temperature cooling needed. As will be discussed, the main issues thus far with solid-state cooling are the low coefficient of performance (COP) of solid-state coolers. The COP is the ratio of heat transferred to the power supplied to move the heat. Current fully integrated solid-state microscale systems have COPs less than one, which leads to difficulties with operating temperature regimes and thermal runaway. However, a great deal of research is being expended to increase the thermal efficiency of solid-state coolers, such that the COP of the system will potentially be far above 1, approaching that of large-scale mechanical refrigeration systems. We will briefly discuss some of the ongoing research, particularly related to fabricating micro- to nanoscale thermoelectric elements.

Due to the inherently high COP of normal-scale mechanical vapor compression refrigeration systems, which can be as high as 4–8 depending on the temperature lift and absolute temperature, there has been some research into miniaturizing mechanical refrigerators to the meso- and microscales, as will be briefly discussed. However, meso- to microrefrigeration mechanical cooling technologies for electronics cooling have not yet been successfully commercialized, to the author's knowledge. Mechanical refrigeration cooling for portable devices used in military or medical applications is even further from being realized. While mechanical microcoolers also benefit greatly from the passive microcooler technology developed thus far, the main reason for the lack of adoption of mechanical vapor compression refrigeration is the lack of reliable and/or low-energy consumption gas microcompressors. Vapor

compression cycles work by compressing a refrigerant to a higher pressure, increasing the temperature of the vapor. The vapor condenses into a liquid as heat is rejected to the ambient-temperature heat reservoir. On expansion to a lower pressure in the evaporator, the liquid vaporizes and absorbs heat at the low temperature, thereby providing cooling power. Compression ratios greater than 1 are often required for most potential refrigerants. The problem is that the ability to compress gas does not typically scale well as dimensions are shrunk, particularly to the microscale. While there exist microscale methods to achieve high compression ratios, as will be discussed, the process is highly inefficient, again reducing the overall COP to well below 1. We will discuss the state of fluid compressors development and the open questions that remain to be resolved and other aspects of vapor compression microcoolers.

3.16.3 Microcooling Technologies with Related Principles

As noted earlier, nonrefrigeration cooling is only effective in lowering the temperature of a surface much hotter than ambient and therefore has been exclusively developed for electronics cooling. In fact, most of the existing cooling solutions for microelectronics equipment are based on nonrefrigeration cooling. Discussion on nonrefrigeration cooling, therefore, is limited to the application of electronics cooling. Refrigeration cooling also must transfer heat ultimately to an ambient thermal reservoir, so the techniques discussed for electronic cooling are for the most part completely applicable to active systems as well, with respect to condensers, evaporators, and heat rejection heat exchangers and fans. The first system we consider is the use of the mesoscale fan to induce the convective flow around the heat sink, which is known to reach its limit for cooling of high heat flux electronics. Major research efforts have also been, and continue to be, focused on liquid cooling (using a single-phase or two-phase) that shows commercial viability, both for the present and for the near future. A variety of miniature heat pipes, for instance, can be ubiquitously found in many laptop computers as heat spreaders to provide higher cooling power than microfin-based copper sinks, which will be presented. Finally, active systems will be briefly presented: solid-state thermoelectric, electrokinetic, and electrostatic fluid pumps.

3.16.3.1 Air Cooling

Even though the standard air-cooling technique using a fan with a heat sink appears to reach its limit for cooling of high-power electronics, the idea of using ambient air as a coolant will remain valid and attractive for several reasons. Most of the liquid cooling techniques, including heat pipes and microchannel heat exchangers, play a role as heat spreaders and still rely on air cooling for their terminal dissipation to the surrounding air. Moreover, cooling small portable electronic devices requires a low profile, so direct air-cooling techniques may remain viable when other cooling techniques that use liquid pumping or refrigeration cycles may be too large or energetic to satisfy constraints placed on the system. A heat transfer coefficient based on pure natural convection ranges from 1 to $10\,W\,m^{-2}\,K$ while forced convection with a standard rotary fan can push a heat transfer coefficient up to $150\,W\,m^{-2}\,K$ with acceptable noise levels (Lasance and Simons 2005). A recent review article describes the limitations and key challenges of conventional air-cooling technologies (Rodgers *et al.* 2005). Innovative schemes enhancing air movement have emerged in smaller scales to extend the useful range of air cooling by enhancing hA. We will present recent developments on microfans, piezoelectric fans, and microjet cooling.

3.16.3.1.1 Microfans

The seemingly endless pursuit to miniaturize consumer electronics and pack more functionality into them has led to the commercialization of mesoscale (order of 10 cm) fans to cool high-powered chips. However, there are no commercial fans currently available that are small enough to cool very small, portable, high-powered electronic devices. Laptops now use small axial fans to cool microprocessors with integrated heat sinks attached to the chip casing. However, these fan and heat sink combinations are not sufficient to cool more powerful microprocessors that are used in desktop systems that require more powerful fans, heat pipes, and even active cooling systems to enable their use. The miniaturization effort for axial flow fans faces limitations due to two main reasons: difficulty in fabrication and an unfavorable trend in the aerodynamic performance of the fan. Grimes *et al.* (2003) investigated the issues of scaling of microfans by fabricating a series of geometrically similar 3D microaxial flow fans with representative sizes (120, 40, and 6 mm of fan diameters, d) and quantifying the performance of the

fans in terms of entropy generation. They used micro electrodischarge machining (μEDM) to fabricate the smallest fan tested that had a 6-mm diameter and a 25-μm blade tip clearance. They did not use silicon MEMS technology, with which it is difficult to produce 3D shape of the blades.

In general, a reduction in size of a fan results in a reduction in its efficiency, which is caused by a relative increase in entropy generation (Massey 1983). Further analysis showed that there is a larger increase in the local entropy generation rate as the diameter is reduced ($\sim d^{-1/2}$) in the laminar boundary layer than the entropy generation rate in the turbulent boundary layer, which is only weakly inversely dependent on the length scale ($\sim d^{-1/7}$) (Grimes *et al.* 2003). Since laminar flow dominates with microscale fans, their efficiency and performance become poorer as the diameter of the fan is reduced. Recently, the same group from the University of Limerick reported similar aerodynamic disadvantages for micro radial flow fans fabricated by stereolithography as the fan size is reduced below 10 mm (Hanly *et al.* 2005). They also investigated the integration of the microfans into low-profile portable electronics (Walsh and Grimes 2006). **Figure 2** shows a micro radial flow fan made using stereolithography, and the copper heat sink with a center hole that the fan is inserted into. On spinning, cooler air is drawn by the fan across the evenly spaced radial fins, and the subsequently heated air is exhausted.

Along with the penalty that smaller fans run at a lower efficiency than larger fans, acoustic noise generated by a microfan is another important issue. As the heat flux from the electronic devices increases, the fan has to run at a higher rotational speed, and vibrational noise is typically proportional to the harmonics of rotational speed and the tip-to-edge distance per unit volumetric flow rates. Typically, if the radius of the radial fan is decreased one order of magnitude, the rotational speed needs to increase one order of magnitude to maintain the same volumetric flow rate per unit of planform area. Also, it is often difficult to proportionally decrease the tip-to-edge distance when reducing size. Therefore, both the rotational speed and the bypass tip flow rate, which is a major source of noise and losses, are higher. Of course, the smaller size reduces the overall magnitude. However, it can be hard to control the noise level, particularly at higher frequencies. Similarly, the power consumption per unit volumetric flow rate also typically increases with the rotational frequency squared. Thus, smaller-size systems may consume more power for a given cooling power needed.

3.16.3.1.2 Piezoelectric fans

Radial microfans are not the only type of fan being developed. Piezoelectric bimorph-type fans have been proposed and initial development conducted to provide a small, low-noise, low-power devices in thermal management systems for supplemental cooling in hot spots and other stagnant areas of small portable electronics (such as cell phones) where a rotary fan is ineffective (Bürmann *et al.* 2003). A piezoelectric fan utilizes a piezoceramic patch or several patches bonded to a thin flexible blade (shim material) that flaps back and forth due to an alternating voltage applied to both sides of the piezoelectric patches. **Figure 3** shows a schematic of a piezoelectric fan and the electrical driver circuit. The fan produces a streaming airflow in a direction transverse to the blade with vortices shed off from its

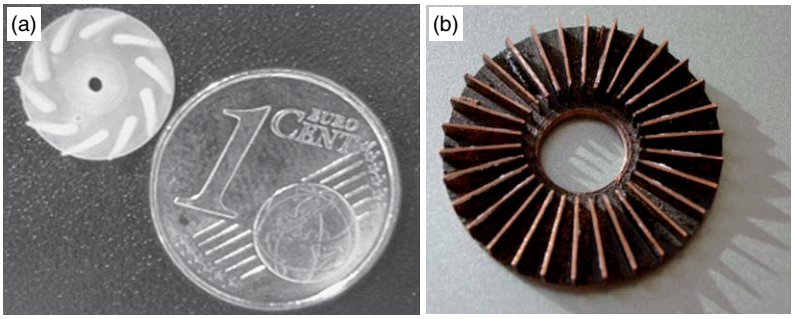

Figure 2 Photographs of (a) a fan and its size relative to a one cent Euro coin and (b) a manufactured heat sink with 30 fins whose thickness is 0.5 mm. (Source: Walsh E, Grimes R 2006 The development of an integrated fan and heat sink solution for thermal management in low profile applications. *Proc. ASME ICNMM2006 4th Int. Conf. Nanochannels, Microchannels, Minichannels*, Limerick, Ireland, June 19–21, 2006).

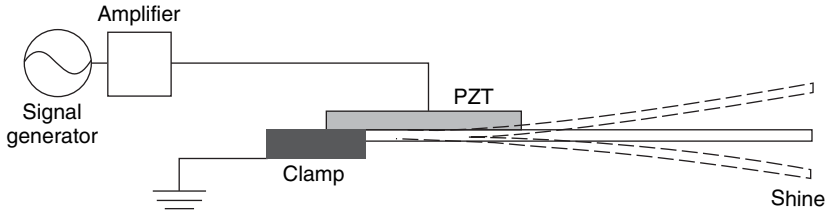

Figure 3 A schematic of a piezoelectric fan and driver system. (Copyright 2004 from Experimental investigation of the thermal performance of piezoelectric fans. *Heat Transf. Eng.* **26(1)**, 4–14 by Açikalin T, Wait S M, Garimella S V, Raman A. Reproduced by permission of Taylor & Francis Group, LLC., http://www.taylorandfrancis.com)

tips. The main features that make the piezoelectric fans well suited for cooling of portable electronic applications are the low acoustic noise levels (via tuning the first mode of resonance outside the range of frequencies audible to the human ear) and low power consumption (via driving the fan at resonant frequency) (Açikalin *et al.* 2004). Of course, air or another fluid will act to damp out the resonance; thus, the design must ensure that the structure is not critically damped or overdamped to exploit resonance driving.

Since Toda first introduced the piezoelectric fans for electronics cooling in the late 1970s (Toda 1979), numerous researchers developed different types of piezoelectric fans and demonstrated the enhanced heat and mass transfer rates for the system interested (Loh *et al.* 2002, Schmidt 1994, Yoo *et al.* 2000). Flow visualization together with the simulation using analytical and computational models has been used to optimize the location of the fans with respect to the cooled surface (Açikalin *et al.* 2004, Bürmann *et al.* 2003, Schmidt 1994). The Garimella group built prototypes of the fans, tested them in enclosures with dimensions similar to a cell phone and a laptop computer, and reported up to a 100% enhancement over natural convection heat transfer (Açikalin *et al.* 2004).

Typical sizes of the fans investigated thus far are rather large, their widths ranging from 1 to 3.5 cm, their lengths from 6.5 to 12.8 cm, which put their overall dimension a bit outside our definition of the microcooler. For a given thickness of the fan (usually tens of microns), smaller sizes of the fans are desired, but their resonant frequency may fall into an audible range. More importantly, high operating voltages (40–140 V) and the complex circuitry needed for the AC power supply have limited this device from being integrated into portable electronic devices, particularly those sensitive to high-voltage-induced noise.

3.16.3.1.3 Microjet cooling

A forced air convection cooling technique using an impinging jet of air is well known and can be found in many industries because of its high heat transfer coefficients with relatively low pressure drops. Martin (1977) summarized early research in macroscale jet impingement heat transfer where the focus was on optimizing the transport processes associated with steady impinging jets. Since this time, it has been proposed to use a single impinging jet to spot-cool critical components in electronic devices, and an array of impinging jets to cool entire circuit boards. Numerous theoretical and numerical computational studies have dealt with microjet impingement cooling of microelectronics (Boeschoten *et al.* 2000, Chiriac *et al.* 2001, Chiriac and Rosales 2003). It should be noted, however, that microjet refers to the size of the jet impinging on the surface, not the overall dimension of the device. These studies commonly report cooling enhancement with the flow transition from laminar to turbulent and from steady to unsteady. Also, the nozzle-to-substrate distance, the geometry of individual nozzles, and array spacing of the nozzles are important design parameters.

Brignoni and Garimella (1999) built a macroscale test setup to experimentally optimize the performance of confined impinging air jets used in conjunction with a pin-fin heat sink. They found that the heat transfer rates are weakly dependent on a nozzle-to-target spacing and are more influenced by the geometry of the impinging substrate and a nozzle diameter for a given Reynolds number. Wu *et al.* (1999) developed a micro impinging-jet heat exchanger integrated with a 8×8 MEMS temperature sensor and heater to facilitate a 2D surface temperature measurements. The MEMS nozzle arrays were made using MEMS fabrication processes, such as photolithographic patterning, KOH etching of bulking silicon, and fusion bonding (**Figure 4**). Using a single microjet (500 μm diameter driven by

(Source: Allan R 1999 MEMS micro heat exchanger employ impinging jets to boost cooling efficiency. *Electron. Des.* **47(7)**, 29–30).

35 kPa pressure), Wu *et al.* were able to cool the temperature of the sensor chip (2 cm × 2 cm) from 70 to 33°C with 1.12 W heat removal. Another silicon microjet array was built to cool electronics by stacking four wafers (Stefanescu *et al.* 1999). Deep reactive ion etching (DRIE) techniques were extensively used to create a 18 mm × 18 mm × 0.4 mm stagnation chamber with an array of 0.25-mm diameter nozzles.

The impinging microjet cooling devices discussed thus far, however, need a pressurized gas source such as compressed air, which limits the utilization of technology for cooling many portable electronics. Recently, synthetic (zero net mass flux) jets have drawn considerable attention as they have the advantage of using ambient air, thus doing away with the necessity of plumbing high-pressure channels associated with traditional jets. A synthetic jet is formed from the entrainment of surrounding fluid that is then expelled in a jet. For spot cooling, cool ambient air is entrained in the synthetic jet device and then the expelled jet impinges on the top hot surface to be cooled, as shown in **Figure 5**. Due to the pulsating

nature of the flow, synthetic jets introduce a stronger entrainment than conventional steady jets of the same Reynolds number and more vigorous mixing between the wall boundary layers and the rest of the flow. A group at Georgia Institute of Technology developed a miniaturized synthetic jet device consisting of a vibrating diaphragm (a circular latex membrane with a diameter of 25 mm and a thickness of 225 μm), a small electromagnetic actuator to drive the diaphragm, and a housing with an orifice of various sizes, as shown in **Figure 6** (Campbell *et al.* 1998, Kercher *et al.* 2003). Campbell *et al.* (1998) reported a 22% reduction in the temperature rise in the CPU of the laptop computer when synthetic jet cooling was used instead of a normal fan. Kercher *et al.* (2003) investigated various design parameters of the synthetic jet cooling device and optimized the cooling performance for resonant frequency, orifice-to-chip spacing, orifice size, etc. Mahalingam *et al.* presented a modified version of the synthetic jet cooler similar to conventional jet ejector and integrated it into a cooling module to determine the cooling performance, which turned out to be six to eight times greater than that of comparable conventional turbulent flow (Mahalingam and Glezer 2003, 2005, Mahalingam *et al.* 2004). More recently, Pavlova and Amitay (2005) experimentally investigated the efficiency of synthetic jet impingement cooling using thermocouples and microparticle imaging velocimetry (μPIV) and concluded that synthetic jet cooling is up to three times more effective than steady jets at the same Reynolds number.

Clearly, the synthetic jet cooling technique exhibits its high potential to be utilized in electronics cooling because of its sourceless, simple operation with relatively low power consumption (less than a half watt to drive a solenoid). Further miniaturization of the jets in specific geometries related to specific device placement has real potential to revolutionize many microcooler applications. However, the heat transfer

coefficients achieved thus far range from 77 to 94 $W\,m^{-2}\,K$ (Kercher *et al.* 2003) compared with about 400 $W\,m^{-2}\,K$ for a large high-performance fan with heat sink. Therefore, further improvement still needs to be made to outperform a conventional fan-based air cooling, perhaps by augmenting liquid thermal management solutions for high heat flux electronics.

3.16.3.2 Liquid Cooling

Tremendous research efforts have been directed to develop small liquid cooling devices to take full advantages of the potential of liquid cooling. Microelectromechanical systems (MEMS) and microfluidics are relatively new technologies that exploit existing microelectronics infrastructure to create complicated micromachines or devices that can move and control fluids. Recent progress in MEMS and microfluidics can potentially provide a microfluidic-based thermal management solution for cooling integrated circuits with high heat fluxes. The eventual goal for liquid thermal management is to integrate miniaturized or microcooling techniques (e.g., flow heat exchangers, liquid jet or spray coolers, and heat pipes) into electronic circuitry on the same substrate using the same fabrication facility, so that low-cost, but highly advanced and functional systems can be created.

Liquid cooling for application to electronics can be categorized in a couple of different ways: (1) indirect or direct liquid cooling, depending on whether the liquid is in a direct contact with the components to be cooled or pass through separate heat exchangers and/or other material structures (Lasance and Simons 2005) and (2) single-phase or two-phase fluidic cooling (Mudawar 2001). The direct cooling method such as immersion cooling can theoretically produce higher cooling power because of the absence of the interfacial thermal resistance but limits the choice of the liquid coolants and the type of the fluid actuation. Two-phase cooling, in general, can produce a large increase in the removal rate of heat flux with only a modest increase in device temperature, but with potential complications in fluid dynamics and system complexity and control. There is, however, no clear distinction of which device belongs to what category. In fact, many of the cooling devices discussed in the literature can be realized in either way; for example, a thermosyphon can be configured in a direct or an indirect mode, and the microchannel heat exchanger can have a single-phase and/or two-phase cooling. In the context of microcooler technology, we discuss the important working principles of cooling for each system, such as boiling heat transfer in two-phase cooling, and focus on examples of liquid cooling devices employing such principles.

Before beginning the discussion, the main motivation of why liquid coolants are heavily researched and developed in microcoolers is the potential for increasing heat flux removal. Compared with that of air, the capacity of most liquids to store energy is considerably higher, i.e., the intensive heat capacity, c_p, of liquid water at room temperature ($\sim$4.2 $J\,g^{-1}{}^{\circ}C^{-1}$) is four times that of air, and the mass specific capacity, ρc_p, is 4000 times greater. In addition, the thermal conductivity at room temperature ($\sim$0.6 $W\,m^{-1}{}^{\circ}C^{-1}$) is 24 times greater than air ($\sim$0.024 $W\,m^{-1}{}^{\circ}C^{-1}$). Of course, water is an extraordinary molecule, and other liquids that are used for their dielectric properties such as fluorocarbons have considerably lower differences but are still far higher than air. Therefore, single-phase liquids can adsorb and transfer significantly more heat. Allowing a liquid-to-vapor phase change increases the amount that can be absorbed and transferred by orders of magnitude more than for a single phase of the same substance. Recent reviews on various liquid coolants and their thermophysical properties are available elsewhere (Mohapatra 2006, Mohapatra and Loikitis 2005). Gambill and Lienhard (1989) estimated the maximum theoretically possible heat flow removed by boiling based on water molecules turning into vapor without influencing each other to be 2000 $k\,W\,cm^{-2}$, although the highest reported experimental value is over 200 $k\,W\,cm^{-2}$, using high velocities and high pressures (Lasance and Simons 2005), which is still nearly three orders of magnitude higher than the highest air-based transfer. Some liquid microcooler devices discussed later can handle a few hundred watts per square centimeter, and there is significant potential by making use of nano- to microstructured geometries of pushing the microscale heat transfer much closer to the theoretical maximum, which is why liquid microcooler research is so promising.

3.16.3.2.1 Passive two-phase heat spreaders

In traditional electronics cooling, heat sinks of high thermally conducting materials are utilized to conduct heat from the electronic chip to the larger surface areas of the heat sink where the heat is rejected to the coolant via natural or forced convection. The merit of heat spreading to lower the heat flux density by increasing heat transfer area can be

compromised, however, as the device size becomes smaller and the thermal resistance across the smaller and/or thinner heat sink is no longer negligible. Passive two-phase heat spreaders such as thermosyphons or heat pipes have been developed and nowadays have found use as heat spreaders for CPU in many computers. The advantages of thermosyphons or heat pipes stem from harnessing the two-phase phenomenon including (1) the latent heat of vaporization of the coolant can take away considerably more heat than the sensible heat change of the fluid and (2) liquid temperature in the cooler is approximately constant, minimizing thermal resistance and entropy generation in heat spreaders. According to Fourier's law, the ability of transporting large amounts of thermal energy between two points (evaporator and condenser) with a small temperature difference is equivalent to having an extra high thermal conductivity (higher than copper), which is analogous to near superconductor under an electrical field (Tien 1975). Thermosyphons and heat pipes are also attractive for microcooler devices because there is no need to drive fluid with active micropumps, making them simpler, lighter, more compact, and less expensive. These advantages become even more important as the device size is miniaturized further, and the space to accommodate a microcooler becomes tighter.

One of the key issues in heat spreader technology is the choice of thermal interface materials (TIMs). The TIMs must possess high thermal conductivity and often require that its coefficient of thermal expansion be similar to silicon in order to eliminate unwanted mechanical failures. Recent developments of TIMs using metallic nanoparticles or carbon nanotubes (CNTs) are an interesting topic, but beyond the scope of this work. Those interested can refer to recent articles (Prasher *et al.* 2003, Wu *et al.* 2005, Xu and Fisher 2006) and reviews (Dani *et al.* 2005, Gwinn and Webb 2003).

3.16.3.2.1.(i) Thermosyphon – Boiling A two-phase closed thermosyphon, also known as a wickless heat pipe, is a hermetically sealed chamber partially filled with a volatile fluid and free of noncondensable gases. Thermosyphons have been under study as thermal management solution for the past 50 years (Tuma 2006). A device to be cooled can be either immersed directly into a pool of inert dielectric liquid or indirectly cooled by transferring heat to the boiler part of the thermosyphon, as shown in **Figure 7**. Once the liquid is heated by the chip, it vaporizes in the boiler. The vapor travels to the condenser and condenses while dissipating heat to the ambient via natural or forced convection. The condensed liquid is returned to the evaporator, typically by gravitational force in classical thermosyphons, completing a closed loop. The operation of thermosyphons is similar to that of heat pipes except that a heat pipe employs a wicking structure for driving a condensate back to the evaporator. Early research on macroscale thermosyphons configured as indirect liquid cooling for microelectronics was reviewed by Palm and Tengblad (1996).

Among the several different types of resistance that limits the performance of a thermosyphon such as boiling resistance, condensation resistance, and vapor drag, the primary limitation in many designs

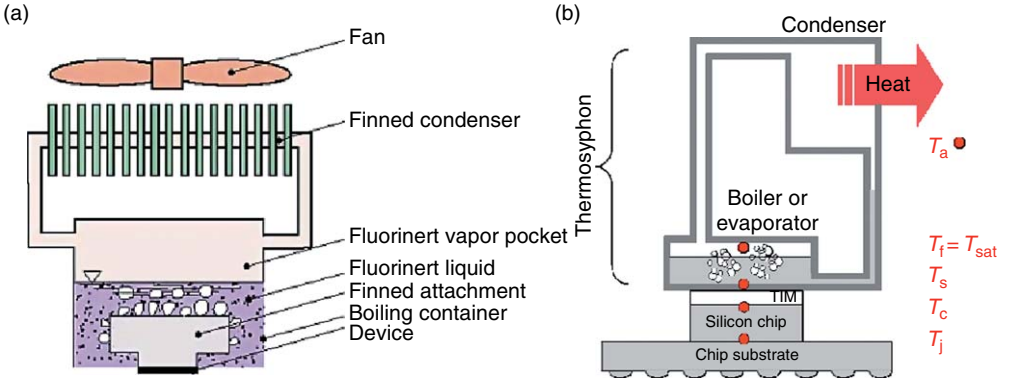

Figure 7 Schematic diagrams of thermosyphon configured with (a) direct immersion cooling (Source: Mudawar I 2001 Assessment of high-heat-flux thermal management schemes. *IEEE Trans. Comp. Packag. Technol.* **24(2)**, 122–41 cooling (© 2001 IEEE)) and (b) indirect cooling modes. (Source: Tuma P E, Mortazavi H R 2006 Indirect thermosyphons for the cooling electronic devices. *Electronics Cooling* **12(1)**, 26–33. http://www.electronics-cooling.com/articles/).

lies in boiling, i.e., evaporation at a solid–liquid interface. Therefore, a basic understanding of boiling heat transfer is required to properly design a thermosyphon and analyze its performance. The type of boiling occurring in a thermosyphon is called saturated pool boiling, often characterized by the critical heat flux (CHF) that is the maximum heat flux, q_{CHF}, in the nucleate boiling regime. A higher heat flux than the CHF lets the vapor bubbles coalesce to form a stable vapor blanket on the surface, effectively limiting the heat transfer. The boiling heat transfer coefficient, h_{boil}, is defined as

$$h_{boil} = \frac{q_{CHF}}{A_{surf}\Delta T_{sat}} \quad [1]$$

where A_{surf} is the projected geometrical area where boiling occurs and $\Delta T_{sat}(= T_{wall} - T_{sat})$ the wall superheat. Therefore, a higher projected heat transfer coefficient can be achieved either by increasing q_{CHF} or by decreasing the excess temperature overshoot. Nakayama and his coworkers (1980a, b, 1982, 1984) utilized a 3D network of interconnected microchannels made of multilayers of perforated copper with relatively large pore sizes and evaluated boiling enhancement, as shown in **Figure 8**. Mudawar and Anderson (1993) used the similar enhanced structures to achieve the CHF greater than 100 W cm^{-2} with FC-72. These enhanced surfaces can provide (1) more nucleation sites for bubbles to initiate and grow and (2) an extended surface from which sensible heat transfer takes place. Along with a manifold increase in the CHF, the enhanced structures also effectively lower temperature overshoot prior to boiling initiation, which should lead to reliable operation of the electronic devices (Mudawar 2001). Surveys of various surface treatment techniques employed for boiling enhancement can be found in Thome (1990) and in Webb and Kim (2005), including 3D cavities, etched grooves, electroplating, attached wire and screen promoter, oxide and ceramic coatings, porous surfaces, and structured rough surfaces. These enhanced surfaces commonly have reentrant cavities, entrapping vapors and creating active nucleation sites for boiling initiation. Examples of the enhanced surfaces from the literature are shown in **Figure 9**. Apart from the surface enhancement effect, other studies reveal that the CHF is also dependent on (1) subcooling of coolants (Bergles 1997, Vandervort *et al.* 1994), (2) the surface orientation (Chang and You 1996, El-Genk and Guo 1993, Howard and Mudawar 1999, Mudawar *et al.* 1997), and (3) external vibration (Park and Bergles 1988).

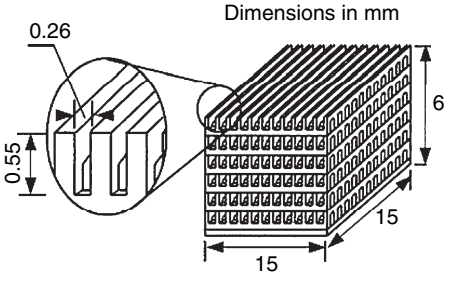

Figure 8 Enhanced evaporator structure with six bonded layers of perforated copper. (Sources: Nakayama W, Nakajima T, Hirasawa S 1984 Heat sink studs having enhanced boiling surfaces for cooling microelectronic components. *ASME Paper No. 84-WA/HT-89*; Pal A, Joshi Y K, Beitelmal M H, Patel C D, Wenger T M 2002 Design and performance evaluation of a compact thermosyphon. *IEEE Trans. Comp. Packag. Technol.* **25(4)**, 601–7. (© 2002 IEEE)).

Recent boiling heat transfer studies whose experiments are configured for electronics cooling are summarized in **Table 1**. With various boiling enhanced surfaces, many researchers employed traditional machining to build macroscale prototype thermosyphons and measure the heat transfer characteristics when cooling microelectronic components over a range of heat fluxes (Pal *et al.* 2002, Webb and Yamauchi 2002). Up to 200 W cm^{-2} of the CHF and 13.5 W cm^{-2} K of h_{boil} have been reported using water or dielectric fluorocarbon fluids as coolants (Klett *et al.* 2004, McGillis *et al.* 1990). A group led by Joshi at the Georgia Institute of Technology has been developing miniature or microthermosyphon systems for on-chip cooling. Ramaswamy *et al.* (2000, 2003) used the 3D boiling enhanced structure similar to Nakayama's to make a compact thermosyphon and investigated the effects of the chamber pressure, subcooling temperature, vapor space confinement, and the orientation of the evaporation structures. Employing a similar microfabricated copper structure, Murthy *et al.* (2000, 2002, 2004) further developed a miniature thermosyphon system as an on-chip cooling system as shown in **Figure 10**. They also demonstrated the orientation-independent performance derived from geometrical designs of the chamber (Murthy *et al.* 2003).

Loop thermosyphons (LTSs) ideally have less hydraulic resistance for the liquid returning to the evaporator compared with conventional thermosyphons because of the absence of the vapor drag from the counter flow. The driving force to maintain the vapor flow in LTS is the pressure head generated from the liquid column in the liquid return channel. In turn, the major pressure drop occurs in the vapor

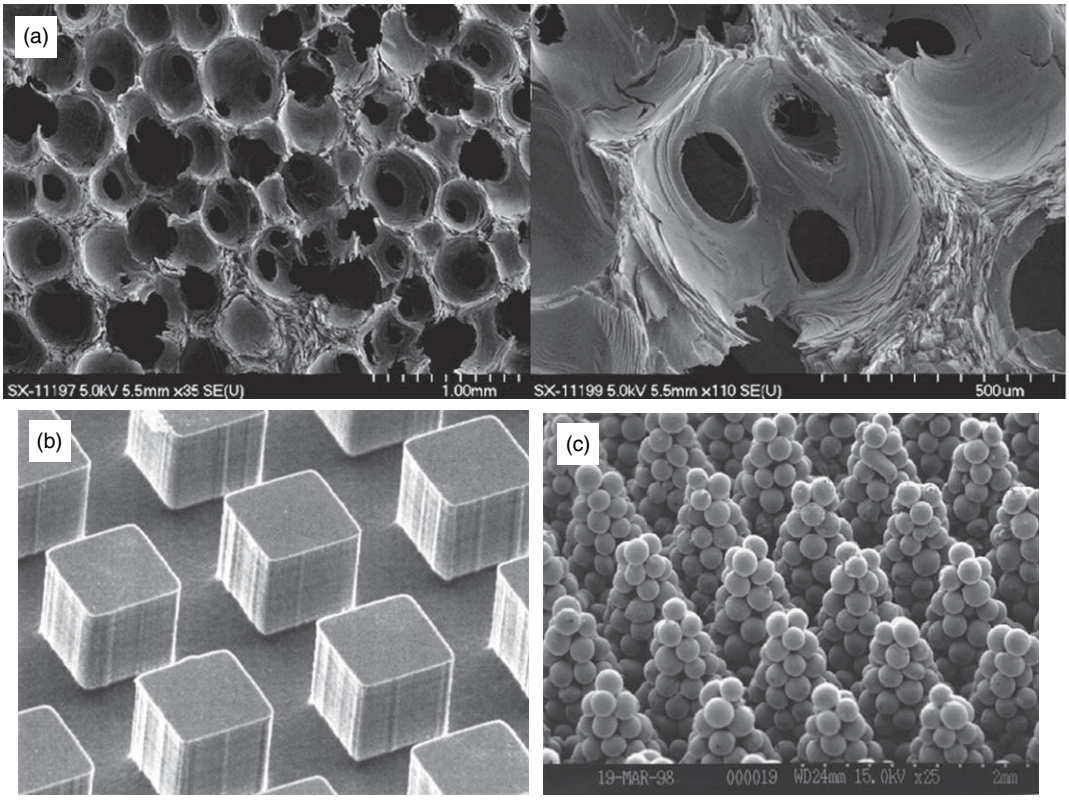

Figure 9 Scanning electron micrographs of various enhanced surface structures to extend boiling regime. Device Mater. Reliabil.* **4(3)**, 626–37. (© 2004 IEEE)), (b) DRIE-etched silicon pin-fin array (Source: Honda H, Takamastu H, Wei J J 2002 Enhanced boiling of FC-72 on silicon chips with micro-pin-fins and submicron-scale roughness. *ASME J. Heat Transf.* **124**, 383–90.), and (c) height-modulated porous-layer coating of spherical copper particles (of diameter 200 μm) (Source: Reprinted from Liter S G, Kaviany M 2001 Pool-boiling CHF enhancement by modulated porous-layer coating: theory and experiment. *Int. J. Heat Mass Transf.* **44**, 4287–311., Copyright 2001, with permission from Elsevier).

channel, giving rise to fluid transport limitation. Chu *et al.* (1999) built a macroscale LTS and experimentally investigated the effects of fill volume, heat load, and condenser airflow rate on overall thermosyphon performance. Average heat transfer coefficients on the flat-plate evaporator ranging from 0.38 to 0.8 $W\,cm^{-2}\,K$ were reported. Khrustalev (2002) reported 12 LTSs, sharing one cold plate to simulate the cooling of multiple electronic components.

With all these extensive studies on pool boiling heat transfer, many of their data were collected in an apparatus or under conditions that are impractical for microcoolers (Tuma 2006). As summarized in **Table 1**, some of the reported heat transfer coefficients for miniaturized thermosyphon systems are much smaller than those of macroscale counterparts (Murthy *et al.* 2002). As the device size is reduced further, the condensation resistance becomes significant as the area for the terminal heat rejection to ambient by subsequent forced-air or forced-liquid cooling decreases. In addition, entrainment of fluid within the flow paths plays a much larger role in limiting performance than for macro- or even mesoscale systems. Another issue in two-phase passive heat spreading is the sensitivity of the system to orientation, which causes dry-out to occur when the condenser outlet and the evaporator inlet lie in the same horizontal plane (Pal *et al.* 2002). Of course, for microscale systems, the effect of gravity as the driver of returning liquid to the evaporator becomes much weaker as the size is reduced, and if the dimensions are too small, gravity becomes a negligible force. Thus, as size is reduced to the microscale, thermosyphons begin to employ wicking structures for the return, at least over part of the path, which leads to our discussion of micro heat pipes (MHPs).

3.16.3.2.1.(ii) Micro heat pipes The working principle of the heat pipes is similar to that of the thermosyphons (i.e., near-isothermal evaporation–condensation cycle) and differs only in that the liquid condensed in the condenser returns to the evaporator via the capillary force of the wick. Since the thermosyphon is a gravity-dependent device that can be used neither for space applications nor for orientation-dependent applications, conventional heat pipes have provided the viable thermal management in numerous applications including terrestrial applications. The concept of an MHP was introduced for electronics cooling by Cotter (1984) who defined the MHP as "one so small that the mean curvature of the vapor–liquid interface is necessarily comparable in magnitude to the reciprocal of the hydraulic radius of the total flow channel." Due to their size, material, and manufacturing process, instead of traditional wick structures, MHPs often employ microchannels with a cusped cross section (e.g., polygon), having a diameter in the range of about 10–500 μm. The surface tension gradient that drives the capillary liquid flows is generated at the sharp corners in MHPs as shown in **Figure 11**. Due to lesser liquid in the evaporator section (**Figure 11**, A–A), the radius of curvature of the meniscus is smaller at the vapor–liquid interface, leading to a lower liquid pressure compared to that in the conderser (**Figure 11**, D–D) and thus the liquid moving from the conderser to the evaporator.

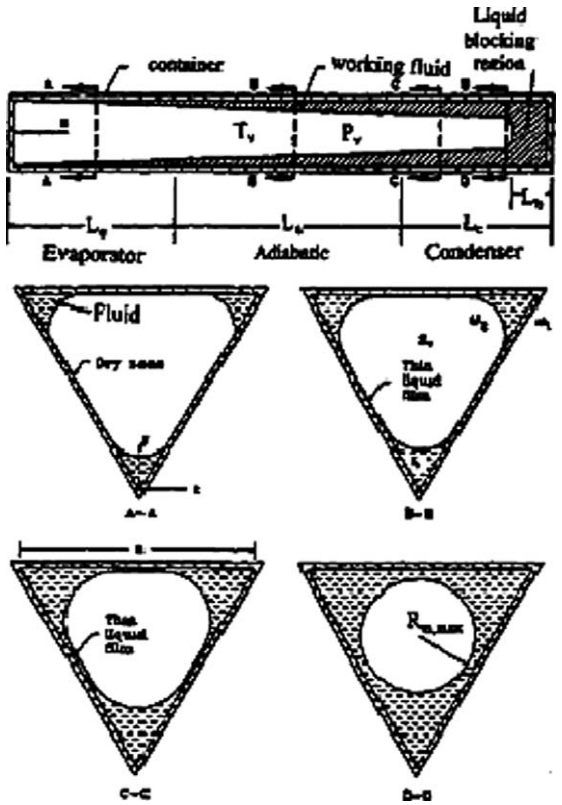

Figure 11 Schematic of micro heat pipes. (Source: Khrustalev D, Faghri A 1994 Thermal analysis of a micro heat pipe. *ASME J. Heat Transf.* **116**, 189–97).

Excellent reviews on the MHP by Faghri (1995) and Peterson (1992, 1996) encompass the early efforts in the development and characterization, emphasizing numerical analysis, fabrication, and testing of MHPs, manufacturing as standalone devices or fabricated as an integral part of the silicon wafers. Since then, great advances in research related to arrays of MHPs, flat-plate MHPs, and capillary loop heat pipes have preceded commercial success, and state-of-the-art MHPs can be found in many current laptop computers as primary heat spreaders (Wuttijumnong *et al.* 2004). Here we summarize the efforts on MHPs appearing after these reviews and focus on the direct integration of MHPs into silicon substrates. The readers can also refer to recent reviews on micro and miniature heat pipes as electronic component coolers (Groll *et al.* 1998, Vasiliev 2005, 2006).

Table 2 summarizes the materials, manufacturing, and performance of various miniature and micro heat pipes to date. An objective parameter characterizing the system efficiency is the effective thermal resistance (R_{th}) determined by the ratio of the temperature difference (ΔT) between the heat source (evaporator) and the heat sink (condenser) to the value of the dissipated capacity (q_{in}) (Pastukhov *et al.* 2003). Some researchers reported the effective thermal conductivity (k_{eff}) of their MHPs, which is related to the effective thermal resistance by

$$k_{eff} = \frac{1}{R_{th}} \cdot \frac{L_{eff}}{A_{eff}}, \quad R_{th} = \frac{\Delta T}{q_{in}} \qquad [2]$$

where L_{eff} is the effective length between the evaporator and the condenser and A_{eff} the cross-sectional area of the MHP. The heat removed by the MHPs ranges from a few watts per square centimeter to over $300\,W\,cm^{-2}$. A water–copper heat pipe system, manufactured by traditional

machining or EDM, dominates in the MHP literature and shows a heat transfer capacity of 5–100 W cm^{-2}. Kang *et al.* (2004) used a chemical etching technique to shape radial grooves in copper and stacked three Cu layers to build a flat-plate MHP array as shown in **Figure 12**. Moon *et al.* (2004) utilized a high-precision drawing process to fabricate the copper tube with a polygon cross section. **Figure 13** depicts the cross section of their MHPs, having sharper edge in the corners for higher capillary forces.

Together with conventional machining, MEMS fabrication processes such as bulk silicon micromachining have been increasingly implemented to fabricate MHPs with hydraulic diameters on the order of 50–500 μm as an integral part of the silicon substrate. The use of directionally dependent etching of silicon was proposed in the earlier work of Peterson and coworkers (Mallik *et al.* 1992, Peterson 1992) and has been experimentally verified (Peterson *et al.* 1993). Since then, an extensive investigation has been directed toward refining the fabrication procedure and developing flat-plate MHP arrays. **Figure 14** illustrates the fabrication processes for the star-grooved MHP arrays in which each corner with more acute angles provides better capillarity (Kang and Huang 2002). Many other silicon-based MHPs follow the similar process sequence with a modification in the bonding step, such as Si–Si direct fusion bonding instead of Au–Au eutectic bonding (**Table 2**). Le Berre *et al.* (2003) coupled typical KOH-etched triangular channels with arteries, as shown in **Figure 15**, for the separate liquid transport and demonstrated 300% enhancement in the effective thermal conductivity compared with the MHPs without the arteries. DRIE of silicon has also been used to create an array of capillary grooves and the MHP prototype proving the comparable performance (Lai *et al.* 2004). **Figure 16** shows DRIE etched grooves and a schematic of a flat-plate silicon MHP. A polymer-based MHP system using SU-8 photocurable resin and low-temperature (less than 110°C) bonding have been used as the thermal management solution to InP/InGaAs-based devices, which often cannot withstand a high-temperature wafer-to-wafer bonding (over 500°C) process (Liu *et al.* 2003). The effective thermal conductivity of these MHPs reported in the literature varies from 250 to 16 000 W m^{-1}°C^{-1} as summarized in **Table 2**. Many of these MHPs can conduct a relatively high load of heat farther away than either copper or diamond (**Table 3**).

The performance limitation of the MHPs can originate from many different phenomena such as flow within the capillary structures, sonic choking of the vapor velocity, entrainment of refrigerant, and boiling regimes similar to the conventional heat pipe case. It has been shown, however, that the MHPs primarily suffer from capillary and boiling limits (Hopkins *et al.* 1999). A capillary limit is reached when the capillary pressure difference in the liquid phase is not large enough to overcome the sum of the pressure drops associated with the liquid flow, vapor flow, and phase change phenomena, to return the fluid back to the evaporator. A boiling limit occurs when intense heat in the evaporator region gives rise to vapor bubbles, obstructing the flow of liquid into the evaporator. In addition, Cao and Faghri (1994) identified the vapor continuum limitation associated only with MHPs. As the size of the MHPs decreases, the mean free path of the vapor is comparable with the minimum dimension of the vapor passage, where the vapor may lose its continuum characteristics. Due to these limitations, the effectiveness of an MHP, in general, decreases with decreasing lengths. For MHPs with a length less than about 1 cm, the performance of a solid piece of metal such as copper is often comparable (Lasance and Simons 2005), whereas for larger heat pipes, the effective thermal conductivity can be many times that of copper. The effect of the gravity on the operation of the MHPs has been investigated analytically (Sugumar and Tio 2006) and experimentally, and it is shown that the orientation (i.e., the angle of inclination) can significantly influence their performance and that the degree of the gravity effect depends on the cross-sectional shape of the MHPs. Detailed descriptions of thermal analysis and heat transfer limitations of MHPs and LHPs are not discussed here but can be found elsewhere (for MHP: Faghri 1995, Khrustalev and Faghri 1994, Lefèvre and Lallemand 2006, Suman *et al.* 2005, Tio *et al.* 2000; for loop heat pipe (LHP): Hamdan *et al.* 2003, Kim and Golliher 2002).

Recently, LHPs or capillary pumped loops (CPLs) have gained more interest. The advantages of the LHP or CPL over the conventional HPs or flat-plate MHPs are (1) greater potential of geometric freedom in design, (2) higher heat loads due to the concurrent nature of the vapor and liquid flows, as opposed to the countercurrent flows in the conventional HPs, and (3) the potential to easily integrate new components (e.g., valves and pumps) for further performance enhancement (Kirshberg *et al.* 2000). The capacity of these LHPs or CPLs to accommodate a heat flux was

shown to be as high as 625 W cm^{-2} theoretically by Kim and Golliher (2002) for a particular configuration, and a flux of 104 W cm^{-2} was experimentally found by Chung *et al.* (2001).

As promising as these enhanced heat transfer microcooler technologies are, it is important to note that an MHP, or two-phase coolers in general, cannot provide additional cooling beyond that of the ambient environment. MHPs often are a part of an integrated system and require additional cooling techniques such as forced air cooling or liquid cooling to minimize condensation resistance and to enhance heat transfer to the surroundings. In addition, there are several engineering and reliability issues, such as charging the two-phase coolant into the device chamber while excluding condensable gases and keeping condensable gases from diffusing into the channels and the refrigerants from diffusing out. The later issue becomes more important as the size is reduced, since the total charge becomes quite small compared with miniature and mesoscale systems, and the surface area-to-volume ratios can become huge.

3.16.3.2.2 Liquid impinging jet and spray cooling

Liquid jet impingement cooling and spray cooling are well-established techniques typically found in applications that need to dissipate highly concentrated heat loads, such as quenching metal alloy parts. For electronics cooling applications, jet impingement or spray cooling with dielectric fluorocarbon coolants have been widely used to maintain relatively low, steady temperature in ultra-high heat flux (above 10 kW cm^{-2}) devices such as lasers, X-ray anodes, and modules in supercomputers (Mudawar 2001, Pautsch and Bar-Cohen 2001). Both jet impingement and spray cooling involve spraying a liquid on the hot surface, which spreads as a thin film and evaporates (Webb and Kim 2005). This active two-phase cooling provides essentially the advantages equivalent to passive two-phase devices but offers higher cooling power (faster heat removal rates). There is a subtle difference between the two techniques in that spray cooling is specifically denoted for the liquid impinging on the surface as small droplets.

Recent studies about the heat transfer characteristics of liquid jet and spray impinging on relatively small areas with a nozzle diameter larger than 1 mm are summarized together with the electronics cooling experiments in Wolf *et al.* (1996) and Mudawar (2001). A heat flux removal of more than 400 W cm^{-2} was reported with a wall superheat of 30–40°C and flow rates of 120 l min^{-1} (Wolf *et al.* 1996), making this technique among the highest reported heat removal method. Since the majority of cooling from a single jet is confined within the impact zone, an array of jets is commonly used to spread out the cooling concentration and achieve relatively uniform cooling over the larger areas of chip surfaces. With a 3×3 array of rectangular jet impingement, Mudawar and Wadsworth (1991) developed a multichip cooling module that was able to supply an FC-72 coolant independently to each chip. The dependence of the CHF on jet width, jet velocity, subcooling, and a distance between nozzles and impact surfaces was also investigated with a conclusion that the CHF was mostly influenced by fluid temperature and the jet velocity (Estes and Mudawar 1995, Ma and Bergles 1986, Mudawar and Wadsworth 1991, Vader *et al.* 1992). Furthermore, the same surface enhancement structures used in pool boiling research can improve jet impingement cooling by offering higher heat transfer rates and lower overshooting of the temperature beyond the boiling temperature (Wadsworth and Mudawar 1992), which typically improves the overall performance.

Apart from the nonuniform distribution of cooling on chips, high-speed jet impingement can be aggressive and damage the heated surface with a large change in momentum between the impinging liquid, which should be avoided for delicate devices (Mudawar 2001). Spray cooling can diminish this impact and flow rate requirement and simultaneously increase the cooling uniformity by distributing droplets over the larger surface area and delaying the liquid separation from the wall during boiling, as depicted in **Figure 17**. However, there are disadvantages with spray cooling, particularly at the microscale, including (1) high pressure drop at the nozzles, requiring high-pressure sources, (2) susceptibility of micronozzel clogging, which impacts the reliability of long-term operation, and (3) difficulties in producing the predictable and repeatable impact patterns (Mudawar 2001). Recent investigations into spray boiling for electronics cooling can be found elsewhere (Estes and Mudawar 1995, Mudawar and Estes 1996, Yang *et al.* 1996).

Typical flow rates associated with macrojets are too large to be practically implemented for integrated VLSI chip cooling system due to the necessary pumping capability and the size constraints. Equipment accompanying jet impingement cooling and spray cooling is rather bulky and difficult to miniaturize. Therefore, as promising as the method is, there are relatively few instances of this technique being used

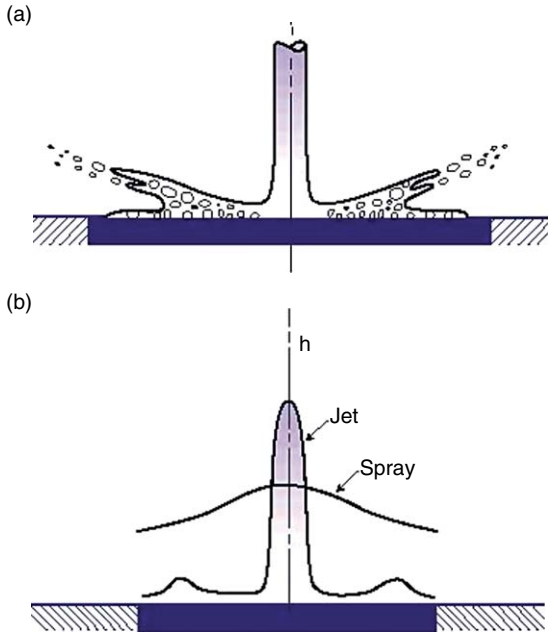

Figure 17 (a) Liquid wall layer splashing and separation at CHF in free circular impinging jets and (b) a qualitative comparison of heat transfer coefficient spatial variation for sprays and free jets. (Source: Mudawar I 2001 Assessment of high-heat-flux thermal management schemes. *IEEE Trans. Comp. Packag. Technol.* **24(2)**, 122–41, (© 2001 IEEE)).

in microcooler technology. A group at the Carnegie Melon University developed a droplet impingement cooling device which they called an embedded droplet impingement for integrated cooling of electronics (EDIFICE), to remove chip heat fluxes higher than $100\,W\,cm^{-2}$ by capitalizing on two-phase cooling with dielectric fluids (Amon *et al.* 2001, 2005, Yao *et al.* 2001). Micron-sized droplets (50–100 μm) of dielectric coolants were dispensed through an array of micronozzles and impinged on the microstructured surfaces to provide a direct cooling for chips in portable and desktop electronics. To make these impingement devices, microfabrication techniques such as DRIE have been extensively utilized to create (1) micronozzles, swirl nozzles, and microinjectors for jet breakup, (2) microstructured surfaces for increasing the spreading of liquid and promoting boiling heat transfer, and (3) electrostatic microvalves to regulate the coolant flow rates. **Figure 18** shows a schematic of the EDIFICE design and how it is connected to the entire system. Similar to the LHP, the vapor generated at the heated component travels through the system to the heat sink or air-cooled condenser, where the condensed coolant returns to the EDIFICE by the micropumps. The heat removed can also be stored in a detachable heat storage unit that contains an organic phase-change material with a low melting temperature of 50 to 60°C (Vesligaj and Amon 1999). A CHF of $42.1\,W\,cm^{-2}$ with HFE-7200 on a microstructured surface 2.5 cm × 2.5 cm in area was demonstrated with a relatively small flow rate of $4.64\,g\,cm^{-2}$ min but with a high pressure of 500 kPa.

In order to eliminate the need for high-pressure pumps and the associated fluid routing, Glezer's group developed vibration-induced droplet atomization (VIDA) coolers utilizing a piezoelectric actuator to vibrate a plate at the resonant frequency, which produces small liquid droplets (diameter 70–800 μm) and propels them onto a heated surface (Heffington *et al.* 2000, 2002). These droplets form a thin liquid film that evaporates on the chip surface. The vapor can be taken to a remote condenser or condensed on the internal surface of the chamber wall, as shown in **Figure 19**. The condensed liquid travels back to the piezoelectric actuator via gravity, which makes this cooler orientation dependent (Heffington *et al.* 2002). Fundamental studies and numerical simulations of VIDA phenomenon are available in James (2003a, b), and the spray characterization in Vukasinovic *et al.* (2004). Over $200\,W\,cm^{-2}$ of heat flux with a 100°C temperature rise was transferred with a chilled water heat sink as the external heat removal device (Heffington *et al.* 2002). To overcome the orientation dependence, a new gravity-independent version of the VIDA coolers was constructed using a piezoelectric diaphragm pump to supply a constant stream of liquid to the VIDA atomizer (Heffington and Glezer 2004). Moreover, the addition of a synthetic jet was made to the new design, as shown in **Figure 19(b)**, accelerating the transport of atomized droplets and the vapor and thus increasing heat transfer characteristics. It was shown that the VIDA–synthetic jet combination was capable of removing heat fluxes as high as $420\,W\,cm^{-2}$ at a surface temperature of 133°C, but it needed on the order of 3 W of input power, which may limit it for many microcooler applications.

To test different types of microfabricated liquid jet coolers, Wang *et al.* (2004) experimentally investigated the performance of single-jet and multijet arrays with an orifice diameter ranging from 40 to 76 μm in a confined geometry for liquid-phase and two-phase heat transfer. **Figure 20** shows a schematic of the microjet device bonded to the microfabricated heater and temperature sensors and images of a jet orifice and a heater die. With DRIE, an array of orifices was micromachined in the jet chip, which

was anodically bonded to a glass wafer for sealing. A cooling rate of 92 W cm^{-2} with a 100°C temperature rise was achieved with a flow rate of only 8 ml min^{-1} and a pressure drop of 50 kPa. Although not yet demonstrated, a relatively low flow rate requirement in this microjet cooling may permit the integration of a closed-loop electroosmotically pumped cooling system in the near future (Yao *et al.* 2003).

Syst.* **13**, 833–41, (© 2004 IEEE)).

3.16.3.2.3 Microchannel heat exchangers

Not all devices can permit direct liquid contact of the coolant. Therefore, another heavily researched and developed liquid-based heat transfer method is via microchannel heat exchangers (μHEX). Microchannels are typically defined as micromachined channels having hydraulic diameters of 10 μm to a few hundred micrometers. Thus, most liquid flow in microchannels is the low Reynolds number, laminar flow, which in the absence of phase change gives rise to a heat transfer coefficient that is inversely proportional to the hydraulic diameter (Mudawar 2001). Unfortunately, the pressure drop increases with the inverse of the second power of the channel width for a fixed flow rate. Thus, the smaller the channel dimension is, the more the heat transfer is enhanced, but at the expense of a more severe pressure drop and a higher pumping cost. So, unlike passive two-phase heat spreaders, active pumping is needed to drive liquid flow in the μHEX. Therefore, the main limitation in μHEXs has to do with the development of micropumps capable of overcoming the pressure drop. Moreover, small microchannels with a hydraulic diameter less than 200 μm were shown to be easily clogged, hampering the robust operation of the device and thus setting up the practical minimal channel dimensions (Mudawar 2001).

Despite these issues, μHEXs have been heavily reported, in part due to the ability to directly integrate μHEX with silicon chips to maximize heat transfer from electronic devices made in Si. More generally, Tuckerman and Pease (1981) pioneered the development of the μHEX and reported heat removal of 790 W cm^{-2} with a water flow rate of 516 ml min^{-1}, a pressure drop of 207 kPa, and a temperature increase of 71°C using single-phase liquid convection in the microchannels. Since then, tremendous research focusing on μHEX has been conducted with and without boiling. For flow boiling in the microchannels, Bowers and Mudawar (1994) demonstrated 200 W cm^{-2} of heat removal with flow rates less than 65 ml min^{-1} and pressure drops of less than 35 kPa. Comprehensive reviews are available for thermal and hydraulic performance of the single-phase microchannel devices by Ho and Tai (1998), Mehendale *et al.* (2000), Garimella and Sobhan (2003), Garimella and Singhal (2004), and Kandlikar (2005) and for boiling and two-phase flow in microchannels by Ghiaasiaan and Abdel-Khalik (2001), Mudawar (2001), and Bergles *et al.* (2003). Fabrication techniques involved in making

microchannel heat sink are reviewed by Joshi and Wei (2005). Correlations developed for macrochannels have been used to estimate the Nussel numbers, friction factors, and flow transition Reynolds numbers for microchannels, with some noted discrepancies, in particular for two-phase flows (Joshi and Wei 2005, Mehendale *et al.* 2000). Further studies have focused on understanding these discrepancies (Baviere *et al.* 2004, Lee and Garimella 2003, Liu and Garimella 2002, Sharp *et al.* 2000, Xu *et al.* 2000, Zeighami *et al.* 2000), but the conclusive explanations are not yet available (Garimella and Sobhan 2003). In this section, we will review the recent literature published since 2003 for liquid cooling using μHEX.

3.16.3.2.3.(i) Single-phase liquid cooling

High heat flux rates in the range of 1–100 kW cm^{-2} have been achieved with various μHEX using active pumping schemes. Micropumps related to the liquid microchannel cooling will be briefly discussed in a later section. A great deal of recent research on the optimization of μHEX (a single-layered microchannel or a microchannel stack) has been reported to increase the overall thermal performance by minimizing thermal resistances for a given pumping power. Wei and Joshi (2003) reported the optimization study of stacked microchannel heat sinks based on a simple thermal resistance network model. Other optimization studies for the microchannels in single-phase liquid cooling systems have been reported (Khan *et al.* 2006, Koo *et al.* 2005, Park *et al.* 2006, Zhang *et al.* 2005a). The latest review articles for single-phase μHEXs are available elsewhere (Hassan *et al.* 2004, Morini 2004, Schmidt 2003).

The μHEXs developed by companies have also been reported on or made commercially available. Colgan at IBM demonstrated a practical implementation of a single-phase silicon μHEX directly bonded to the back of a chip with low-resistance TIMs (Colgan *et al.* 2005). **Figure 21** illustrates the multilayer stacks of

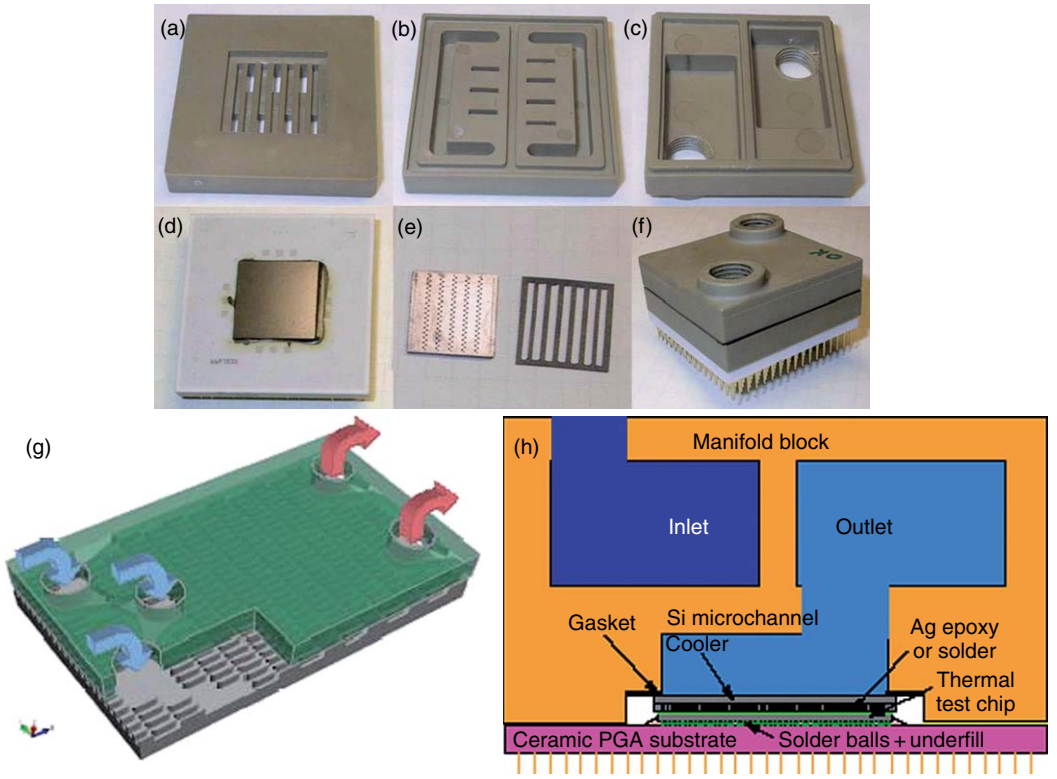

Figure 21 Schematics of microchannel single-chip module cooler. (a–c) Manifold blocks made of a high-temperature plastic, (d) test chip mounting stage, (e) microchannel cooler, and (f–h) a complete microchannel single-chip module. (Source: Colgan E G, Furman B, Gaynes M, Graham W, LaBianca N, Magerlein J H, Polastre R J, Rothwell M B, Bezama R J, Choudhary R, Marston K, Toy J, Wakil J, Zitz J, Schmidt R 2005 A practical implementation of silicon microchannel coolers for high power chips. *Proc. IEEE 21st SEMI-THERM Symp.*, pp. 1–7, (© 2005 IEEE)).

a microchannel single chip module cooler with a 3D and cross-sectional schematic view. Using water, the authors reported cooling power of 300 W cm^{-2} with a reasonable flow rate of 1.2 l min^{-1} and a pressure drop in the μHEX of <35 k Pa. Chang *et al.* (2005) at the Intel Corporation reported the direct fabrication of μHEXs into the back of silicon chips and integrated front-side heaters and temperature sensors to estimate reduction in thermal resistance and pressure drop. The lowest thermal resistance of 0.09 K cm^2 W^{-1} was obtained for a 61-μm-wide and 272-μm-deep microchannel. Some μHEX-based cooling technologies using both single-phase and two-phase flow are commercially available. Several examples of these companies are Mikros Technologies (http://www.mikrostechnologies.com/), Nanolytics (http://www.nanolytics.com/), Advanced Cooling Technologies (http://www.1-act.com/), iCurie (http://www.celsiatechnologies.com/), Lytron (http://www.lytron.com/), Koolance (http://www.koolance.com/), Novel Concepts (http://www.novelconceptsinc.com/), and Microcooling Concepts (MC2, http://www.microcoolingconcepts.com/) to name a few.

3.16.3.2.3.(ii) Two-phase cooling Flow boiling heat transfer and two-phase hydrodynamics have been heavily studied and are currently investigated by many researchers. The Mudawar group experimentally determined hydrodynamic and heat transfer correlations in two-phase μHEX and predicted pressure drops and CHFs for various geometries and applications (Lee and Mudawar 2005a, b, Qu and Mudawar 2002, 2003a, b, c, 2004). Experiments in micromachined silicon channels with a range of 27–171 μm in hydraulic diameter and with varying surface roughness were conducted to investigate the boiling process and two-phase flow behavior such as bubble nucleation, flow patterns, and transient pressure fluctuations (Zhang *et al.* 2005a). Faulkner *et al.* at MicroEnergy Technologies reported a prototype of a 1000 W cm^{-2} cooling system for microwave electronics, employing flow boiling heat transfer in a parallel μHEX. Heat fluxes up to 125 W cm^{-2} for saturated boiling and 280 W cm^{-2} for subcooled (25°C) boiling were removed with water as a coolant and a flow rate of 0.75 l min^{-1} (Faulkner *et al.* 2003). Researchers at Intel studied the effects of nonuniform heating conditions on the thermal performance of the two-phase μHEX to address cooling of local hot spots and observed temperature fluctuation as high as 30°C (Prasher *et al.* 2005).

Thin-film and flexible microchannel heat exchangers were developed by the Shannon group (Pourmohamadian *et al.* 2004, Selby *et al.* 2001). These heat exchangers, shown in **Figure 22**, are made from heat-sealable Kapton (special polyimide films from Dupont) and range from a thickness of 200 to 250 μm. The outer panels, or caps, in the figure are 50 μm thick. Even with a relatively low thermal conductivity (~1 W m^{-1}°C^{-1}) of the Kapton, the thermal resistance is still small (order 5×10^{-5}°C W^{-1}). When the four panels shown in **Figure 22(a)**, which have channels cut for the heat exchanger, manifold, and caps are bonded and assembled into a single unit, the result is a flexible microchannel heat exchanger that can withstand pressures over 18 atm. The maximum pressure is determined by delamination and/or rupture at the critical point shown in **Figure 22(b)**. Under pressure, the polymer channels inflate, increasing the effective cross-sectional area. These flexible heat exchangers were developed for two-phase heat transfer, specifically for R-134a (~13 atm absolute pressure at room temperature). Applications for these types of heat

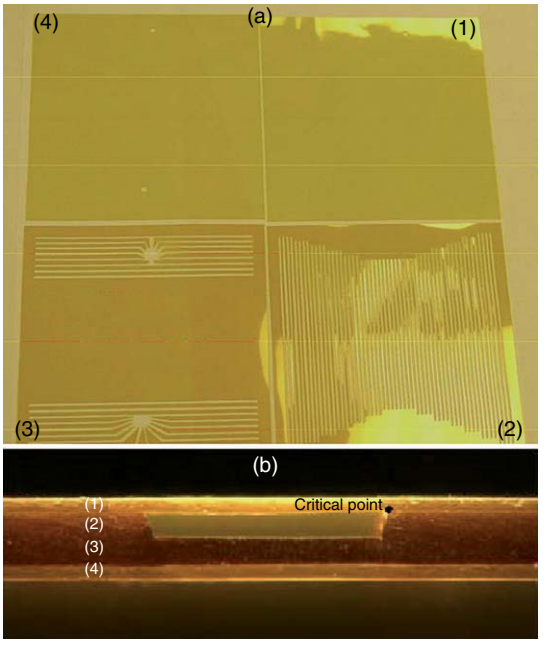

Figure 22 (a) Four polyimide panels comprising the flexible microheat exchangers. (b) Cross-sectional view of the four bonded layers, showing 75 by 750 μm channel. NAMRI/SME, XXIX*, pp. 469–76).

exchangers include insertion into cooling garments for people working in hot environments, and for providing large area, light weight, thin-film heat exchangers for electronics.

3.16.3.2.3.(iii) Liquid metal cooling Liquid metal as a coolant can often be found in high-temperature heat pipes, thanks to metal's high vapor pressure on boiling and high thermal conductivity as a liquid (Faghri 1995), while the density-weighted heat capacity (ρc_p) is smaller, but of the same order, as water, which allows significant heat to be carried per unit volume of evaporated liquid. The thermophysical properties of several liquid metals are summarized in **Table 4**. Recently, the liquid metal-based cooling using magnetofluid dynamic (MFD) pumping has been proposed and commercialized by Nanocoolers (Ghoshal 2005a, Miner and Ghoshal 2004). Due to its high thermal conductivity, $Ga^{68}In^{20}Sn^{12}$ can provide a heat transfer coefficient from the case to the evaporating liquid that is an order of magnitude higher than that of water for laminar flows (Miner and Ghoshal 2004). An MFD direct current (DC) conduction pump utilizing $Ga^{61}In^{25}Sn^{13}Zn^{1}$ (melting point ~8°C) as the working fluid generated a maximum pressure head and a maximum efficiency of approximately 25 kPa and 10%. **Figure 23** shows the typical configuration of a liquid metal cooling loop. Cooling power over 200 W cm^{-2} with high heat transfer coefficients of 20 W cm^{-2} K has been reported with this type of cooler (Ghoshal 2005a). Despite their advantages of being power efficient compared to the electrokinetic-based pumps, no-moving parts, and independence on orientation to gravity/orientation, MFD-based liquid metal coolers also face challenges such as dealing with potential material incompatibilities and the need for nontraditional power supplies because the MFD DC conduction pumps operate at low voltages and high currents.

3.16.3.2.3.(iv) Electrowetting and thermocapillary pumping and cooling Electrowetting refers to the phenomenon that an electric field can modify the wetting behavior of a droplet in contact with an insulated electrode and allows us to control surface tension between the liquid and the solid surface, thus changing the contact angle from hydrophobic to hydrophilic (Oprins and Baelmans 2006). Individual droplet manipulations (merging, cutting, and transporting) in microfluidic applications have already been demonstrated using electrowetting and/or electrothermocapillary actuations (Cho *et al.* 2003, Pollack *et al.* 2000, 2002, Prins *et al.* 2001). The combination of microchannel cooling with electrowetting actuation was first proposed by Pamula *et al.* as a real-time active and smart cooling method where nanoliter-sized discrete liquid droplets are spread or transported to hot spots without external pumps (Paik *et al.* 2004, Pamula and Chakrabarty 2003). Their calculations showed that a heat flux of more than 90 W cm^{-2} can be removed with a flow rate of only 0.4 ml min^{-1}. More in-depth theoretical and experimental studies were followed to understand the oscillating droplet behavior on the microchannel surfaces (Oprins *et al.* 2004, 2005). Taking advantage of the high thermal conductivity of liquid metals, Mohseni (2005) recently proposed digitized electrowetting of liquid metals for active thermal management of high-power microsystems. No experimental results are yet available for heat transfer or cooling from any of these electrowetting coolers.

3.16.3.2.3.(v) EHD augmented MHPs MHPs generally suffer from the capillary limit in the performance, just as the macroscale counterpart does. In order to enhance the effectiveness of fluid transport that maximizes heat transfer within heat pipes, Jones (1973) first proposed to use electrostatic fields on a dielectric liquid coolant inside heat pipes to create forces to move the fluid. When the electrical field interacts with the flow field in a dielectric fluid medium, three important forces arise: (1) coulombic forces acting on free charges, (2) dielectrophoretic forces, created by a local change of the permittivity in an electrical field, in this case occurring at the interface between a liquid and a vapor, and (3) electrostriction forces due to the nonuniform electrical field imposed on a dielectric fluid (Suman 2006). Jones and Perry (1974) later conducted the experiments by replacing the capillary wick structure with an electrohydrodynamic (EHD) pump that utilized polarization forces (the dielectrophoretic and electrostriction forces acting on dipoles) to collect, guide, and pump the condensate liquid to the evaporator. Since then, several researchers reported developing EHD enhanced heat pipes at the macroscale (Bologa and Majboroda 1993, Bologa and Savin 1990, Loehrke and Debs 1975); however, none of these experiments showed significant enhancement in heat pipe performance compared to capillary heat pipes.

As heat pipes are reduced in size, mainly to the microscale, EHD pumping becomes more viable. Bryan and Seyed-Yagoobi (1997) reported over 100% enhancement for a monogrooved heat pipe using EHD pumping operating at 20 kV. Hallinan and his coworkers successfully demonstrated a six-fold increase in the heat transport capability of EHD augmented MHP arrays and developed an analytical model to predict the maximum heat transport capability for various electrical field intensities and MHP geometries (Hallinan *et al.* 1998, Yu *et al.* 2002). Mo *et al.* (2000) investigated the application of the EHD technique to the CPL and showed that enhancement, up to three times, could be obtained in heat transfer coefficients and that the depriming conditions of a CPL can be prevented. Suman (2006) recently presented a comprehensive steady-state model for the fluid flow and heat transfer in an EHD augmented MHP and argued that the EHD technique could increase the critical heat input by 100 times.

A different type of the EHD pumping was also investigated to enhance the heat transport capacity of MHPs (Babin *et al.* 1993, Seyed-Yagoobi *et al.* 1995, Yu *et al.* 2000). Instead of employing polarization forces, an ion-drag pump-assisted MHP harnesses the coulombic force exerted on free charges, which are created within a dielectric fluid by emission of the emitter as a corona source. As free ions travel toward the collector via an applied electric field, the working fluid is dragged along because of the friction developed. Both experiments and analytical models show the feasibility of achieving active temperature control and increasing the capillary limit of the heat pipes (Babin *et al.* 1993, Yu *et al.* 2000).

3.16.3.3 Solid-State Cooling

One of the earliest active cooling systems that were developed for miniature and smaller systems is based on solid-state cooling via the thermoelectric and thermionic effect, which are reviewed here, touching on efforts to miniaturize to the microscale.

3.16.3.3.1 Thermoelectric microcoolers

Thermoelectric coolers (TECs), also named Peltier coolers, are small electronic heat pumps capitalizing on the Peltier effect, so that when a temperature change occurs in the vicinity of the junction between dissimilar conductors, a current passes through the junction, resulting in the transfer of heat across the junction, since the heat is carried by the charge carriers. A typical TEC module consists of a number of alternating ingot-shaped n- and p-type semiconductor thermoelements, which are connected electrically in a series with metal connecting strips, sandwiched between two electrically insulating but

thermally conducting ceramic plates, as depicted in **Figure 24** (Rowe 1995). When a positive DC voltage is applied to the n-type thermoelement, electrons flow from the p-type element to the top metal connector, then to the n-type element. As heat is absorbed by electrons at the top junction and that heat energy is carried away from the junction via the Peltier effect, the cold-side (chip) temperature decreases. The electrons carrying heat energy travel to the bottom connector, where excess heat is released through an external heat sink. If the bias is reversed, the device will operate as a heat pump. The advantages of TECs are in general (1) an ability to reduce chip operating temperature locally, (2) the potential for system-level integration with on-board electronics, (3) high reliability (>250 000 h), (4) no moving part (silent), (5) small and lightweight, and (6) no gas or chemicals involved.

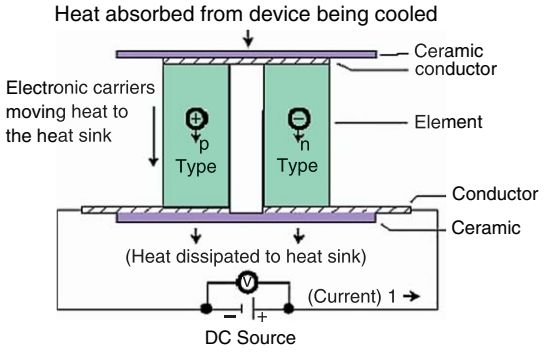

Figure 24 Schematic of a simple Peltier cooler. (Source: Lasance C J M, Simons R E 2005 Advances in high-performance cooling for electronics, *Electronics Cooling* **11**, 22–39, http://www.electronics-cooling.com/articles/).

The thermoelectric performance of a material at a given absolute temperature T is characterized by the nondimensional figure of merit, $ZT = \sigma S^2 T/\lambda$, where S, σ, and λ refer to the Seebeck coefficient and the electrical and the thermal conductivity of the material, respectively. The most challenging task in any thermoelectric application is to find materials that provide low thermal conductivity, to reduce heat losses due to heat conduction between the hot and the cold side, and a high electrical conductivity, to minimize Joule heating and allow for more heat conduction for the applied electric field. For metal and metal alloys, the ratio of the thermal conductivity to electrical conductivity is a constant (Wiedemann–Franz–Lorenz law). Thus, metals with the highest possible Seebeck coefficients ($\sim$10 μV K^{-1}) only produce efficiencies of a fraction of 1%. Through an exhaustive and long journey to find the right material, bismuth telluride (Bi_2Te_3) and its alloys of synthetic highly doped semiconductors were found to possess the highest ZT value (around 1 at room temperature). With these materials, heat pumping rates have been achieved ranging from a few milliwatts to a few tens of watts, and the maximum temperature difference is around 70°C for rejection of heat to a room-temperature reservoir. In **Figure 25**, the theoretical COP and efficiency of thermoelectric coolers and power generators for different ZT values are plotted and compared with other cooling and power generation technologies (Chen and Shakouri 2002). However, TECs made with conventional bismuth telluride compounds ($ZT \sim 1$) cannot compete against the mechanical refrigeration cooling in a large-scale cooling

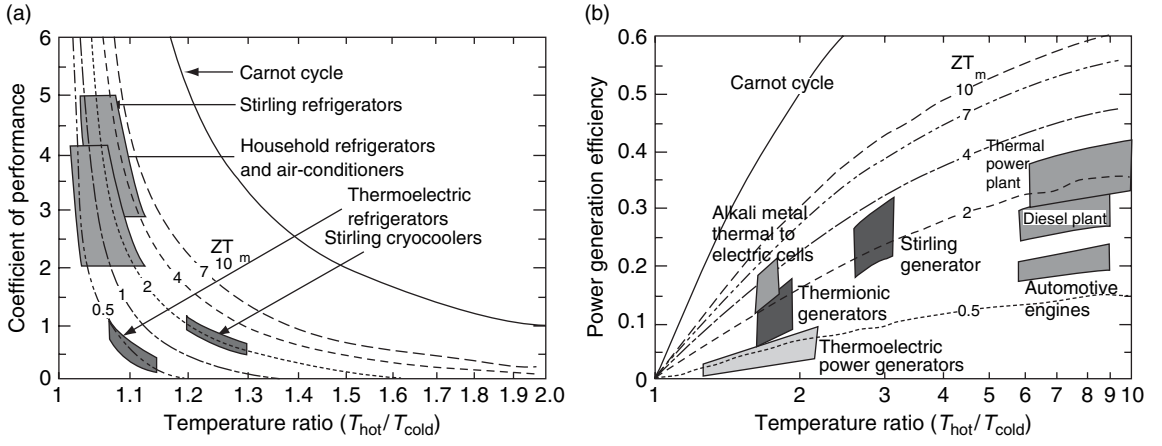

Figure 25 Comparison of thermoelectric technology with other energy conversion methods for (a) cooling and (b) power generation. (Source: Chen G, Shakouri A 2002 Heat transfer in nanostructures for solid-state energy conversion. *ASME J. Heat Transf.* **124**, 242–52).

technology. Despite their low efficiency, TECs are used for applications in areas such as (1) cooling of semiconductor lasers, infrared detectors, charge-coupled devices, blood analyzers, and microprocessors, where accurate control of cooling is required below ambient temperature and (2) small portable refrigerators and picnic coolers (Lasance and Simons 2005).

Along with the low efficiency, the relatively high manufacturing cost of thermoelectric materials has also limited TECs from being widely applied in electronics cooling or as the refrigeration source for consumer product coolers (Phelan *et al.* 2001), although as volumes are increasing and new TEC elements are being created, prices are dropping and more TEC applications are being found. Conventional crystal growth techniques, such as the Bridgeman method, to produce bismuth telluride impose significant limitations on thermoelectric element dimensions due to poor manufacturing yields. The weak bonds holding adjacent crystals together fall apart during wafer processing. A great deal of research has been directed to develop a smaller size of Peltier elements because the cooling capacity of the TEC is inversely proportional to its leg length. A review of the recent industrial efforts can be found elsewhere (Chu and Simons 1999, Lasance and Simons 2005). Bierschenk and Johnson (2005) at Marlow Industries reported new fine-grain microalloyed bismuth telluride materials that can offer high heat capacity over $40\,\mathrm{W\,cm^{-2}}$. Nanocoolers Inc. claims to develop wafer-scale thin-film TEC technology by which the small Peltier coolers are monolithically fabricated (Ghoshal 2005b). A small, flexible thermoelectric module with overall dimension of $16\,\mathrm{mm} \times 20\,\mathrm{mm} \times 0.05\,\mathrm{mm}$ has been made using copper foil as a template (Qu *et al.* 2001). Multiple micro Sb–Bi thermocouple strips are electroplated on a thin Cu foil previously coated with a patterned epoxy layer. As another viable technique, a pulsed layer deposition was used to grow high-quality thermoelectric $Ca_3CO_4O_9$ thin film formed on top of an SiO_x amorphous layer in a self-assembled manner (Hu *et al.* 2005). Bulk thermoelectric material (cubic $AgPb_mSbTe_{2+m}$) with $ZT \sim 2.2$ at 800 K was synthesized using a standard ingot crystallization process, but at room temperature, the ZT is less than 1 (Hsu *et al.* 2004). To develop a microscale TEC device, Snyder *et al.* (2003) developed a novel MEMS-like electrochemical process to fabricate a thermoelectric microcooler device containing 126 n-type and p-type $(Bi, Sb)_2Te_3$ thermoelements, 20 μm in length and 60 μm in diameter with bridging metal interconnects as shown in **Figure 26**. Both cooling and power generation using this device were demonstrated. However, the performance has not yet been optimized partly because the electrodeposited thermoelectric materials have defect structures that effectively reduce their Seebeck coefficients.

In parallel with searching for high-ZT materials, extensive research on the thermoelectric properties of low-dimensional structures has been performed and shows promise in future microcoolers. Pioneering work by Hicks and Dresselhaus (1993) on nanostructured superlattice materials for enhancing the thermoelectric figure of merit started a renewed interest and inspired much of the recent research on the subject. Superlattices are made of alternating thin layers of different thermoelectric materials stacked periodically (Bottner *et al.* 2006). Many bulk materials with relatively good thermoelectric properties have been explored with superlattice TECs: V–VI semiconductors such as Bi_2Te_3/Sb_2Te_3 (Beyer *et al.* 2002, Venkatasubramanian *et al.* 2001), IV–VI semiconductors such as PbTe/PbSe (Beyer *et al.* 2002, Harman *et al.* 2000), IV–IV semiconductor such as Si/Ge (Zeng *et al.* 1999), and V–V semiconductor such as Bi/Sb (Cho *et al.* 2001). Compared to the research in bulk materials that focuses on decreasing the thermal conductivity, nanostructures provide a means to alter both the electron and the phonon transport through the use of quantum and classical size and interface effect (Chen and Shakouri 2002). Outstanding examples of nanostructured materials with high ZT (up to 2.4) were reported with the use of thin-film superlattices (Venkatasubramanian *et al.* 2001) and quantum dot superlattices (Harman *et al.* 2002). Venkatasubramanian *et al.* (1999) used low-temperature organometallic epitaxy to form a Bi_2Te_3/Sb_2Te_3 heterogeneous superlattice structure, with one of the individual layers as small as 10 Å. The anticipated quantum-well-type, heterostructure band diagram with various short periods (10–50 Å) is shown in **Figure 27(a)**, and this ultra-short period superlattice offers significantly higher in-plane mobility while at the same time more phonon backscattering at the interface, thus reducing the thermal conductivity. With a $ZT \sim 2.4$ for their p-type device, the COP shown in **Figure 27(b)** should be comparable to typical mechanical refrigeration systems ($\mathrm{COP} = 2 \sim 4$) when combined with a similar ZT n-type structure, with an estimate of the cooling power density as high as $700\,\mathrm{W\,cm^{-2}}$ at 353 K, which is over 300 times that of the bulk material

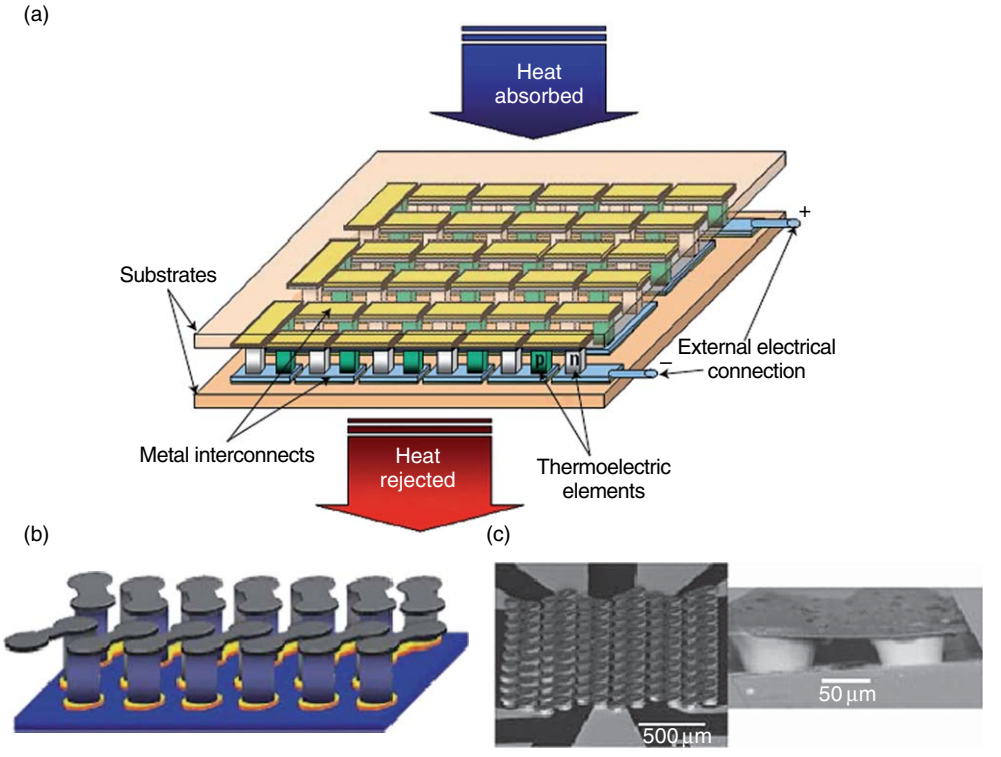

Figure 26 (a) A typical thermoelectric device in which over a hundred n–p couples are connected electrically in series, but thermally in parallel between the hot and the cold side. (Venkatasubramanian *et al.* 2001). Harman's group (2000) utilized molecular beam epitaxy to grow Bi-doped (n-type) $PbSe_{0.98}Te_{0.02}/PbTe$ self-assembled quantum dot superlattices and showed a significantly higher ZT (~2) than their corresponding bulk materials. It is believed that the enhancement in ZT values may result from a delta-function-like feature in the electron density states, increased phonon scattering (Harman *et al.* 2002), and possibly electron energy filtering (Shakouri 2004). Very recently, Zhang *et al.*

(2006a) demonstrated a 3D silicon microrefrigerator that could cool at a maximum of 1.2°C at room temperature and an easy integration of a microcooler into a silicon chip to remove hot spots.

A direct profiling of the Seebeck coefficient, *S*, across a semiconductor p–n junction with nanometer resolution was investigated using scanning thermoelectric microscopy in order to better understand the effects of low dimensions and nanoscale structures on *S* (Lyeo *et al.* 2004). Thorough knowledge of nanostructures' dependence on Seebeck coefficients and thermal and electrical conductivity will help to design and optimize these superlattice thermoelectric coolers. Theoretical treatments with rigorous reviews on the progress of low-dimensional thermoelectric materials research can be found elsewhere (Böttner *et al.* 2006, Chen 2006, Chen and Shakouri 2002, Chen *et al.* 2003, DiSalvo 1999, Shakouri 2004, Tritt 2001). As an example of the progress, the Majumdar group at the University of California, Berkeley, have recently investigated the thermoelectric properties of metal–molecular junctions with scanning tunnelling microscopy and introduced the possibility of developing inexpensive and efficient molecular TECs (Reddy *et al.* 2007).

3.16.3.3.2 Thermionic microcoolers

The concept of thermionic energy conversion is relatively new and is based on the concept that a hot, high work function cathode in contact with a heat source will emit electrons, which are absorbed by a cold, low work function anode separated by a vacuum gap, resulting in a current flow across a voltage potential caused by the work function difference (Hatsopoulos and Kaye 1958). When the anode and the cathode are connected through an external load, electrons flow and electric power can be measured to calculate the efficiency. A thermal efficiency of about 13% was reported with a cathode held at higher than 1500 K. Mahan (1994) proposed a vacuum diode-type refrigerator based on the same principle by imposing a current in the opposite spontaneous current direction. Mahan pointed out that thermionic refrigerators would not work at room temperature because of a high work function of a typical cathode. The minimum work function currently available for a cathode is over 0.7 eV, for which the refrigerator would work only at temperatures above 500 K with the theoretical efficiency of over 80% of the Carnot value. Another practical limitation is that space charge can also create an additional potential barrier imposed by free charges in the space between the anode and the cathode, thereby diminishing the thermionic current. Since this seminal work, many researchers have attempted to create efficient thermionic refrigerators running at room temperature.

Since no material has a work function less than 0.3 eV for a viable room-temperature thermionic refrigerator in a metal–vacuum–metal system, metal–semiconductor or semiconductor–semiconductor layers have been considered to make lower-temperature thermionic systems (Mahan and Woods 1998, Shakouri and Bowers 1997). Shakouri and his collaborators at the University of California, Santa Cruz, and Bower at the University of California, Santa Barbara, proposed heterostructure integrated thermionic (HIT) coolers that use semiconductor heterolayers with a smaller barrier height (0.1–0.4 eV) determined by the band edge discontinuity (Shakouri and Bowers 1997). The calculation based on nonlinear transport regime of $Hg_{1-x}Cd_xTe$ heterolayers with a barrier thickness of about 1 μm can achieve room-temperature single-stage cooling of 20 to 40°C and cooling power densities over 100 W cm^{-2} (Shakouri and Bowers 1997, Shakouri *et al.* 1998). Experimental investigation of HIT cooling was performed by fabricating a single InGaAsP barrier (~1.3 μm thick and 0.1 eV) surrounded by an n^+-InGaAs and lattice-matched to InP substrate (Shakouri *et al.* 1999a). Cooling of 1° at 80°C with cooling power densities exceeding 50 mW cm^{-2} were observed. The monolithic integration of this cooler with optoelectronic devices was demonstrated, and it was shown that the performance of the single-barrier HIT device with monolithic structures was limited by the nonideal effects, such as Joule heating and the metal–semiconductor contact resistance (LaBounty *et al.* 2000, 2001). Mahan and Woods (1998) proposed to utilize thermionic emission in the multilayer structures, but focusing on the use of the Schottky barriers between some metals and semiconductors. A barrier height less than 0.1 eV can be made for the Schottky barriers such as InGaAs/Au (Kajiyama *et al.* 1973), InSb/Au, and EuPbTe/PbTe (Hicks *et al.* 1996). The authors argued, based on their analyses, that a multilayer is necessary to reduce the thermal conduction loss by maintaining a small bias and thus a small temperature difference (<1 K) for each layer and that their ZT values increased by a factor of 2 from the bulk counterpart.

In thin-film heterostructure devices, thermionic cooling differs from thermoelectric cooling in that the selective emission of hot electrons, equivalent to evaporation cooling, brings about strong electron–electron and electron–phonon interactions to restore

the quasiequilibrium distribution in the cathode by absorbing energy from the lattice, subsequently cooling the emitter junction (Shakouri and Bowers 1997). A larger thermoelectric power factor (σS^2) than that of bulk materials can be obtained, thanks to an increase in the effective Seebeck coefficient by selective emission while maintaining high electrical conductivity. Further investigations showed that in the superlattice structure, the thermoelectric power factor of the TEC devices is higher than that of thermionic devices and that its ZT enhancement is associated with reduced lattice (or phonon) thermal conductivity rather than improved electronic transport (Radtke *et al.* 1999, Vining and Mahan 1999). Ulrich *et al.* (2000) also concluded that for all known materials, single-barrier thermionic refrigeration is less efficient than TEC refrigeration.

However, although high electrical conductivity and low thermal conductivity are still necessary for an HIT cooler to work, the requirement of high bulk Seebeck coefficients is relaxed in thermionic cooling, which broadens the selection of materials and corresponding fabrication processes, making HIT still potentially useful for microcoolers. It is also important to note that the HIT coolers with SiGe or III–V semiconductors are not intended to provide highly efficient and macroscopic chip cooling but to selectively cool local hot spots in the chip, where the efficiency of the microcooler is no longer important and the small-size refrigerator with minimal additional thermal resistance is required (Shakouri and Zhang 2005). Many multilayer HIT coolers for high–heat flux optoelectronic devices and hot spots in microprocessors have been demonstrated using standard IC fabrication techniques with conventional semiconductor materials such as SiGe/Si (Fan *et al.* 2001a) and SiGeC/Si (Fan *et al.* 2001b). Zeng *et al.* experimentally investigated the cooling power density of SiGe/Si HIT microcooler consisting of a 3-μm thick 200 × (5 nm Si0.7Ge0.3/10 nm Si), MBE-deposited superlattice films by integrating thin-film resistor heaters (also serving as resistive temperature detectors (RTDs)) on the cooling surface, as shown in **Figure 28(a)** (Shakouri and Zhang 2005, Zeng *et al.* 2004, Zhang *et al.* 2004). Net cooling of over 4.1 K with a cooling power density of 600 W cm^{-2} for 40 μm × 40 μm devices were reported at room temperature. A more recent study on a similar HIT microrefrigeration system (**Figure 28(b)**) for cooling localized hot spots demonstrated a maximum cooling of 7 K with a maximum cooling power density of over 500 W cm^{-2} at 100°C (Fukutani *et al.* 2006). A noncontact thermoreflectance technique was also used to map the temperature distribution on top of the microcoolers as shown in **Figure 28(c)**. Fast transient response less than 40 μs was recently demonstrated with these microcoolers for on-chip high speed localized cooling (Zhang *et al.* 2006a).

A recent breakthrough in HIT microcooler experiments from Shakouri's group is related to the use of 3D structured thermoelectric elements. When HIT elements are combined with a tall barrier, highly degenerate superlattice structures such as multiple quantum wells and quantum dots, thermoelectric power factors an order of magnitude higher than the bulk values can be potentially achieved (Shakouri *et al.* 1999b). A detailed theoretical analysis of electron and thermoelectric transport perpendicular to heterostructure superlattices revealed that the high performance of metal-based superlattices with tall barriers occurs from the nonconservation of lateral momentum during the thermionic emission process (Vashaee and Shakouri 2004a, b). Analysis based on a Monte Carlo transport model also supported that a nonplanar potential barrier structure in HIT can achieve a much larger emission current, increasing the thermoelectric figure of merit (Bian and Shakouri 2006).

Along these lines, modifications to existing thermionic microcoolers have been discussed in the literature to improve cooling. Xuan (2002) suggested replacing the passive metal conductor in a vacuum thermionic refrigerator with an active p-type thermoelectric element to form a combined thermionic–thermoelectric refrigerator. More efficient and higher cooling power than either thermionic cooler or TEC was predicted for ideal materials. Mal'shukov and Chao (2001) suggested an optothermionic refrigerator, combining the ideas of the laser cooling and thermionic cooling, which consists of a narrow quantum well embedded in the middle of a p–n junction. Electrons in the n-doped region and holes in the p-doped region are thermally excited into the quantum well and recombined to emit light, extracting heat from the system. A quantitative analysis of competing events of cooling by radiative recombination and heating by nonradiative recombination at the junction showed that a cooling rate of a GaAs/AlGaAs optothermionic refrigerator was calculated to be several watts per square centimeter. Further analysis suggested that a cooling rate as high as 10 W cm^{-2} is possible with the same cooler system (Han *et al.* 2006). Experiments are still needed to validate this idea.

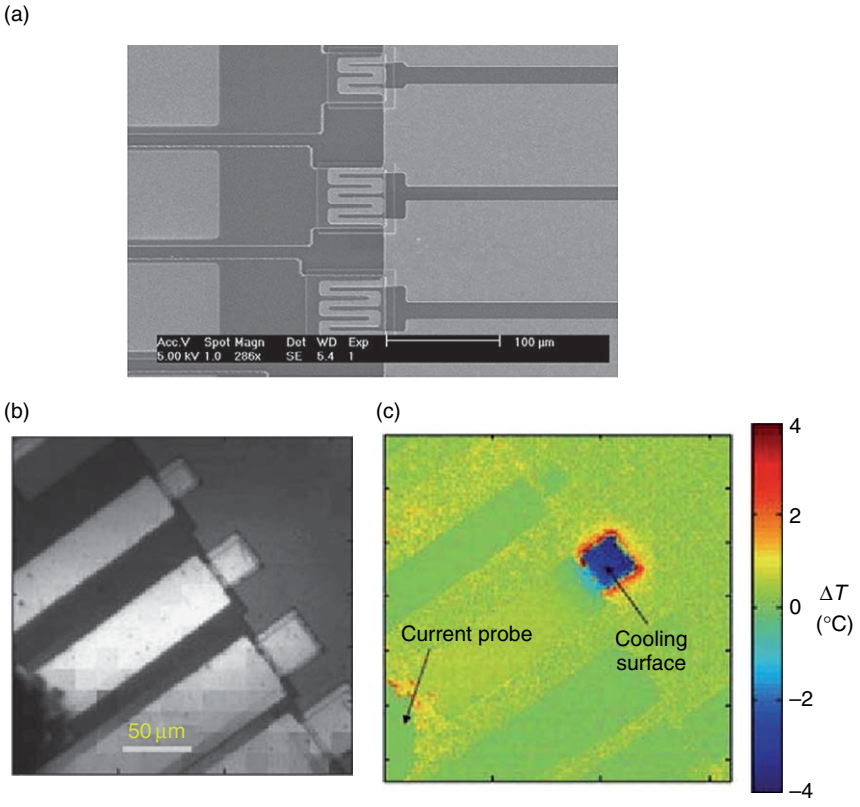

Figure 28 (a) Scanning electron micrographs of SiGe/Si HIT microcoolers integrated with thin-film resistive temperature detectors (RTDs). Symp. Proc.* **793**, S2.2.1–2.2.7), (b) scanning electron micrographs of SiGe/Si HIT microcoolers, and (c) temperature distribution of (b) showing uniform local cooling. (Source: Fukutani K, Zhang Y, Shakouri A 2006 Solid-state microrefrigerator on a chip. *Electronics Cooling* **12(3)**, http://www.electronics-cooling.com/articles/).

Finally, a brief description of thermionic tunneling (or so-called thermotunneling) is useful for this discussion of solid-state microcoolers. The idea is to use electron tunneling at nanometer-thick vacuum gaps for thermionic microcoolers to operate at room temperature. To ensure only hot electrons (originating above the Fermi level) participate in tunneling, the barrier height can be adjusted by size and bias (Hishinuma *et al.* 2001) or by using heterogeneous structures (Hishinuma *et al.* 2002). Preliminary experiments, however, did not show substantial cooling (<1 mK) and posed significant fabrication challenges, such as maintaining uniform nanometer gap sizes and atomically clean electrode surfaces (Hishinuma *et al.* 2003). An increase in the emission current by 10 orders of magnitude must be accomplished for practical cooling capabilities of 10–1000 W. Other approaches were discussed to increase the thermionic emission currents using resonant tunneling or the inverse Nottingham effect (Korotkov and Likharev 1999, 2000, Tsu and Greene 1999), as well as sharp nanostructured tips like nanotubes (Fisher and Walker 2002, Fisher *et al.* 2003). No experimental results on cooling have yet been reported at near room temperature. In addition, significant improvements in developing lower work function materials should be made to capitalize the nanogap vacuum thermionic emission.

3.16.3.4 Mechanical Refrigeration Methods

While a majority of work in microcoolers has focused on solid-state refrigeration, the pursuit of building the mesoscale/microscale mechanical refrigerators has continued in both academia and industry due to the potential for mechanical systems to have high COP and to move relatively large heat fluxes. Unlike the solid-state cooling systems just covered, which have relatively low COP at the normal scale, but offer potentially higher COP at the

microscale, mechanical cooling systems regularly achieve high COP at the normal scale but have not yet succeeded to do so at the microscale. In terms of development effort and maturation, microscale mechanical coolers are still a nascent technology. Miniaturization efforts using micromechanical machining and MEMS processes have been reviewed for energy systems in general (Ameel *et al.* 1997) and for refrigerators or cryocoolers (Burger 2001, Phelan *et al.* 2002). The performance and feasibility of various miniaturized mechanical refrigeration systems are compared using a simple thermodynamic model (Phelan *et al.* 2003). No complete mechanical refrigeration system has been demonstrated in the length scale of interest here, but we will discuss the basic working principles and preliminary attempts to build such systems. In addition, we will cover outstanding research issues that need to be resolved before mechanical microcoolers find wide acceptance.

3.16.3.4.1 Active two-phase cooling systems

Even though heat flux spontaneously moves from hotter to colder reservoirs, higher heat fluxes can be achieved using active pumping schemes to increase fluid flow rates. Goodson *et al.* developed a closed-loop, two-phase microchannel cooling system to remove high heat fluxes in VLSI circuits (Jiang *et al.* 2002, Tripp *et al.* 2004). Utilizing an electroosmotic micropump made of a porous glass frit, which produces a maximum pressure of 160 kPa and flow rate of 7 ml min^{-1}, and microchannel heat exchangers, the cooling system can remove 38 W with a pump power of 2 W. Cooligy Inc. has developed a closed-loop liquid cooling system based on this electroosmotic pumping principle that can handle heat fluxes greater than 500 W cm^{-2} for desktop computers and servers (Upadhya *et al.* 2003, 2004, Zhou *et al.* 2004). **Figure 29** shows the schematic of their recent prototype cooling system presented recently (Upadhya *et al.* 2006).

3.16.3.4.2 Vapor compression refrigerators

A detailed description of the vapor compression refrigeration is available in any basic thermodynamics textbook. All vapor compression refrigerators are made of four main components: a compressor, a condenser, an expansion orifice, and an evaporator. Briefly, a refrigerant (e.g., R-134a) enters the evaporator as a two-phase (but mostly liquid) liquid–vapor mixture, and as the refrigerant absorbs heat from the cold region, it changes phase from liquid to vapor, leaving the evaporator as a saturated vapor. The refrigerant is then compressed adiabatically and sent to the condenser, where the refrigerant rejects heat to the warm region and changes phase from a saturated vapor to a saturated liquid. Finally, the refrigerant passes through an orifice (or expansion valve), expands to a two-phase mixture, and enters the evaporator, thus completing a cycle. The advantages of vapor compression refrigerator are its (1) capability of removing large quantities of heat with a small mass flow of refrigerant, (2) high efficiency, arguably one of the most efficient refrigeration systems at the macroscale, producing high COP, and (3) the capability of achieving subambient temperature without injecting additional pumping energy at the cold junction that too must be removed.

Unfortunately, vapor compression refrigerators typically perform less efficiently as their sizes become smaller. Since the cooling capacity scales with the volume of gas while many loss mechanisms, such as friction and heat loss, scale with the surface area, losses tend to begin to dominate as the surface-to-volume ratio increases and the size shrinks, making efficient microscale mechanical-based refrigerators difficult to achieve (Shakouri and Zhang 2005). A few companies attempted to develop

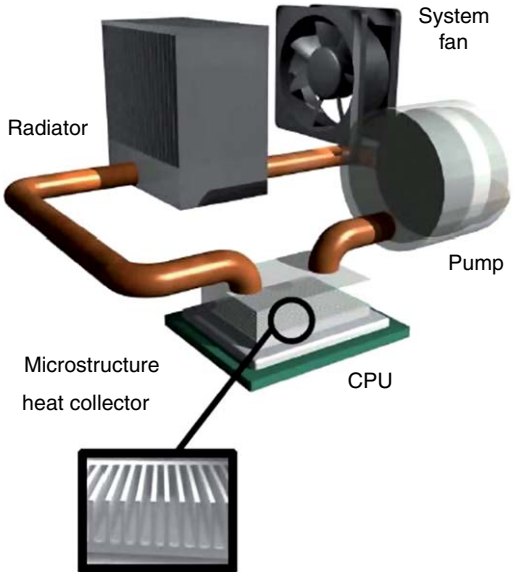

Figure 29 Schematics of the microscale liquid cooling system from Cooligy, Inc. (Source: Upadhya G, Munch M, Zhou P, Horn J, Werner D, McMaster M 2006 Micro-scale liquid cooling system for high heat flux processor cooling applications. *IEEE 22nd SEMI-THERM Symp.*, San Jose, CA, USA, pp. 116–19. (© 2006 IEEE)).

relatively small vapor compression refrigerators for electronics cooling, but their sizes are rather big and considered more suitable for larger, less portable applications. IBM employed refrigeration cooling in the large server (IBM S/390 G4 CMOS system, first shipped in 1997) to improve the system performance. The size of the cooling unit is 26 cm × 26 cm × 70 cm with a weight of 27 kg (Schmidt 2000, Schmidt and Notohardjono 2002). KryoTech was one of the first companies to have introduced to the commercial market a vapor compression refrigerator that can be incorporated to cool an AMD CPU chip down to −40°C or 25°C (Peeples 2001). As shown in **Figure 30**, the refrigeration system is made to be installed below the desktop tower, resembling a typical refrigeration unit in a dorm room. The evaporator of the refrigerator is placed on the high-speed microprocessor to maintain it at the desired temperature and allow overclocking far beyond what is possible with conventional air/liquid cooling. Fujitsu Ltd. in Japan also presented a prototype dual-loop vapor compression refrigerator mounted on CPU-MCM package for a heat load ranging from 250 to 2500 W (Wei *et al.* 2003a, b). Despite the superior cooling performance, these vapor compression-type refrigeration systems for commercial electronics cooling are not yet popular in the market because of the issues of packaging, cost, noise, and reliability of mechanical systems.

More analyses and experimental investigations continued to improve the miniature vapor compression refrigeration systems for electronics cooling application (Bash 2001, Heydari 2002, Trutassanawin *et al.* 2006). Chiriac proposed constructing a miniaturized mechanical refrigeration system onto the printed circuit board by integrating commercially available, miniature components and analyzed each component (evaporator, condenser, compressor, and valve) to optimize the COP of the overall system (Chiriac and Chiriac 2005). Using R-134a refrigerant, the refrigeration system was optimized for cooling power ranging from 20 to 100 W, with the COP up to 4.5. However, the size of these refrigeration systems for electronics cooling is too large, putting them outside of the micro-cooler realm.

The main challenges in miniaturizing vapor compression refrigeration systems for designs based on normal-scale systems have to do with component miniaturization and integration. Especially the development of a small, yet efficient, gas compressor is the most crucial factor in all the mechanical refrigeration systems. Based on the qualitative calculations of the entropy generation rates for each component, Jeong (2004) has argued that the mechanical compressor due to frictional and heat transfer across gradients is the most difficult component to be miniaturized in a vapor compression refrigerator. Different alternatives of actuation in a mesoscale compressor were discussed by Phelan *et al.* (2004). Our group and others have attempted to build a micropump that can pump a refrigerant (gas phase) at high pressure ratio (Laveau *et al.* 2000, Shannon *et al.* 1999). A group at the University of Central Florida employed electrostatic actuation integrated with centrifugal

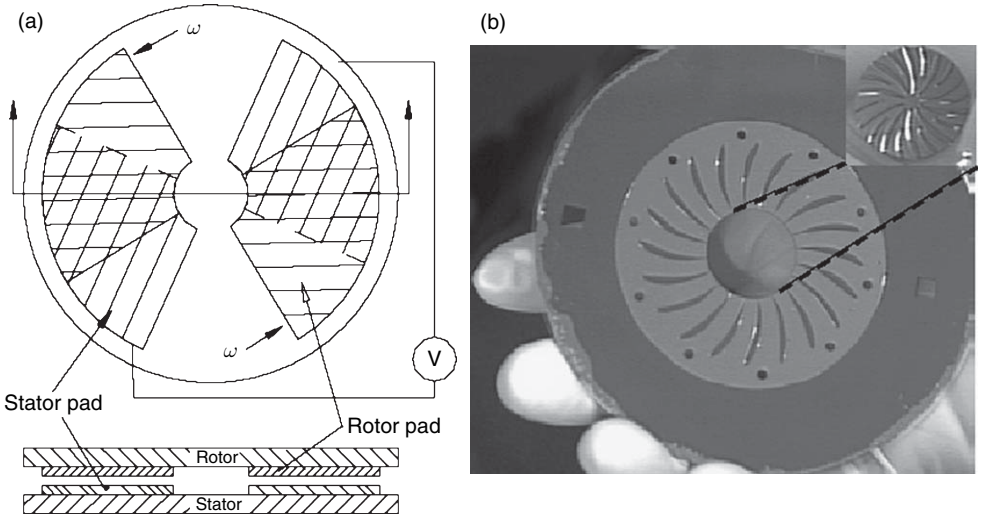

Figure 31 (a) A schematic of a simple variable capacitance motor and (b) an impeller micromachined in a silicon wafer. (Source: Agrawal R, Hasan Q, Ashraf N, Sundaram K B, Chow L C, Kapat J S, Vaidya J 2003 Design and fabrication of meso-scale variable capacitance motor for miniature heat pumps. *J. Micromech. Microeng.* **13**, 1–7).

compression and built a three-phase variable capacitance motor (VCM) by means of the standard Si MEMS technologies (Agrawal *et al.* 2003, Carter *et al.* 1999, Laveau *et al.* 2000). The intended application of their technology is to integrate a heat removal system for microelectronics with an actively cooled jacket. As shown in a schematic of a simple VCM in **Figure 31(a)**, the top rotor pads freely rotate with low friction slightly above the bottom stator pads and experience fluctuation of electrostatic force parallel to the surface of the plates as two conducting plates are displaced with respect to each other and change overlap areas. By switching on and off the excitation to the stator pads, the rotor continues to rotate either by electrostatic attraction or by inertia. The impeller and the diffuser of a compressor unit were fabricated on silicon and are shown in **Figure 31(b)**. The size of the compressor is about 7.5 cm in diameter. Although some electrical (capacitance) measurements showed a feasibility of the method, no pumping/compression data have yet been reported.

The development of a mesoscale flexible vapor compression refrigeration system based on a micro-scale compressor was attempted at the University of Illinois by Shannon *et al.* (1999). As seen in **Figure 32**, the entire system fits within a 100 mm × 100 mm by a 2.5-mm thick structure. An electrostatic compressor shown in **Figure 33** operating on touch capacitance was developed in an attempt to produce a microscale pump that could compress R-134a to 8.5 atm. The underlying principle of touch capacitance is shown in

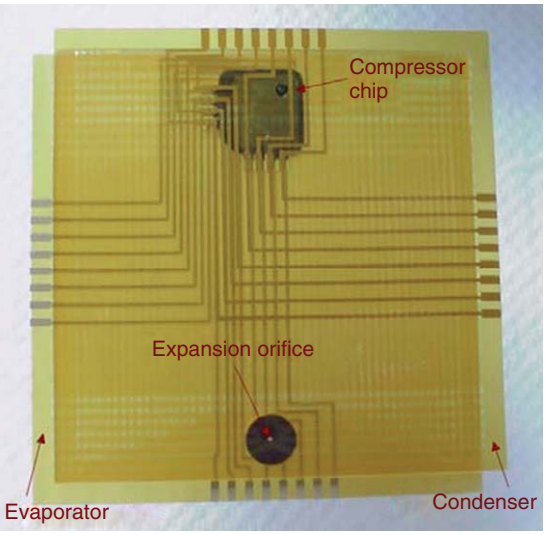

Figure 32 A picture of an integrated mesoscale vapor compression cycle cooler. The heat exchangers are 100 × 100 mm wide and 250 μm thick. The expansion orifice is a drilled alumina pore encased in steel, and the compressor chip is electrostatically actuated.

Figure 34. For very thin dielectric layers (t_1 and t_3 of order 0.2 μm), the electrostatic force per unit area (F_E/A) that compresses the refrigerant at a pressure, P, can be high ($F_E/A > 10$ atm) for relatively modest voltages (~100 V). The ultimate maximum pressure is determined by the electrostatic breakdown strength and the strain energy that needs to be overcome in the membrane. This type of electrostatic

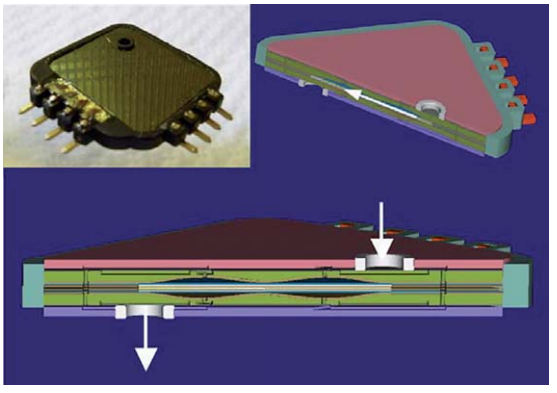

Figure 33 A picture of compressor chip (*upper left*), with cross-sectional views showing the fluid flow. The cross-sectional views are enlarged in the thickness to see internal features. The overall packaged size is 22 mm × 22 mm × 2 mm thick.

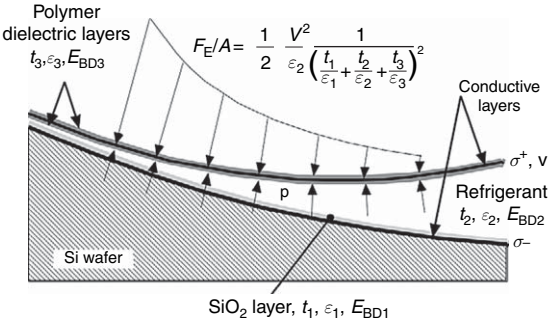

Figure 34 The operating principle underlying touch-capacitance compression. Refrigerant vapor is compressed between a movable polymer membrane and the silicon wafer as an electrostatic force on application of a voltage, V, pulls the two conductors together, zipping the membrane into contact with the wafer. The electrostatic force per unit area F_E/A is at a maximum when the gap, t_2, between the membrane and wafer is zero.

actuation improves with scaling to the microscale, since the amount of PV work is delivered from the total contact area, and thus improves with higher surface area to volume ratios. Moreover, the touch-mode actuation does not generate any sliding or frictional losses. The primary loss mechanism is via electrical resistance and heat transfer across the membrane. While a promising technique for compression, this method can be used to achieve a maximum pressure of less than 2 atm, due primarily to bubble modes that occur from nonaxisymmetric mode compression and charge transfer through the membrane that causes charge shielding, which can dramatically reduce the effective electric fields doing the compression work. Research has been ongoing to solve both the compression modes and charge shielding (Wu and Shannon 2004).

3.16.3.4.3 Stirling refrigerators

A Stirling refrigeration cycle is the most general case of the regenerative cooling cycle in which reversible work is performed on the warm surroundings when heat is absorbed at the cold side of the system. Depending on the methods of compression, expansion, and movement of the regenerator, variations from a Stirling cycle were invented, such as the Gifford–McMahon, Vuillemier, and pulse tube. In a Stirling refrigerator, compression, displacement, and expansion of a gas are performed using two reciprocating pistons and one displacer (regenerator), which can pose significant challenges in miniaturizing the system. These types of the regenerative refrigeration cycles are often found in the spacecraft, for example, cooling detectors of thermal imaging systems. Peterson investigated the lower size limit of a Stirling refrigerator and suggested that a refrigerator made of a low thermal conductivity material can scale down to under 1 cm (Peterson and Al-Hazmy 1997). Organ (1999) developed a comprehensive model to simulate the performance of the Stirling refrigerator. Sunpower Inc. patented a silicon-based micromachined free-piston cryocooler. As with other mechanical refrigerators, a complete Stirling refrigerator with the length scale of interest here is not available to the authors' knowledge.

3.16.3.4.4 Joule–Thompson refrigerators

Joule–Thompson (J–T) refrigerators are a broad category of the refrigerators capitalizing on cooling that occurs with the expansion of the high-pressure gas, utilizing the J–T effect. Typically, high-pressure gas (either from a cylinder or from a compressor) passes down a heat exchanger at cold side through a porous plug or expansion capillary, and this process can be combined with other thermodynamic cycles. One of the simplest modes of J–T refrigerators is to use Linde–Hampson (L–H) regenerative cycle, in which a cooled gas from a J–T valve is rerouted to a counterflow heat exchanger to precool the incoming high-pressure gas. The J–T refrigerator with its variations is one of the most popular methods to provide low-temperature cooling of electronic components such as IR detectors, SQUID, and IC chips (Ng *et al.* 2002). In order to obtain acceptable efficiencies, J–T coolers must be operated with very high pressures (200–500 atm). Therefore, many J–T

coolers employ an open-cycle operation using a high-pressure gas cylinder in spite of cost and inconvenience. Closed-loop operation of the J–T devices is conceivable but requires the high-pressure compressors that can produce a pressure ratio of 100–1000. This type of compressor is extremely difficult to make and expensive even at the macroscale, and therefore, miniaturizing these compressors to build a completely miniaturized J–T refrigerator has proved to be extremely difficult. Recently, electroosmotic microscale pumps have been developed with reported pressures of 0.35 MPa that have the potential to go much higher in pressure (Tripp *et al.* 2004). However, this is pumping of liquid and there would need to be a liquid-to-gas converter. The pumping rates are also very small (on the order of 0.01 ml min^{-1} at ~0.3 MPa) and would be even smaller at higher pressure. Efforts have also been made to reduce the size of the J–T devices in open-cycle operation because the small gas consumption would greatly reduce the cost. Little (1984) reviewed the early development of the miniature J–T cryogenic refrigerator. His group utilized photolithographic techniques to fabricate a small J–T cold stage (15 mm × 2 mm × 0.5 mm) out of glass plates and demonstrated a cooling power of 25 mW at 101 K with a N_2 flow rate of 3.1×10^{-6} kg s^{-1} at a pressure of 16.5 MPa (Garvey *et al.* 1983). Holland *et al.* (1998) presented a small L–H cooler with glass tube heat exchanger with a length of 270 mm and an outer diameter of 0.67 mm that has a cooling power of 60 mW at 88 K with a N_2 flow rate of 7.3×10^{-6} kg s^{-1} at a pressure of 10 MPa. More recently, a J–T microrefrigerator was incorporated into high-resolution magnetic resonance imaging for cryogenically cooling an rf detector coil to enhance image signal-to-noise ratio (Wright *et al.* 2005). A two to three times enhancement in performance was observed. Numerical studies on a miniature J–T refrigerator were also followed to reveal steady-state behaviors and provide the design guidelines (Chua *et al.* 2006, Ng *et al.* 2002). As long as the compressed gas cylinder is used as the high-pressure source, a true miniaturized, portable J–T cooler is not likely to be achieved.

3.16.3.4.5 Brayton gas refrigerators

The Brayton refrigeration cycle, better known as the gas refrigeration cycle, is the reverse of the closed Brayton power cycle, in which a working refrigerant remains a gas throughout a cycle without going through phase change. The cycle is similar to J–T refrigerators but differs by the fact that a J–T valve is replaced by a turbine enabling the expansion work to be recovered. Gas refrigeration systems in general require high pressure and volumetric flow rates and suffer from higher cost and lower COP compared to vapor compression. However, in cryogenic applications (below −100°C), temperatures well below the liquid–vapor saturation temperature of normal refrigerants are needed, and gas refrigeration system can achieve temperatures of below −150°C. The miniaturization of Brayton refrigerators involves the manufacturability of small, efficient turbines as well as compressors. The same group at the University of Central Florida extended their related work on a miniature centrifugal compressor (Laveau *et al.* 2000) to build a single-stage, lightweight, and compact Brayton refrigerator for space applications (Zhou *et al.* 2000). Implementing a microscale recuperative heat exchanger in their preliminary design, they anticipated a COP of about 0.2 at 80 K, the performance comparable to a corresponding Stirling refrigerator. A complete system has yet to be built and tested to show cooling performance.

3.16.3.4.6 Sorption refrigerators

Sorption refrigeration cycles have some features in common with the vapor compression cycle but differ in two main aspects. Instead of an ordinary mechanical compressor (compressing vapor between the evaporator and the condenser), a sorption compressor has a material with a large surface area to absorb an extra refrigerant to maintain a constant pressure in the chamber. After desorbing from sorption materials via heating, the sorption compressor can generate high pressure that pushes the refrigerant to a J–T valve and the evaporator. A heat sink is often required to return the temperature of the sorption material to ambient, completing a cycle. Since there is no moving part necessary in sorption refrigerators, they are expected to be more reliable in operation and more miniaturizable. However, sorption refrigerators face their own challenges such as periodic (not continuous) operation limiting heat capacity and required high heat input (Phelan *et al.* 2002). Macroscale sorption refrigerators find applications in power plants to take advantage of the waste heat for desorption or for space missions where the reliability and long-term operation are crucial (Duband and Collaudin 1999).

Despite continuous research efforts in macroscale sorption refrigerators, there have been only a few attempts to miniaturize this cooling technique. A

group at the University of Twente in the Netherlands developed a miniature sorption refrigerator for cooling of small low-temperature electronic devices with a cooling power in the range of 10 mW at 80 K (Burger *et al.* 1998, Ter Brake *et al.* 1997). A prototype sorption compressor cell is approximately 5 cm long and 5 mm in diameter. Various configurations of sorption compressors combined with J–T cold stages were analytically investigated to provide active cooling of cryogenic electronics in the space mission, thanks to its vibration-free operation (Burger *et al.* 2002). A thermodynamic analysis based on nitrogen–charcoal adsorbate–adsorbent pair was presented to design a sorption compressor for cryogenic cooling of electronics and showed a relatively small COP (Suman *et al.* 2005). This study suggested two important research directions to improve the COP of a miniature sorption refrigerator: (1) the development of absorbent materials with stronger affinity to refrigerants and (2) the design of a multistage compressor with multiple thin flat absorbent beds with fast heating/cooling response.

3.16.4 Integration of other MEMS Devices into Microcoolers

3.16.4.1 Micropumps

As discussed in the previous section, the success of active microcooler technologies such as active liquid cooling and mechanical refrigerators depends on the development of small, efficient, and reliable micropumps. Pumping a liquid for microchannel cooling systems is often the most critical factor for widespread commercial use because of the large pressure drops encountered in microchannels (Singhal *et al.* 2003). A comprehensive review of existing micropumps can be found in Laser and Santiago (2004). Micropumping technologies for driving fluid through microchannels are also reviewed (Joshi and Wei 2005, Singhal *et al.* 2004) with an emphasis on small-scale electronics cooling applications.

3.16.4.2 Microvalves

Microvalves are another critical component in all microfluidic applications, and the operation of micropumps often relies on how well passive/check microvalves can perform. A recent review of various actuation schemes and applications of microvalves can be found elsewhere (Hesketh *et al.* 2004). The review articles on micropumps in previous sections also describe the functions and challenges of the microvalves. Here we briefly discuss examples of microvalves used in microcooler applications. In fabricating the EDIFICE liquid jet impingement cooler, Amon *et al.* (2001) addressed a need to develop a microvalve that can regulate a flow rate with high back pressure. As a part of efforts to develop a miniature sorption refrigerator, Burger *et al.* (1999) reported a check valve that can hold gas pressure up to 10 MPa in the closed direction with a low cracking pressure in the forward direction. We have developed electrostatically actuated microvalves to control high-pressure flows through a microcompressor for a mesoscale flexible vapor compression refrigeration system (Philpott *et al.* 2000). Employing pneumatic assistance to balance the pressure between inlet and outlet, Bae *et al.* (2006) built a bidirectional electrostatic microvalve and demonstrated a valve switching times less than 50 μs. **Figure 35** shows a schematic and photographs of the fabricated microvalve with the three electrode layers. This type of microvalve with a fast switching response can be exploited in many microfluidic applications including microcoolers.

3.16.4.3 Integrated MEMS Sensors

To optimize the operating conditions of the microfabricated cooler devices, a macroscale testing setup is often used to take measurements such as temperature, pressure, and flow rate. However, due to a large thermal mass with macroscale measurements, collecting accurate information may be challenging. To this end, many researchers attempted to integrate MEMS sensors into microcooler devices. A few examples of simple RTD-type sensors to accurately measure temperatures and flow conditions in the microcooler applications are introduced here. Wang *et al.* (2004) integrated heaters and temperature sensors into their liquid microjet cooling devices using the same fabrication steps. LeBerre *et al.* (2006) processed the temperature sensor arrays together with silicon MHP arrays to accurately measure the axial temperature variations along the length of the heat pipe arrays. In addition to the temperature measurements, we have developed a thin-film RTD sensor that can detect liquid mass fraction at the evaporator exit of the vapor refrigeration system (Hrnjak *et al.* 2001, Shannon *et al.* 2001).

(© 2006 IEEE)).

3.16.5 Nanotechnology in Microcoolers

Recently, the exponential increase of interest in nanotechnology has encouraged researchers to incorporate nanoscale materials into microcooling technologies. CNTs, the number one driver in nanotechnology, have gained significant attention in the microcooler community because of their unique mechanical and electrical properties. CNT-based TIMs were discussed in Section 3.16.3.2. Utilizing CNT's excellent vacuum field emission properties (low turn-on voltage and high current density), a group at Purdue proposed a microscale air pump in which the ionized air molecules under the influence of an electric field induce a secondary flow (Peterson *et al.* 2005, Schlitz *et al.* 2004). The numerical simulation of this microscale ionic wind reveals an enhancement in local heat transfer coefficients (Go *et al.* 2006), but experimental verification has not yet been presented. Another group at Purdue utilizes CNT arrays on the chip surface to delay the CHF and enhance boiling heat transfer (Ujereh *et al.* 2005). An increase of 50% in the CHF and a reduction of 60% in the wall superheat were observed with CNT-coated surfaces, which resulted in a 400% enhancement of the effective heat transfer coefficients. Instead of silicon fins, Mo *et al.* (2004, 2005) proposed to use aligned CNTs grown in the surface of microchannel heat exchangers, which can dissipate heat more efficiently due to CNT's high thermal conductivity. Many features discussed in thermoelectric/thermionic coolers are intrinsically related to nanotechnology in terms of (1) the related materials such as thin-film superlattice structures, quantum well, and quantum dots and (2) the underlying physics governing the nanoscale heat transport of electrons and phonons. The development of scanning probe microscopes also helps to understand thermoelectric materials at the nanoscale (Lyeo *et al.* 2004, Miner *et al.* 2001, Reddy *et al.* 2007).

3.16.6 Summary and Conclusions

Clearly, the converging trends of ever-higher-powered and ever-smaller electronic systems as well as new types of portable lightweight devices have led to a rapid growth in microcooler technologies. Microcooling technologies for the most part are not simply scaled down from normal-scale systems, and the often-exploited physics where high surface area to volume ratios enhance heat transfer. Moreover, for single-phase convective heat transfer, the heat transfer per unit area can dramatically increase using microjet technology over normal-scale systems, and two-phase heat transfer coefficients in microchannel heat exchangers also see a dramatic increase in heat transfer coefficients. MHPs and looped thermocapillary systems see some enhancement in heat transfer,

although not uniformly in similar devices over normal scale. Nonetheless, due to the high effective heat conductivity of such devices over even the highest thermal conductivity materials, they are finding extensive use in practical systems. Active microcoolers, however, do not share the same extensive adoption. Solid-state coolers have found applications in microscale coolers and are used to reduce temperatures below ambient or to increase the heat rejection temperature of the heat sink. Solid-state devices also potentially scale well with size reduction. However, they still suffer from high cost, low efficiency, and nonlinear response with applied load, which further research, materials advancements, and overall adoption should all improve. Solid-state cooler technologies are mature compared with mechanically active coolers. Although many microscale mechanical coolers offer the promise of higher performance, efficiency, and stable response with load, a fair amount of research and development is still needed to move the technology forward. For all microcooling technologies, more work is needed to increase reliability due to important mechanical issues such as fatigue and fracture due to thermal cycling and coefficient of thermal expansion mismatch, materials incompatibility with refrigerants and solvents, and wear. In addition, manufacturing costs for microcooling technologies still need to be reduced for greater adoption. With this being said, the compelling need to create new, robust, low-cost microcooling technologies is not going to abate any time soon, and better integrated systems, particularly those with active heat pumping, are needed. Hopefully in time we will see this progress come to pass.

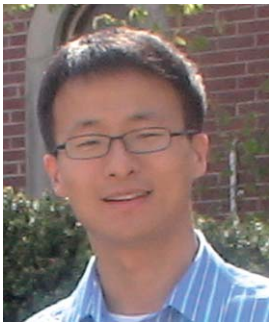
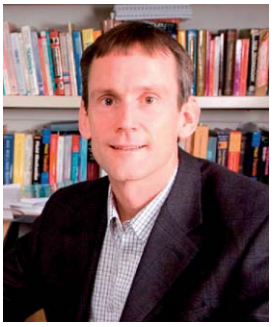
Biographies



Junghoon Yeom is a PhD candidate of Mechanical Science Engineering at University of Illinois and received his B.S. (2000) from Yonsei University, Seoul, Korea and M.S. (2003) from University of Illinois. During his graduate study, he has been involved with several DARPA projects including micro-formic acid fuel cell and micro gas chromatography system and developed an expertise in designing and fabricating MEMS devices and microfluidic systems. Mr. Yeom has 5 journal publications, 13 peer-reviewed conference proceedings, 3 conference presentations, and 1 patent application.



Mark A. Shannon is the Director of a NSF STC the WaterCAMPWS, which is a multiple university and government laboratory center for advancing the science and engineering of materials and systems for revolutionary improvements in water purification for human use. He is also the Director of the Micro-Nano-Mechanical Systems (MNMS) Laboratory at the University of Illinois at Urbana-Champaign, a 2000 sq. ft class 10 and 100 cleanroom laboratory devoted to research and education in the design and fabrication of micro- and nanoelectromechanical systems (MEMS and NEMS), microscale fuel cells and gas sensors, high-temperature microchemical reactors, micro-nano-fluidic sensors for biological fluids, and has published over 100 papers on these subjects. He chairs the Instrument Systems Development Study Session for the National Institutes of Health. He is the James W. Bayne Professor of Mechanical Engineering at UIUC, and received his B.S. (1989) M.S. (1991) and Ph.D. (1993) degrees in Mechanical Engineering from the University of California at Berkeley. He received the NSF Career Award in 1997 to advance microfabrication technologies, the Xerox Award for Excellence in Research (2004), the Kritzer Scholar (2003–2006), the Willet Faculty Scholar (2004–2007), the BP Innovation in Education Award in 2006, and the CERL 2006 Research, Development, or Operational Team Award.

3.17 Resonators, Oscillators, and Frequency References

CC Beam Clamped-Clamped Beam

FF Beam Free–Free Beam

VCO Voltage Controlled Oscillator

3.17.1 Standards for Frequency References

Frequency reference unit usually consists of a resonator that defines the frequency and an electronic circuitry that sustains the oscillation. Over the past 30 years, people have been using vibrating mechanical resonators, such as ceramic resonators, quartz crystal, and surface acoustic wave (SAW) resonators, for frequency references. These mechanical resonators can be excited only at some specific frequencies defined by their geometry and mode shape. The vibration energy is confined within this geometry so well that the energy loss is very small. Therefore, these resonators exhibit good frequency selectivity and stability compared to electrical resonators such as inductor–capacitor (LC) tanks.

Frequency reference standard is well-defined based on the accuracy of the oscillator frequency. This accuracy is defined as the frequency variation across all environmental parameters (e.g., temperature) and one year of aging. As shown in **Table 1** (Vig 2005), the frequency accuracy ranges from 10^{-4} to 10^{-12}, while of course the cost per unit ranges from 50 cents to $50 000.

One of the earliest works that micromechanical systems (MEMS) resonators researchers reference to is Nathanson's article 'The resonant gate transistors' published in 1967 (Nathanson *et al.* 1967). In this paper, gate oxide of a transistor was removed to allow metal gate to mechanically vibrate. This vibration provided high quality factor (Q) frequency selection. A 12-kHz integrated oscillator was demonstrated together with 90–150 ppm per degree Celsius of thermal stability.

Table 1 Frequency standard of oscillators

Oscillators type[a]	*Accuracy*[b]	*Typical applications*
IC oscillators	10^{-2} to 10^{-3}	Toys
Crystal oscillator (XO)	10^{-5} to 10^{-4}	Computer, camcorder, HDD
Temperature -compensated crystal oscillator (TCXO)	10^{-6}	Cell phones, GPS,
Oven-controlled crystal oscillator (OCXO)	10^{-8} (with 10^{-10} per g option	Navigation system clock and frequency standard, MTI radar
Small atomic frequency standard (Rb, RbXO)	10^{-9}	Satellite terminals, bistatic, and multistatic radar
High-performance atomic standard (Cs)	10^{-12} to 10^{-11}	Strategic C^3, EW

[a] Sizes range from <5 mm^3 for clock oscillators to >30l for Cs standards. Costs range from <$0.5 for clock oscillators to >$0.5 000 for Cs standards.
[b] Including environmental effects (e.g., −40°C to +85°C) and 1 year aging.

To date (the end of year 2006), MEMS oscillator is able to fulfill all the accuracy requirements in crystal oscillator (XO) category (i.e., 10–100 ppm frequency variation from −40°C to 85°C) with the advantages of lower cost, higher mechanical reliability (Hsu 2006), and fully compatible system applications. The future development would place the MEMS oscillator into the temperature-compensated crystal oscillator (TCXO) category for communication applications.

3.17.2 Resonators

3.17.2.1 Resonator Materials

As the key component that determines the oscillator frequency, the resonator requires materials that exhibit excellent reliability and stability in all operation conditions. The major requirements of the materials are (1) low mechanical stress, (2) no or negligible hysteresis, and (3) low aging rate.

In the literature, materials such as single-crystal silicon, polycrystalline silicon (Tang *et al.* 1989), silicon germanium (Franke and Howe 1999), AlN (Piazza *et al.* 2005), tantalum nitride (Pacheco *et al.* 2004), titanium (Parker *et al.* 2005), poly-diamond (Wang *et al.* 2004), and plated nickel (Hsu and Nguyen 1998) have been recorded as resonator materials. Each material has its advantages and disadvantages. For example, polycrystalline silicon has the advantage of being a complementary metal oxide semiconductor (CMOS)- compatible process, so almost all the foundries have the process. But the deposition temperature of standard poly-Si prevents it from being deposited directly on finished CMOS wafers, thus in turn becoming an obstacle for integration. Another example is metal resonators can be fabricated directly on top of CMOS wafers with low-temperature processes; however, metal resonators often exhibit stronger hysteresis effects.

3.17.2.2 Resonator Designs

The MEMS resonator can be defined as a micromachined mechanical structure that vibrates at its natural resonance frequency due to external excitations. One mechanical structure could be excited to different vibration modes at different frequencies. The external excitations of micromechanical resonators could be electrostatic, piezoelectric, laser, mechanical vibrations, and magnetic field. But regardless of the resonators and the excitations mechanism, for oscillator applications, the resonator should be excited to a specific mode with highest quality factor, lowest motional impedance, and highest power before resonator peaks reach the nonlinear region.

Table 2 shows a variety of micromechanical resonators that can be used for oscillators ranging in frequency from low kilohertz to possibly gegahertz. As shown, folded-beam resonators with interdigitated comb-drive transducers that resonate at 32.768 kHz are used for real-time clock (RTC) in power management chips or in watches. The challenges to manufacture commercial grade kilohertz oscillators are making low bias voltage for electrostatic transducer and designing oscillator circuits with low operation power. An integrated clock oscillator was first demonstrated in 1993 (Nguyen and Howe 1993). The state-of-the-art RTC oscillator was presented in Cioffi and Hsu (2005), where the resonator can be operated at 1.5 V and the IC consumes only <1 μA of current.

Table 2 Resonators in difference shapes and modes

Flexural mode		*Bulk mode*	
Folder beam		Disk (contour mode)	Clamped-clamped beam		Disk (wine-glass mode)	Free-free beam		Square (extension)	Square		Square (deform)	
The folded-beam comb-drive resonator structure may not be scaled to achieve tens of megahertz in frequency due to its large mass. The highest frequency that a comb-drive resonator achieved is 1 MHz (Roessig *et al.* 1998). Instead, as shown in **Table 2**, resonators with parallel capacitor transducer between resonator body and driving/sensing electrodes would enable resonators to be operated in 1–100 MHz frequency range. The examples are flexural clamped-clamped beams, free-free beams, and coupled square resonators. They exhibited good Q as high as 8 000–22 000 (Demirci *et al.* 2003, Hsu and Cioffi 2004), Hsu *et al.* 2001a, b, Wang *et al.* 2000) with polysilicon as the resonator material. Flexural resonators fabricated on silicon-on-insulator (SOI) wafers also exhibited good quality factor (Kim *et al.* 2005, Pourkamali *et al.* 2003).

For higher-frequency vibration, resonator stiffness needs to be higher. Therefore, other than flexural type of resonator, bulk acoustic mode resonators came into play after researchers figured out a process to form a lateral nanometer gap between electrodes and resonators for efficient electrostatic actuations (Hsu *et al.* 2001a, b). The resonators include disk resonator operating in radial mode (Clark *et al.* 2000, 2005), wine-glass mode (Abdelmoneum *et al.* 2003, Hao *et al.* 2004, Pourkamali *et al.* 2004), and the square resonator in extensional mode (Kaajakari *et al.* 2003). Bulk acoustic mode resonators have demonstrated quality factor as high as 98 000 in vacuum and 70 000 in air, which is very good for oscillator applications.

3.17.2.3 Resonator Mode of Operation

This section details the operation and mechanical design of MEMS resonators, using the simplest flexural modes as examples. **Figure 1** shows the simulated mode shapes of clamped-clamped beam, cantilever beam, and free-free beam, which will be discussed in this section.

The equation of motion of flexural beams can be expressed as

$$\frac{\partial^4 u(x)}{\partial x^4} = \left(\omega_0^2 \frac{\rho A}{EI}\right) u(x) = k^4 u(x) \qquad [1]$$

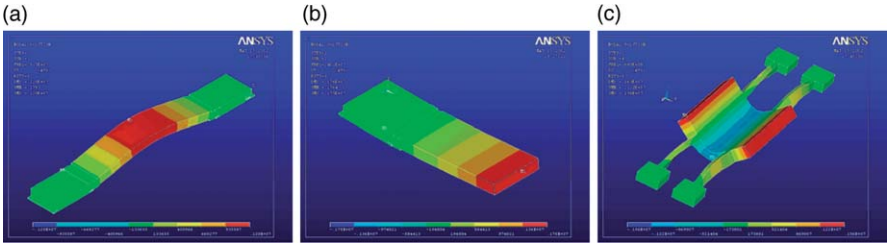

Figure 1 Mode shapes for flexural resonators: (a) clamped-clamped beam, (b) cantilever beam, and (c) free-free beam.

where ω_0 is the resonator frequency, ρ is the density of the material, E is the Young's modulus of the beam, A and I are the cross-section area and inertia of the resonator, respectively. Assume the solution is

$$u(x) = A\cosh kx + B\sinh kx + C\cos kx + D\sin kx \quad [2]$$

and apply various boundary conditions to the beam, frequency equations different mode shapes revealed the following:

(1) Clamped end: $u = 0$ and $u' = 0$
(2) Free end: $u'' = 0$ and $u''' = 0$
(3) Simple end (allow rotation but not movement): $u = 0$, $u'' = 0$

Clamped-clamped beam means both ends of the resonator beam are fixed or anchored to the substrate. Therefore, the boundary condition is $u(0) = 0$, $u(L) = 0$, $u'(0) = 0$, and $u'(L) = 0$. Therefore, the mode shape is

$$u_n(x) = \gamma_n(\cosh k_n x - \cos k_n x) + (\sinh k_n x - \sin k_n x) \quad [3]$$

where

$$\gamma_n = \frac{\sinh k_n L - \sin k_n L}{\cosh k_n L - \cos k_n L} \quad [4]$$

where k_nLs are the solutions of $\cosh kL \cos kL - 1 = 0$. Therefore, $k_1L = 4.73$, $k_2L = 7.853$, $k_3L = 10.966$, $k_nL \sim (n\pi + \pi/2)$ for $n > 3$.

The frequency equation becomes

$$f_n = \frac{(k_nL)^2}{2\pi L^2}\sqrt{\frac{EI}{\rho A}} \quad [5]$$

Cantilever beam means that one end is fixed while the other end is free. For a cantilever beam, applied clamped boundary condition is on one end and free boundary condition is on the other end, thus $u(0) = 0$, $u''(\mathrm{L}) = 0$, $u'(0) = 0$, and $u'''(L) = 0$. The mode shape is

$$u_n(x) = \gamma_n(\cosh k_n x - \cos k_n x) + (\sinh k_n x - \sin k_n x) \quad [6]$$

where

$$\gamma_n = \frac{\sinh k_n L + \sin k_n L}{\cosh k_n L + \cos k_n L} \quad [7]$$

and k_nLs are the solutions of $\cosh kL \cos kL + 1 = 0$. Therefore, $k_1L = 1.875$, $k_2L = 4.694$, $k_3L = 7.855$, $k_4L = 10.966$. Frequency of cantilever beam can be expressed as

$$f_n = \frac{(k_nL)^2}{2\pi L^2}\sqrt{\frac{EI}{\rho A}} \quad [8]$$

For a free-free beam, the boundary condition is $u''(0) = 0$, $u''(L) = 0$, $u'''(0) = 0$, and $u'''(L) = 0$ and the mode shape is

$$u_n(x) = \gamma_n(\cosh k_n x + \cos k_n x) + (\sinh k_n x + \sin k_n x) \quad [9]$$

where

$$\gamma_n = -\frac{\sinh k_n L - \sin k_n L}{\cosh k_n L - \cos k_n L} \quad [10]$$

where k_nLs are the solutions of $\cosh kL \cos kL - 1 = 0$. Therefore, $k_1L = 4.73$, $k_2L = 7.853$, $k_3L = 10.966$, $k_nL \sim (n\pi + \pi/2)$ for $n > 3$. The frequency equation becomes

$$f_n = \frac{(k_nL)^2}{2\pi L^2}\sqrt{\frac{EI}{\rho A}} \quad [11]$$

Note that the frequency equation of the free-free beam is the same as that of the clamped-clamped beam.

In theory, both ends of free-free beam are free. However, it is not possible to have a beam without any support. In reality, the free-free beam is supported on its nodal points by nonintrusive supporting beams that are strategically designed to isolate the resonator beam from its anchors via quarter wavelength impedance transformations to achieve a real free-free boundary condition (Wang *et al.* 2000). The mode shapes of the above beams are shown in **Figure 2**.

3.17.2.4 Quality Factor

The theory of the above section is for free vibration. It means the system does not need to work against resistive force, so its total energy remains constant at all times. In reality, the vibration system is always resisted by dissipative forces such as friction, acoustic transmission, air viscosity, and internal dissipations. This dissipative force is proportional to the speed of movement. Also assume that the vibration system is set to continuous vibration by a driving force

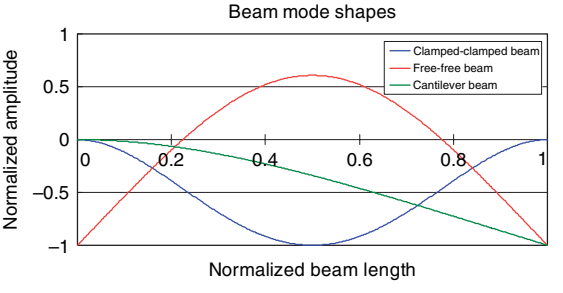

Figure 2 Normalized mode shapes of three flexural beams.

$F = F_0 \sin(\omega t)$; the mass–spring system can be modeled by a second-order mechanical system as

$$m\ddot{x} + kx + c\dot{x} = F_0 \sin(\omega t) \quad [12]$$

where m is the mass of the resonator beam, c is the friction coefficient, and k is the spring constant. Using $\omega_0^2 = k/m$ and $n = c/2m$, and assuming that the damping is small, which is the case for most resonators, the solution is

$$x_1 = A\mathrm{e}^{-nt}\left(\sin\left(\sqrt{(\omega_0^2 - n^2)}t + \alpha\right)\right) = A\mathrm{e}^{-nt}\sin(\omega_r t + \alpha) \quad [13]$$

$$x_2 = B\sin(\omega t - \varphi)$$

Substitute x_1 and x_2 into eqn [12]

$$B = \frac{\frac{F_0}{m}}{\sqrt{(\omega_0^2 - \omega^2)^2 + 4n^2\omega^2}} = \frac{\frac{F_0}{k}}{\sqrt{\left(1 - (\omega/\omega_0^2)^2\right)^2 + 4(n/\omega_0)^2(\omega/\omega_0)^2}} \quad [14]$$

and the phase lag is

$$\varphi = \tan^{-1}\left(\frac{2n\omega}{\omega_0^2 - \omega^2}\right) \quad [15]$$

This is the phase lag between free vibration frequency ω_0 and the driving force frequency ω. Therefore, while $\omega \to \omega_0$, $\varphi = 90°$. It means that the phase of the mechanical system is 90° behind the driving force if the driving frequency is close to the natural resonance frequency. For oscillator application, this will be the case and the amplitude is close to

$$B(\omega_0) = \frac{F_0 m\omega_0}{kc} = \frac{F_0}{k}Q \quad [16]$$

where Q is defined as the quality factor. In physics, quality factor is defined by the total energy in the system divided by the energy dissipated by damping in one cycle of oscillation. The total energy of the system is

$$E = \frac{1}{2}m\dot{x}^2 = \frac{1}{2}mA^2\omega_r^2 \quad [17]$$

The energy dissipated in one cycle is

$$\Delta E = \frac{1}{2\pi}\int_0^T c\dot{x}\,dt = \frac{cA^2\omega_r}{2} \quad [18]$$

and

$$Q = \frac{E}{\Delta E} = \frac{m\omega_r}{c} \quad [19]$$

Let us consider a case where the resonator vibrates for half of the maximum energy. In this case the vibration amplitude is $1/\sqrt{2}$ of the $B(\omega_0)$ in eqn [16]. At this point, the vibration frequency can be the solutions ω_1 and ω_2 of

$$\frac{1}{\sqrt{\left(1 - (\omega/\omega_0)^2\right)^2 + 4(n/\omega_0)^2(\omega/\omega_0)^2}} = \frac{1}{\sqrt{2}}\frac{m\omega_0}{c} \quad [20]$$

$$\Delta\omega = \omega_1 - \omega_2 = \frac{2n}{\sqrt{1 - 2(n/\omega_0)^2}} \quad [21]$$

Therefore, in frequency domain, the Q is defined by the resonance frequency divided by 3 dB bandwidth, which is equal to $\Delta\omega$ in eqn [21]. We can see that this definition matches with the previous mechanical definition in eqn [19]

$$Q = \frac{\omega_r}{2n}\sqrt{1 - 2(n/\omega_0)^2} \approx \frac{\omega_r}{2n} = \frac{m\omega_r}{c} \quad [22]$$

As shown, resonator Q strongly depends on the friction coefficient, i.e., energy dissipation of the resonator beam. The energy dissipation is usually directly related to how well the resonator is anchored to the substrate. Here are some examples of how different anchors affect the Q.

3.17.2.5 Frequency Pulling

In Section 3.17.2.4, a general driving force was discussed. This section focuses on driving resonators with electrostatic force, which conserves the quality factor of the resonators better than other electrical actuation such as piezoelectric.

Electrostatic force generated by a parallel plate can be expressed as

$$F = \frac{1}{2}(V_P - v_i)^2\frac{\partial C}{\partial x} \quad [23]$$

Assume $v_i = |v_i|\cos(\omega t)$, according to eqn [15], the resultant displacement is $x = |x|\sin(\omega t)$. Thus

$$F = \frac{1}{2}(V_P - v_i)^2\frac{\partial C}{\partial x} = \frac{1}{2}\left(V_P^2 - 2V_P v_i + v_i^2\right)\frac{\partial}{\partial x}\left[C_0\left(1 + \frac{x}{d_0}\right)^{-1}\right] \quad [24]$$

Assuming x is small compared to d_0 and takes only the terms at ω_0, we have

$$F = V_P\frac{C_0}{d_0}|v_i|\cos\omega_0 t + \frac{C_0}{d_0^2}V_P^2|x|\sin\omega_0 t \quad [25]$$

Note that if $V_P = 0$, the driving force at ω_0 is zero. The first term is the driving force that is applied directly to the system. On the other hand, the second term represents a positive force that is dependent on the displacement. It means that this force is the same as the mechanical spring restoring force, which acts opposite to the input force. Therefore, we can define

$$k_e = \frac{C_0}{d_0^2} V_P^2 \quad [26]$$

as the electrical spring constant, which is subtracted from mechanical spring constant, changes the resonant frequency. Now the expression for the resonant frequency is

$$f = f_0 \left(1 - \frac{k_e}{k_m}\right)^{1/2} = f_0 \left(1 - \frac{V_P^2 C_0}{k_m d_0^2}\right)^{1/2} \quad [27]$$

The electrical spring constant pulled the frequency of the resonator.

3.17.2.6 Equivalent Circuit Model

As mentioned in Section 3.17.2.5, the resonator vibrates when the frequency of the AC excitation signal matches the resonant frequency of the resonator beam. To obtain a circuit model for the future oscillator design, an RLC equivalent circuit of the micromechanical resonator is derived in this section.

Since a DC bias is applied on the resonator, the capacitive gap between the electrode and the resonator now acts as a DC-biased time-varying capacitor yielding an output current

$$I_0 = \frac{d(C(t)V(t))}{dt} = C(t)\frac{dV(t)}{dt} + V(t)\frac{dC(t)}{dt} \quad [28]$$

where

$$C = C_0 + x\frac{\partial C}{\partial x} \quad [29]$$

$$V = -V_P + v_i \quad [30]$$

Substituting $v_i = |v_i|\cos(\omega t)$ and $x = |x|\sin(\omega t)$ into the equation, the output current becomes

$$I_0 = C_0\omega_0|v_i|\sin\omega_0 t - V_P\frac{\partial C}{\partial x}\omega_0|x|\cos(\omega_0 t) + \frac{\partial C}{\partial x}|v_i||x|\sin 2\omega_0 t \quad [31]$$

The first term is related to static parallel capacitance, which is not related to resonator's vibration motion. The second term is the output current related to the resonator vibration at ω_0, while the third term is the harmonic current at $2\omega_0$.

At resonance frequency ω_0, the displacement of the beam is

$$|x| = \frac{Q}{k} V_P|v_i|\frac{\partial C}{\partial x} \quad [32]$$

Then

$$I_0|_{at\omega_0} = -\frac{\omega_0 Q}{k}\left(V_P\frac{\partial C}{\partial x}\right)^2|v_i| \quad [33]$$

The motional impedance becomes

$$R_x = \left[\frac{\omega_0 Q}{k}\left(V_P\frac{\partial C}{\partial x}\right)^2\right]^{-1} = \frac{kd_0^4}{\omega_0 Q V_P^2(\varepsilon_0 A_{electrode})^2} \quad [34]$$

L_x and C_x can be calculated based on R_x, Q, and ω_0

$$L_x = \frac{R_x Q}{\omega_0} \quad [35]$$

$$C_x = \frac{1}{R_x Q \omega_0} \quad [36]$$

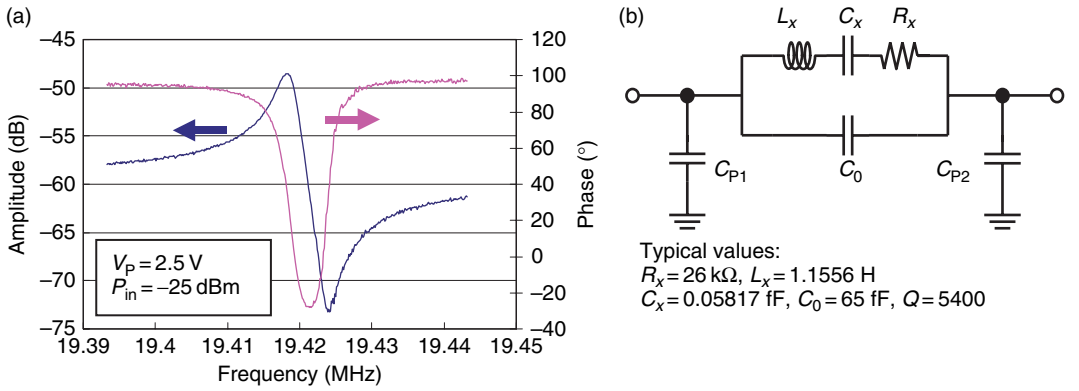

Figure 3 (a) Measured spectrum of a microelectromechanical systems (MEMS) resonator (b) its equivalent model and typical numbers for RLC model.

A typical measured resonator spectrum is shown in Figure 3(a). From the spectrum, Q, ω_0, C_0, and R_x can be extracted. Therefore, L_x and C_x can be calculated. Assuming Z_R is the resonator impedance

$$S_{21} = 10^{\text{level}/20}, \quad |Z_R| = 2.50\Omega\left(\frac{1-S_{21}}{S_{21}}\right) \qquad [37]$$

Based on the Z_R far from the resonance peak, C_0 can be calculated as

$$C_0 = \frac{1}{2\pi f_{\text{far from carrier}}|Z_R|} \qquad [38]$$

Knowing C_0, R_x can be calculated from the insertion loss at the resonance frequency

$$R_x = \frac{|Z_R|}{\sqrt{1-(2\pi f_0 C_0|Z_R|)^2}} \qquad [39]$$

3.17.3 MEMS Oscillators

Oscillator normally consists of a high-Q frequency reference tank, which determines the frequency and the stability of the oscillator, and a circuit that sustains the oscillation. As shown in Figure 4, at the stable oscillation, the loop gain of the oscillator must be 1 and the phase shift of the loop must be zero.

Figure 4 also illustrates how Q's of the resonator affect the frequency stability of the oscillators. As shown, in the case of $Q = 10$, if the phase of the oscillator circuits varies 40° due to external environment, the phase of the resonator needs to be adjusted −40° in order to meet oscillation criteria. In this case, the resonant frequency moves 400 kHz away from the original resonant frequency. In the case of $Q = 1000$, the deviation is only 4 kHz. Therefore, the larger the Q, the less the frequency deviation is.

Figure 5 presents the top-level schematic of the oscillator circuit (Lin *et al.* 2003), where the resonator is represented by its equivalent LCR circuit. As described in previous sections, MEMS resonator is driven by an AC voltage and outputs AC current. Therefore, a series resonant configuration is used, employing a transresistance amplifier in order to accommodate the resistance of the MEMS resonator. The conditions required for sustained oscillation can be stated as the following:

(1) The total phase shift around the closed positive feedback loop must be 0°. In this series resonant topology, both the resonator and the sustaining amplifier have 0° phase shift from input to output.
(2) The gain of the transresistance-sustaining amplifier R_{amp} must be larger than the sum of the motional resistance of the micromechanical resonator and the input and output resistances of the sustaining amplifier, i.e.

$$R_{\text{amp}} \geq R_x + R_i + R_o \qquad [40]$$

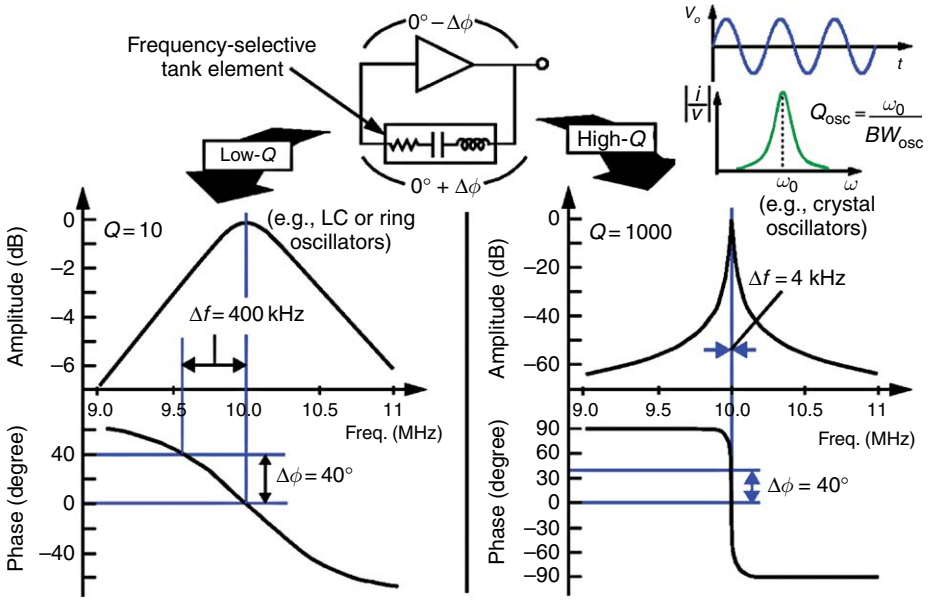

Figure 4 Oscillator diagram and the effect of resonator Q.

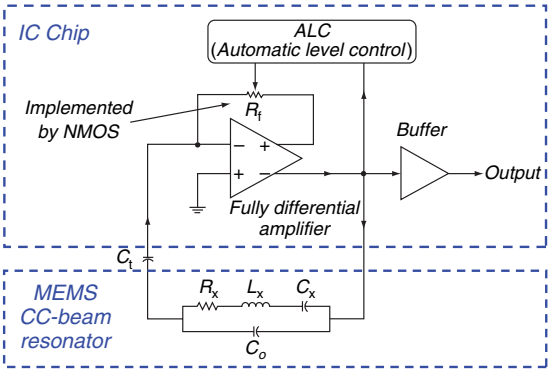

Figure 5 Top-level schematic of a microelectromechanical systems (MEMS) oscillator circuits. (Source: Lin Y-W, Lee S, Ren Z, Nguyen C T-C 2003 Series resonant micromechanical resonator oscillator. *Technical Digest, IEDM'03*, December 2003.)

R_{amp} is required for oscillation start-up to the point where a transresistance amplifier can achieve sufficient gain to instigate oscillation. The particular sustaining amplifier circuit of **Figure 7** achieves the needed 0° phase shift for oscillation in only a single stage instead of two stages, which improves both its noise and bandwidth performance. As shown in the schematic of the circuit, transistors M_1–M_5 comprise the basic differential op amp, while M_{11}–M_{18} constitute a common-mode feedback circuit that sets its bias point. The MOS resistors M_{Rf1} and M_{Rf2} serve as a shunt-shunt feedback elements that allow control of the transresistance gain via adjustment of their gate voltages.

The oscillation amplitude increases from noise till nonlinear effects make the oscillation level saturated. In conventional quartz XOs, the nonlinearity comes from the circuitry. However, for the MEMS oscillator, the resonator often becomes nonlinear before the circuitry. Duffing described the nonlinear effect of mechanical resonators and oscillators in 1918. MEMS researchers first noticed that a clamp-clamp bridge under tensile stress exhibits spring-hardening nonlinearity describable by Duffing's equation. IBM first reported both of the measured and theoretical jumps of MEMS oscillators in their amplitude and phase diagrams of the frequency response due to the spring-softening nonlinearity (Fan and Crawford 1993). As shown in **Figure 6(a)**, if the resonator is measured with lower input power, the resonator spectrum is not changed. However, as the input power increases, the resonance peak starts shifting toward the lower frequency – meaning the spring constant of the resonators is softened by the driving power. While the resonator is operated at the nonlinear region, frequency jumping could be observed at oscillation. **Figure 6(b)** shows the plot of frequency shift versus input power at various temperatures. If 10 ppm frequency shift is the maximum frequency variation we can tolerate due to the resonator nonlinearity, at 40°C, the maximum input power for the resonator is −17 dBm. As Q becomes higher at low temperature (discussed in Section 3.17.4), the resonator starts showing nonlinear effect at −32 dBm of input power. In fact, MEMS nonlinearity contributes the limiting mechanism of the oscillation when the automatic level control (ALC) is not engaged (**Figure 7**).

Therefore, in addition to the basic sustaining amplifier, the oscillator IC better includes an ALC circuit. As shown in **Figure 8**, this circuit consists of

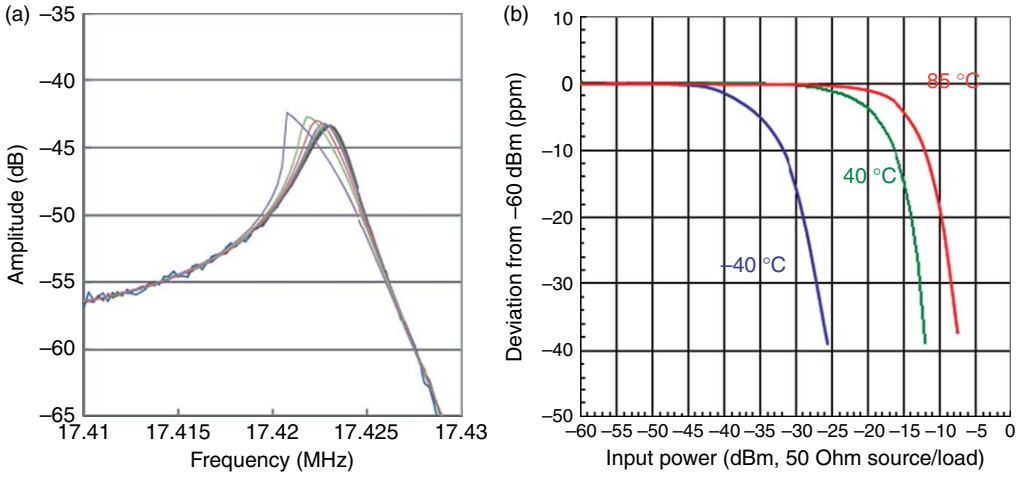

Figure 6 Duffing effect of resonators (a) shown in spectrum and (b) shown in power vs. frequency plot.

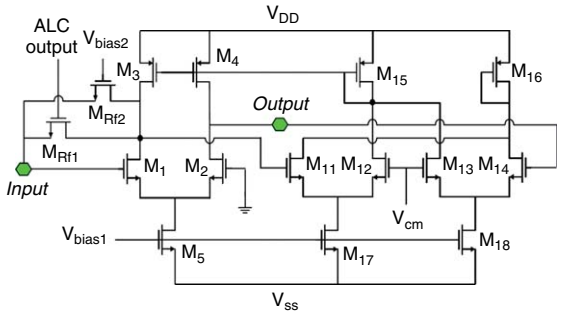

Figure 7 Example circuits for microelectromechanical systems (MEMS) oscillators. (Source: Lin Y-W, Lee S, Ren Z, Nguyen C T-C 2003 Series resonant micromechanical resonator oscillator. *Technical Digest, IEDM'03*, December 2003.)

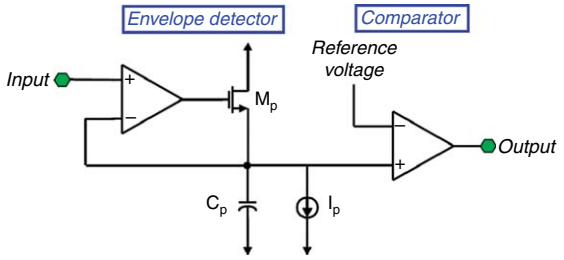

Figure 8 Automatic level control (ALC) circuit. (Source: Lin Y-W, Lee S, Ren Z, Nguyen C T-C 2003 Series resonant micromechanical resonator oscillator. *Technical Digest, IEDM'03*, December 2003.)

an envelope detector that effectively measures the oscillation amplitude and a comparator that feeds back to the gain-setting MOS resistor M_{Rf1} to match the oscillation amplitude to a preset reference level applied to the negative input of the comparator.

Figure 9 presents a plot of phase noise density versus offset from the carrier frequency. It shows a phase noise of $-80\,\text{dBc Hz}^{-1}$ at 1 kHz offset from the carrier, dropping to $-120\,\text{dBc Hz}^{-1}$ at far-from-carrier offsets, with the ALC disengaged. The close-to-carrier noise performance is somewhat poor due to a $1/f^3$ dependence that most likely derives from the Duffing-based limiting of this oscillator. With ALC engaged, this $1/f^3$ noise component is removed, leaving an expected $1/f^2$ close-to-carrier component commonly exhibited by high Q oscillators and allowing a much-improved phase noise density of $-95\,\text{dBc Hz}^{-1}$ at 1 kHz offset. Due to the smaller power level of the oscillator when ALC is engaged, the far-from-carrier phase noise density increased a bit to $-110\,\text{dBc Hz}^{-1}$.

Phase noise of the oscillator is expected to be lower if the power handling of the resonator can be increased. The power handling is defined by the maximum AC input power before the resonator shows Duffing effect. Normally the frequency deviation is defined based on the accuracy requirements of the product. In this chapter, we simply use 10 ppm. At room temperature, the clamped-clamped beam has power handling of about -35 dBm. It could be lower at lower temperature. For free-free beam it is about -20 dBm, while for bulk acoustic type of resonators it could be as high as -10 dBm. However, while pushing

the power handling higher, there will be trade-offs between other important parameters such as V_P, gap spacing d_0, and R_x (Kaajakari *et al.* 2003, Lin *et al.* 2005).

One way to increase the power handling is by connecting multiple resonators together and forcing them to resonate at the same frequency by design (Clark *et al.* 2006, Demirci *et al.* 2003, Lin *et al.* 2005). As shown in **Figure 10**, three disk resonators operated at wine-glass mode were coupled together. As shown, the mechanical connection of the resonators actually realizes a multipole filter structure that has several modes of vibration. Each modal peak corresponds to a state where all resonators vibrate at exactly the same frequency. **Figure 10(b)** presents ANSYS simulations showing the different modes of this structure, which are distinguishable by the phases between the resonators. Because each mode exhibits unique resonator phasings, a single mode can be selected by choosing the input AC signal to match the phasing of the desired mode. For oscillator applications, the first mode of the array is usually selected. It should be noted that the use of half-wavelength coupling beams serves to spread the modal peaks of the filter structure far apart, which facilitates the selection of one, and only one, of the modes. Once a single mode is selected, the structure practically behaves as a single resonator, but with a current-handling ability equal to the sum of the currents from all constituent resonators.

Figure 11 shows a phase noise of $-123\,\text{dBc Hz}^{-1}$ at 1 kHz offset from the carrier and $-136\,\text{dBc Hz}^{-1}$ at far-from-carrier offsets. This far-from-carrier noise floor is about 4 dB better than that of an oscillator using a single wine-glass disk resonator, verifying the

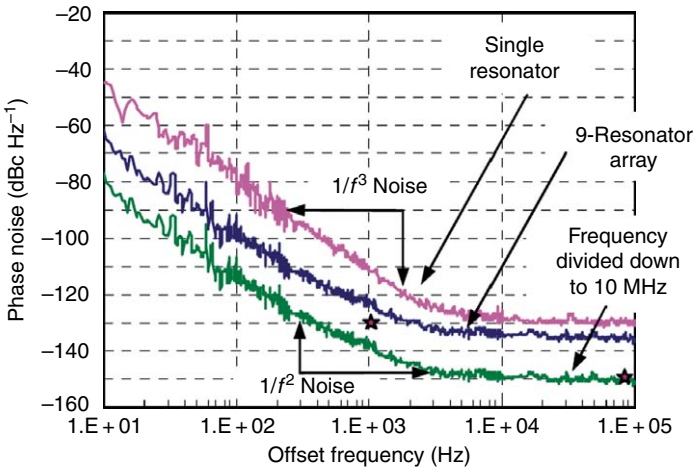

Figure 11 Phase noise of strong coupled wine-glass disk resonator oscillators. (Source: Lin Y-W *et al.* 2005 Low phase noise array-composite micromechanical wine-glass disk oscillator. *Technical Digest, International Electron Device Meeting*, December 5–7, 2005, pp. 4.)

utility of resonator array design. In addition, when a coupled array is utilized the undesired $1/f^3$ noise is removed, due to its increased power handling ability. With $1/f^3$ noise suppressed, an expected $1/f^2$ dependence commonly exhibited by high-Q oscillators then remains, improving the close-to-carrier phase noise at 1 kHz offset from -110 to $-123\,\mathrm{dBc\,Hz^{-1}}$. Dividing down to 10 MHz for fair comparison, this corresponds to $-138\,\mathrm{dBc\,Hz^{-1}}$ at 1 kHz offset and $-151\,\mathrm{dBc\,Hz^{-1}}$ far from the carrier, which more than satisfies (by 8 and 1 dB) the stringent GSM requirement.

3.17.4 Frequency Trimming

As described in previous sections, the frequency of the resonators is determined by both material properties and geometry of the resonators – exactly the same as quartz crystal resonators. Typically, depending on the systems, the oscillator output frequency needs to be within parts per million (e.g., from 1 to 100 ppm) to the target frequency for system applications. However, since semiconductor processes are used for MEMS resonator fabrication, the process variation of film thickness, lithography, and etching made the frequency of the resonators prior to trimming vary between $\pm 1\%$ and $\pm 10\%$, depending on the process control.

Furthermore, it is known that the resonator packaging itself can affect the resonance frequency of a resonator. In other words, the resonance frequency of a resonator can differ before and after encapsulation in a package. If the trimming is conducted before the resonator is packaged, then there is uncertainty as to how much frequency trimming is required.

The resonator frequency can be trimmed after it is packaged by applying voltage pulses to the resonator. This approach is often referred as localized annealing. This causes filament-like heating of portions of the resonator, which results in frequency trimming and improvements in Q (Wang *et al.* 1997). However, the direction of frequency tuning is dependent on the stress of the film. Also localized annealing may introduce unknown aging problems. As a result, this method may not be applied to the trimming that requires ppm level of accuracy.

Since the resonator is small in size, another approach of tuning a MEMS resonator is by creating arrays of resonators with various beam lengths. The variation in beam length results in a difference in resonance frequency between the shortest and the longest beam that is sufficient to account for the typical variation (due to manufacturing tolerances) in the resonance frequency of a resonator (US Pat. No. 6 600 389). This work also discloses that the increment in resonance frequency between adjacent beams is smaller than the targeted frequency variation tolerance of the desired resonator. Therefore, one of the beams will be qualified to serve as the desired resonator. Once that beam is identified, the other beams are disabled.

Material deposition has traditionally been used to trim the resonance frequency of crystals. But traditional material deposition, such as evaporation, has not been considered to be a practical technique for use with MEMS resonators because MEMS resonators are typically much smaller in size than their crystal counterparts. Also, it is desirable to trim a MEMS resonator after it has been packaged. Chiao and Lin (2004) demonstrated a postpackage-pulsed laser deposition frequency trimming for micromechanical resonators as illustrated in **Figure 12(a)**. However, the resonator frequency still failed to reach the accuracy of ppm due to the difficulty in controlling the geometry and the amount of the materials deposited by laser. Furthermore, the quality factor of the resonator is often degraded by additional materials on the resonators because the resonator vibration lost its balance.

As shown in **Figure 12(b)**, a packaged resonator can also be trimmed by directing the electromagnetic energy to the resonator through a transparent portion of the resonator package. The energy removes (e.g.,

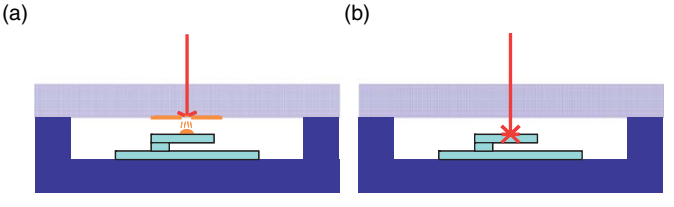

Figure 12 Frequency trimming of packaged resonators via laser enhanced (a) material deposition and (b) material removal.

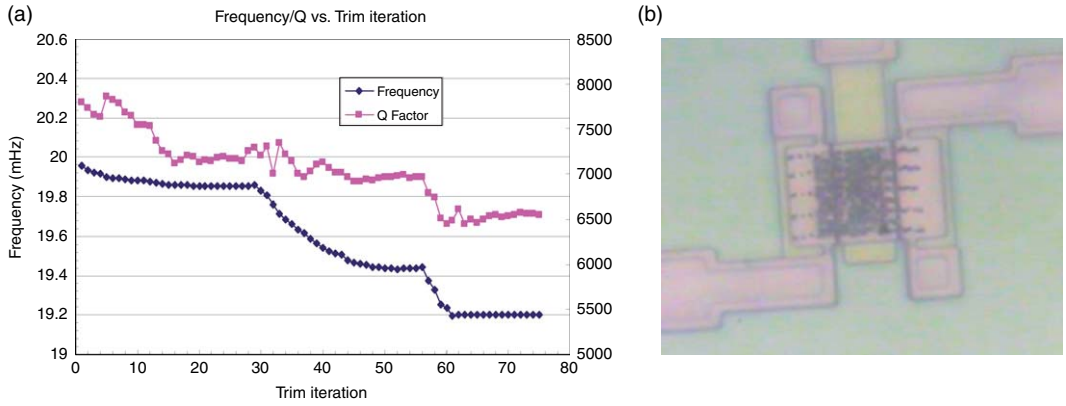

Figure 13 (a) Frequency and *Q* vs. trimming iterations, and (b) trimmed resonator surface.

ablates) the mass at the point(s) of contact on the resonator. Removing the mass from the resonator affects its resonance frequency in a predictable manner. The best electromagnetic energy source, from spot size and energy control point of view, is the femtosecond laser (Hsu and Brown 2007).

Frequency trimming is a function of (1) the amount of mass removed (or deposited) from the resonator and (2) the location(s) on the resonator at which the mass is removed (or deposited). Once the frequency-trimming requirement is determined (i.e., how much change in resonance frequency is required), the trimming is implemented by removing (or depositing) the mass from selected locations on the resonator, because the change in frequency caused by removing (or depositing) the mass is a function of not only the amount of mass but also its location on the resonant element. As a result, a mass-trimming map is developed for identifying the potential mass-trimming sites on the resonator. Each site can be classified as a fine-tuning site or a coarse-tuning site as a function of the magnitude of the change in resonance frequency that is caused by removing (a given amount of) the mass at that site. Fine-tuning sites and coarse-tuning sites tend to group in different regions on the resonator. Moreover, the trimming locations are usually located symmetrically on the resonator surface. This symmetric arrangement has the effect of changing the resonance frequency while the quality factor, *Q*, of the resonator remains substantially unaffected.

As shown in **Figure 13**, resonator trimming was demonstrated by directing femtosecond laser through a transparent potion of the resonator package to remove resonator mass on specific locations. One shot of femtosecond laser creates a 0.5-μm-diameter and 0.3-μm-deep divot. A MEMS resonator with a frequency 4% away from the target was trimmed to 2.5 ppm away from the target. The accuracy is limited by the control of temperature because the resonator has a temperature coefficient of −20 ppm per degree Celsius.

3.17.5 Temperature Compensation

Silicon resonators typically exhibit monotonic temperature-dependent curve. This temperature dependence is mainly due to the temperature coefficient of the Young's modulus of the resonator structure. As a result, depending on the resonator material, the temperature coefficients range from −40 to −15 ppm per degree Celsius. In comparison to the temperature characteristic of quartz crystal resonators, as shown in **Figure 14**, MEMS resonators show a straight line with a slope larger than even the worse case of AT-cut quartz crystals. Based on the experiment results, the temperature coefficient of frequency (TC_f) of the MEMS resonator can be maintained as a straight line from −180 to 150°C.

As defined in Section 3.17.1, the accuracy of the frequency needs to be within 10–100 ppm across all environmental conditions for XO applications. Therefore, TC_f of the MEMS resonators needs to be compensated.

Figure 15 shows the frequency deviation and *Q* of a poly-Si MEMS resonator measured at temperatures ranging from −40 to 100°C. As shown, the frequency line shows a slope close to −20 ppm per degree Celsius. On the other hand, *Q* goes from 6 000 at room temperature to 15 000 at −40°C. As mentioned in Section 3.17.3, resonator vibration

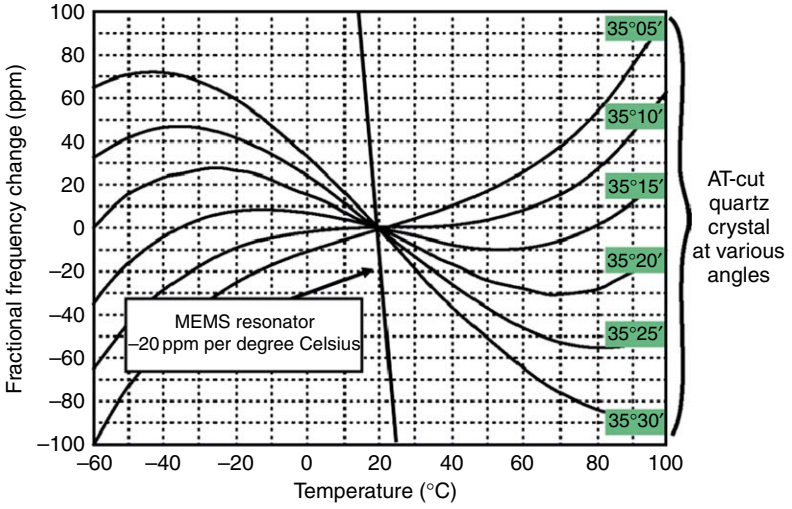

Figure 14 Frequency variations versus temperature of quartz crystals and microelectromechanical systems (MEMS) resonator.

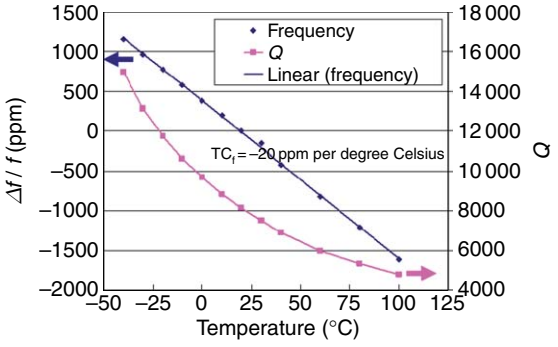

Figure 15 Frequency deviation and *Q* of poly-Si MEMS resonator across the temperature.

amplitude is proportional to Q. Therefore, at low temperature, the vibration amplitude will be 2.5× larger than the amplitude at room temperature, exhibiting Duffing effect thus introducing frequency instabilities. The first task for temperature compensation is to design the sustaining amplifier to prevent resonators from Duffing. This could be done via temperature-dependent gain or Q control circuits.

Temperature compensations for the MEMS oscillators can be categorized into mechanical compensation and electrical compensation. Mechanical compensation means the resonator frequency is adjusted at different temperatures. Electrical compensation, on the other hand, means the resonator frequency is fixed and the frequency adjustment is done on the circuitry.

3.17.5.1 Resonator Compensation

The ideal case of resonator temperature compensation is to design a mechanical structure to adjust the resonator frequency according to the temperature. From Section 3.17.4, we know that the resonator frequency can be expressed as

$$f = f_0\left(1-\frac{k_e}{k_m}\right)^{1/2} = f_0\left(1-\frac{V_P^2 C_0}{k_m d_0^2}\right)^{1/2} = f_0\left(1-\frac{V_P^2 \varepsilon_0 A}{k_m d_0^3}\right)^{1/2} \quad [41]$$

V_P, k_m, and d_0 are parameters that can affect the resonator frequency

$$f = \frac{(k_1 L)^2}{2\pi L^2}\sqrt{\frac{EI}{\rho A}} = 1.013\frac{h}{L^2}\sqrt{\frac{E}{\rho}} \quad [42]$$

So the TC_f of the uncompensated micromechanical resonator is

$$TC_f = \frac{\alpha_E + \alpha_{res}}{2} \quad [43]$$

where α_E and α_{res} are the temperature coefficient of the Young's modulus and the thermal expansion coefficient of the resonator material, respectively. The typical value of the TC_f of a clamped-clamped beam is −20 ppm per degree Celsius. To overcome this negative TC_f of the resonator, parameters in eqn [41] can be adjusted so that the resonator frequency increases with temperature to counteract with the frequency decrease with temperature due to the temperature variation of the Young's modulus.

3.17.5.1.1 Mechanical stiffness

One direct way of temperature compensation is by applying a tensile force along the resonator beam depending on the temperature. The higher the temperature, the larger the tensile force. Thus the tensile force counteracts the negative temperature coefficient of the resonator.

As shown in **Figure 16**, a mechanical compensation structure is designed based on a lateral resonator beam. It consists of a flexural-mode clamped-clamped-like beam anchored to the substrate at one end, but supported on the other by a folded structure comprised of a truss section attached to two outer beams. The outer beams are also designed to be longer than the resonator beam, so that they will expand faster than it with increasing temperature, generating a net tension in the resonator beam, as shown in the figure. This tensile stress serves to increase the beam's resonance frequency and thus oppose frequency decreases caused by the temperature dependence of the Young's modulus, resulting in a smaller overall f_0 excursion over a given temperature range. To ensure that only the resonator beam vibrates when excitation signals are applied, the outer support beams are made much wider than the resonator beam, making them rigid against lateral motions.

In the lateral vibration mode, the beam of **Figure 16** essentially has fixed-fixed end conditions; so the expression for its resonance frequency is identical to that of previous clamped-clamped beam resonators. With a mechanical structure generating an axial stress along the resonator beam, the frequency of the resonator with axial stress σ can be expressed as

$$f = 1.013\frac{W}{L^2}\sqrt{\frac{E}{\rho}}\sqrt{\left(1 + 0.293\frac{L^2}{EW^2}\sigma\right)} \qquad [44]$$

The stress is generated by the thermal expansion difference between the resonator material and the substrate material and the length difference between the resonator beam and the outer compensation beam. The stress is

$$\sigma = E(\alpha_{res} - \alpha_{sub})\Delta T\left(\frac{L_{out}}{L} - 1\right) \qquad [45]$$

The temperature coefficient of frequency

$$TC_f \approx \frac{\alpha_{res} + \alpha_E}{2} + 0.146\left(\frac{L}{W}\right)^2(\alpha_{res} - \alpha_{sub})\left(\frac{L_{out}}{L} - 1\right) \qquad [46]$$

The first term $(\alpha_{res} + \alpha_E)/2$ is the TC_f of uncompensated MEMS resonator. Let us assume that it is -20 ppm per degree Celsius and $TC_f = 0$, we have

$$\frac{L_{out}}{L} = 1 + \frac{136.986}{\alpha_{res} - \alpha_{sub}}\left(\frac{W}{L}\right)^2 \qquad [47]$$

Therefore, TC_f of the resonator is zero when L_{out}/L satisfies eqn [47].

Experimental work of this temperature compensation method shows that the TC_f is reduced from -20 to 2.5 ppm per degree Celsius (Hsu *et al.* 2000). The major drawback of mechanical compensation is that once the geometry of the resonator is defined on the mask, it is hard to compensate for process variations. An array of devices with slightly different L_{out}/L ratio can be fabricated to accommodate the variations.

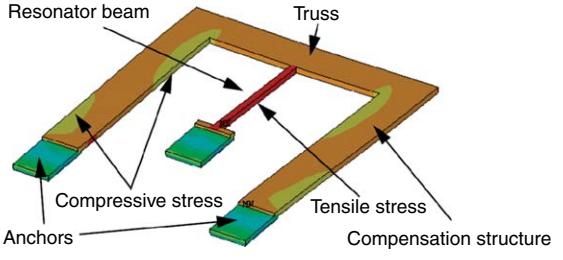

Figure 16 Mechanical temperature compensation structure. (Source: Hsu *et al.* 2000.)

3.17.5.1.2 Electrical stiffness compensation

Resonator frequency changes with bias voltage, V_P, according to eqn [41]. Therefore, it is possible to adjust V_P so that the output frequency remains the same across the temperature. Including the temperature variation into eqn [41], the resonator frequency becomes

$$f_T = f_0(1 - TC_f(T - T_0))\left(1 - \frac{V_{P,T}^2\varepsilon_0 A}{k_m d_0^3}\right)^{1/2} \qquad [48]$$

if f_T is kept the same as f_{T0}, the resonator bias voltage $V_{P,T}$ can be expressed as

$$V_{P,T} = \sqrt{\frac{k_m d_0^3}{\varepsilon_0 A}}\left(\frac{1 - \left(V_{P,T0}^2\varepsilon_0 A\right)/k_m d_0^3}{(1 + TC_f(T - T_0))^2}\right) \qquad [49]$$

Consider 10-MHz clamped-clamped beam as an example. **Figure 17(a)** shows the bias voltage versus frequency of a typical 8 μm × 40 μm beam. In order to generate constant output frequency, a circuit must be designed to supply bias voltage, as plotted in

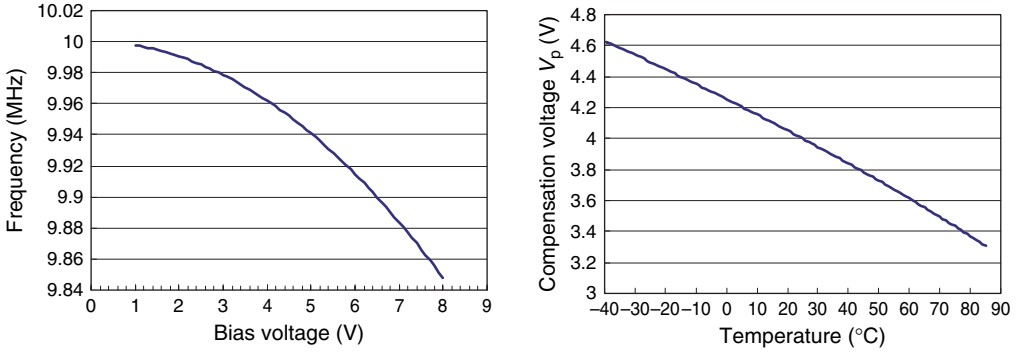

Figure 17 Bias voltage versus frequency for 10-MHz resonator ($d_0 = 1000$ Å, $k_m = 3000$ N, $A = 160\,\mu m^2$).

Figure 17(b). In practice, the variation of d_0 and k_m on the MEMS wafer and V_P accuracy on IC must be taken into consideration. The major drawback of this method is that the variation of R_x is larger. In normal case, as the temperature increases, R_x increases because Q decreases. In order to compensate the resonator frequency, lower V_P will be needed at high temperature, and this low V_P makes R_x even larger than the normal case. Some experimental works are shown in Ho *et al.* (2005).

The other electrical stiffness compensation involves not only bias voltage, but also temperature-dependent gap spacing. Figure 18 presents a cross-sectional schematic conveying the basic concept behind the stiffness-compensated resonator. As shown, this device consists of a polysilicon clamped–clamped (CC)-beam resonator, over which a metal electrode spaced at a distance d_{o2} (e.g., 1000 Å) above the beam has been added as the key instrument for temperature compensation. To simplify the discussion, the anchoring structure for this top electrode is drawn such that it can freely expand in the lateral direction without introducing compressive stresses that might bend the electrode. With this simplification, the overhead electrode in Figure 18 is then effectively supported by blocks free to expand in the vertical direction.

For stiffness compensation, the material comprising these support blocks is chosen to have a thermal expansion coefficient larger than that of the structural material of the mechanical resonator and its anchors. With this selection of materials, when the temperature is increased, expansions are such that the bottom side of the top electrode moves vertically upward faster than the top of the resonator beam, resulting in a net increase in the top electrode-to-resonator gap spacing d_{o2}, as shown in the higher temperature cross section of Figure 18. This increase in the gap spacing then leads to a decrease in the top electrode-to-resonator electrical spring constant and a corresponding increase in the resonance frequency, which then counteracts the decrease in frequency caused mainly by the temperature dependence of the Young's modulus. d_2 can be expressed as

$$d_2 = d_{02} + (\alpha_{electrode} - \alpha_{res}) b_{be} (T - T_0) \qquad [50]$$

Substituting this into eqn [41] and deriving TC_f, we have

$$TC_f = \frac{\alpha_E + \alpha_{res}}{2} + \frac{3}{2}\frac{(V_P - V_C)^2 \varepsilon_0 A}{d_{02}^4 k_r}(\alpha_{electrode} - \alpha_{res}) b_{be} \qquad [51]$$

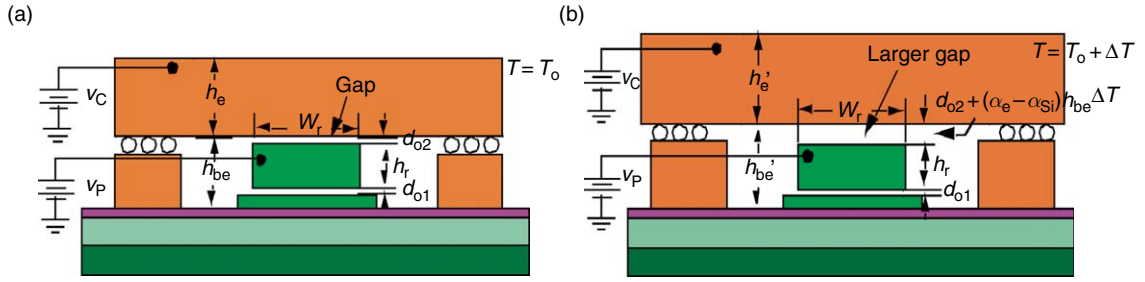

Figure 18 Cross-sectional schematics of a stiffness-compensated resonator (a) at temperature T_o and (b) at an elevated temperature $T_o + \Delta T$.

where V_C is the control voltage applied to the top electrode, k_r is the spring constant of the resonator beam including the effects of the electrical stiffness k_{e1} due to the bottom electrode ($k_r = k_m - k_{e1}$, where k_m is the unbiased mechanical stiffness), h_{be} is the gap between the substrate and the bottom of the top electrode, and $\alpha_{electrode}$ and α_{res} are the thermal expansion coefficients of the electrode and the resonator, respectively. Since the electrical stiffness generated across an electrode-to-resonator gap depends strongly on not only the gap spacing d_{o2} but also the voltage applied across the gap ($V_P - V_C$), the TC_f given by eqn [49] also exhibits a strong dependence on ($V_P - V_C$).

The first term of equation is negative and the second term is positive. Therefore, there must be a combination of $V_P - V_C$ that makes TC_f equals to zero. Plot the frequency variation versus temperature as shown in **Figure 19**, we can see that while $V_P - V_C$ is 8 V, the TC_f is close to zero. In fact, by appropriate adjustment of V_C, the electrical stiffness as a function of temperature can be conveniently optimized to more effectively null the TC_f of the resonator beam – a distinct advantage over other compensation methods.

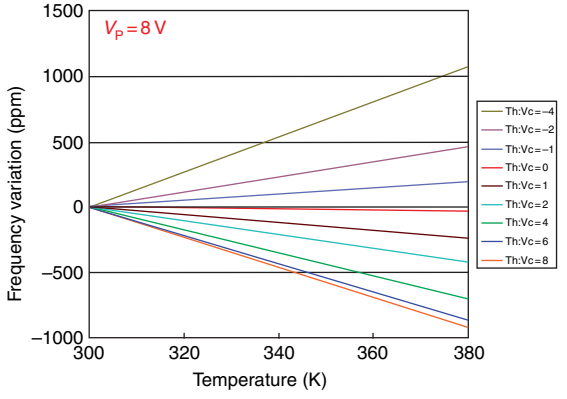

Figure 19 Electrical stiffness compensation plot based on eqn [51].

In practical renditions, the compensation electrode on top of the resonator needs to be designed to avoid bending caused mainly by compressive stresses exerted by the anchors supporting the top electrode. If the top electrode is allowed to bend, the frequency versus temperature function will deviate from the linear behavior predicted by eqn [49]. In particular, depending upon the degree and the rate of bending, the frequency versus temperature curve might look parabolic or might start curving at some high threshold temperatures. Experimental work can be seen in Hsu and Nguyen (2002). The best-achieved compensated resonator shows the TC_f as low as −0.24 ppm per degree Celsius.

3.17.5.2 Digital Trimming and Compensation

Typically the requirement of oscillator frequency accuracy is on the order of 1–10 ppm, while the process variation contributes about 1% frequency variation. Therefore, the basic idea of digital compensation is not only to adjust the frequency across the temperature, but also to set the frequency to the target (Hsu *et al.* 2006).

Figure 20 shows the system diagram of a digital-compensated MEMS oscillator. As shown, a MEMS

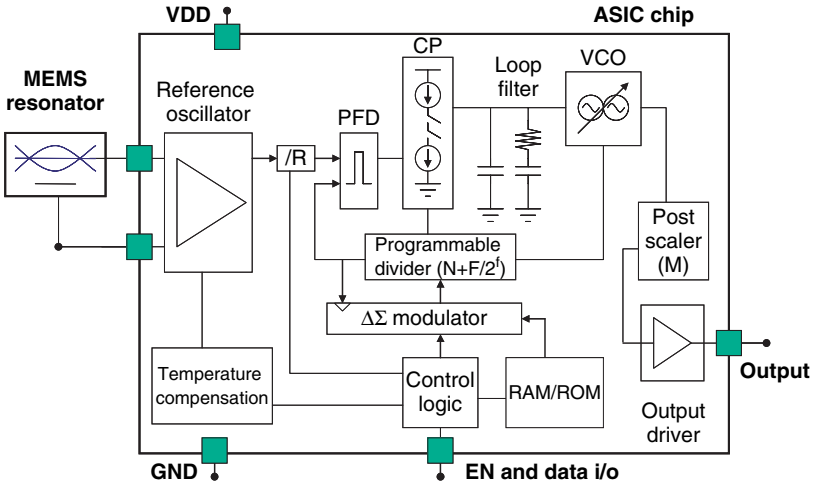

Figure 20 System diagram of a digital compensated MEMS oscillator.

resonator is connected to an IC. The reference oscillator, which is of similar design to that described in Section 3.17.3, accommodates the larger motional resistance and smaller phase shifts seen in MEMS resonators over the temperature range and over all process corner conditions. The output frequency of the reference oscillator is then fed into a fractional-N synthesizer. The main loop for the fractional-N synthesizer consists of a charge pump, a phase-frequency detector, an on-chip loop filter, a wideband voltage controlled oscillator (VCO), and a programmable divider. The programmable divider is modulated by the $\Sigma\Delta$ block. Digital control, programming, and temperature compensation are all monitored by the control circuits. Control logic controls the blocks based on the temperature. All functionality and communication are achieved through four pins, Enable, VDD, GND, and Output, which are the standard oscillator pins.

To calibrate this system, at first, the output frequency of the reference oscillator is measured at room temperature. This frequency is compared with the target frequency. Then the control logic will calculate the numbers to be set in VCO, dividers, and postscaler and store these numbers in the memory. Same steps are performed at another temperature. Based on these two sets of parameters, a look-up table can be easily established simply because the resonator shows monotonic temperature characteristics. The line that connects the two calibration points can set a line with proper slope (TC_f) to extended temperatures. Thus the output frequency of the oscillator is set to the target and is adjusted according to the temperature.

Figure 21 shows the temperature dependence of a digital-compensated programmable MEMS oscillator. It shows total 7 ppm frequency variation in the typical commercial range of temperature (−40°C to 85°C). Compared to digital-compensated programmable quartz XOs with total 25 ppm frequency variation across the temperature, clearly MEMS oscillators are qualified for XO level of applications listed in **Table 1**.

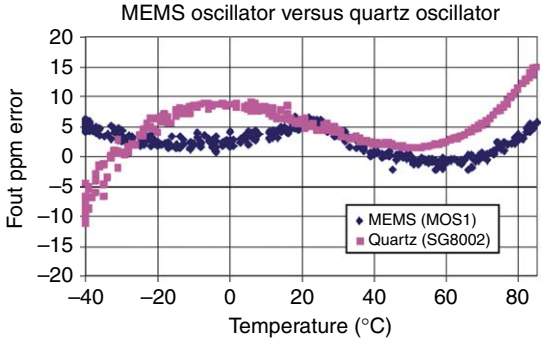

Figure 21 Typical temperature characteristics of a digital-compensated MEMS oscillator.

However, although digital compensation is the best and the easiest temperature compensation method, one drawback of using digital temperature compensation is that the phase-locked loop (PLL) synthesizer and VCO introduced more phase noise into the oscillator output spectrum. This increase in phase noise current prevents MEMS oscillators from having low phase noise and radio frequency (RF) applications. Therefore, further research is needed.

3.17.6 The Future: Research and Business

So far, MEMS oscillators have met all the requirements with respect to phase noise, jitter, temperature stability, power consumption, and reliability (Hsu 2006) for the mainstream 1–125-MHz XO segment. This segment covers high-volume applications including consumer electronics, I/Os such as USB, computing. As indicated in **Table 1**, the next application target for MEMS oscillators is to reach the accuracy requirements of TCXO, which typically exhibits frequency variation of 3 ppm across all the environmental parameters, and $-130\,\mathrm{dBc\,Hz^{-1}}$ at 1-kHz offset and $-150\,\mathrm{dBc\,Hz^{-1}}$ far from carrier of phase noise. Most importantly, the power consumption of the oscillator needs to be low.

Three requirements need to be satisfied in order to promote MEMS oscillators for TCXO applications: (1) temperature stability, (2) low phase noise, and (3) frequency accuracy. MEMS oscillators from different research groups may have satisfied individual specifications, but none has demonstrated meeting three of them at the same time. As a result, this is one of the first and probably the most important research goals for MEMS oscillators.

With the development efforts in universities and in the industry, the MEMS oscillator is getting closer to RF applications. The good news is, due to the reduction trend of cost and size, RF system designers are tweaking system specifications to use low-cost (meaning lower frequency accuracy) and integrated frequency reference sources. As MEMS oscillator researchers are trying to improve the accuracy, system designers are reducing the system

requirements. We believe, in the near future, that these two specs will merge together.

The promise of MEMS resonators has been anticipated for a long time. Finally, the technology is commercially viable and is being rolled out as we speak (by the end of 2006). Industrial analysts have created a new category for MEMS resonator in their reports and expect that this will be a high-volume product. While quartz crystal technology is very important, relevant, and will continue to have its share of the market, that market share will undoubtedly decline over time. MEMS resonators have an opportunity to make a big impact on the market, and will grow and evolve over time. With the ability to put multiple MEMS resonators into footprints the size of quartz crystal resonators, manufacturers will bring new revolutionary products to market.

Biography

Dr. Wan-Thai Hsu is one of the pioneer researchers and inventors in the area of RF MEMS. Part of his doctoral work led to the birth of Discera Inc. in 2001. He is now Chief Technology Officer of Discera. Since 2001, he has built a strong technical team at Discera focusing on making silicon resonator oscillators a reliable commercial product. The efforts include robust resonator design, volume manufacturing process development, MEMS reliability, technology transfer to foundries, product developments for silicon resonator oscillators, and IP strategies.

He is now leading Discera's R&D team on resonator, filter, packaging, and system developments. He also serves as a principal investigator for multiple government-supported research programs on MEMS filters, system integration, and MEMS reliability.

Dr. Hsu received his BS and MS degrees from National Tsing-Hua University and Ph.D. from University of Michigan, all in Electrical Engineering. Dr. Hsu has published more than 25 technical papers and spoken at multiple international conferences. He owns six US patents and has four patents pending. He received *EE Times* 2007 Innovator of the Year Award.

3.18.1 Introduction to MEMS Atomic Clocks

3.18.1.1 Introduction

Frequency references provide the base for a large number of applications such as digital communication, navigation systems, synchronization of networks, or power distribution. As the amount of data transferred increases and data rates become faster, more stringent requirements are placed on the timing systems. At the same time applications have become more mobile, increasing the demand for small low-power frequency references.

Atomic oscillators have provided the most stable frequency references for more than 50 years (Lyons 1950, Quinn 2005, Townes 1951). They provide unmatched frequency stability over long periods of time (from a few seconds to many years), because their resonance frequency is determined by the energy transition of the atoms – in contrast to crystal oscillators, where the resonance frequency is determined by the length of the crystal and is therefore much more susceptible to temperature changes, for example. But in order not to perturb the resonance frequency of the atoms and to probe it, often very complicated setups are required. Therefore, the large size, cost, and power consumption of most atomic clocks have restricted their use in real-world applications. Nevertheless, smaller versions of optically pumped rubidium standards (Bloch *et al.* 1993, Chantry *et al.* 1996, Ho *et al.* 1998, Koyama *et al.* 2000, McClelland *et al.* 1995, 1996, 1999, Rochat *et al.* 2002, Suzuki *et al.* 1998) with volumes around 100 cm^3 and power requirements of a few watts have become commercial standards. They are manufactured in the tens of thousands for use in cellular telecommunication networks (Kusters and Adams 1999). Space-qualified versions became critical members of the clock ensembles in Global Navigation Satellite Systems (GNSS). But a large number of portable in-field applications require smaller and less expensive frequency references with much lower power consumptions. Temperature-compensated quartz crystal oscillators (TCXOs) are small low-power, low-cost devices with relatively good performance over longer times, which have proven useful in such battery-operated portable applications. Nevertheless, their frequency stability at longer times (one hour to several days) is not sufficient for the requirements of many applications in the civil and military navigation and communication sector (Fruehauf 2001, Lee *et al.* 1996, Murphy and Skidmore 1994, Sturza 1984, Vig 1993). **Figure 1** summarizes typical performances of different commercially available oscillators as a function of averaging time (see Section 3.18.3.2 for an explanation of fractional frequency stability). It can be seen that crystal oscillators can be good frequency references over short times (see Section 3.18.2.3), but they are outperformed by atomic clocks at longer times.

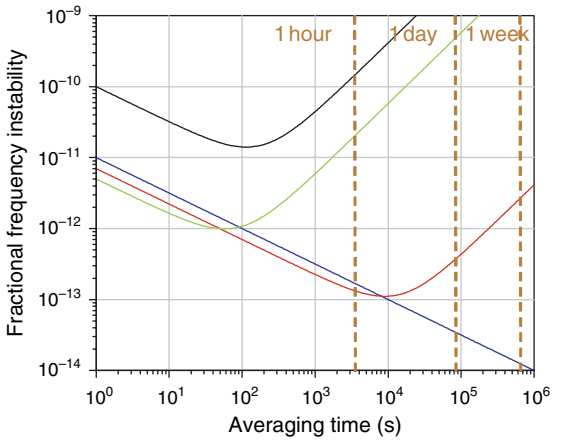

Figure 1 Typical performance of different commercially available oscillators: cesium beam standard (blue), rubidium vapor cell clock (red), oven-controlled crystal oscillator (OCXO, green), temperature-compensated crystal oscillator (TCXO, black).

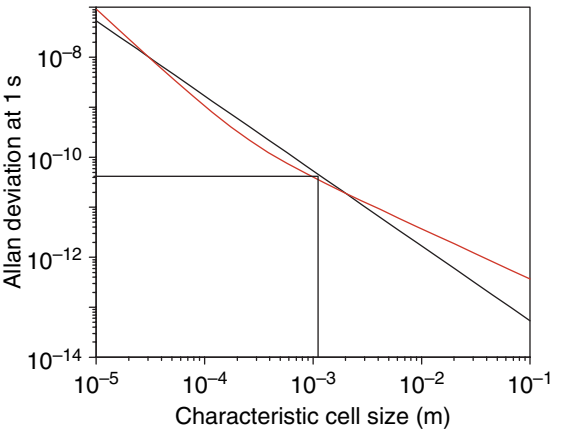

Figure 2 Estimate of the Allan deviation at 1 s as a function of characteristic cell size for a cell with a 100 kPa nitrogen buffer gas (red) or a paraffin wall coating (black).

Furthermore, it can be seen that atomic vapor cell clocks also have drifts over very long timescales (see Section 3.18.3.2.3).

The size of the optically pumped rubidium atomic frequency standards (RAFS) is largely limited by the size of the microwave cavity and the power goes mainly into heating the cell and the lamp. All-optical clocks were proposed years ago (Cyr *et al.* 1993, Levi *et al.* 1997), but the lack of reliable, low-noise, easy-to-use diode lasers at the atomic wavelengths have prevented their implementation into commercial clocks. When single-mode vertical-cavity surface-emitting laser (VCSEL) became available at 852 nm (the D_2 line of cesium) with large modulation bandwidths (King *et al.* 1998), their practicality for coherent population trapping (CPT) spectroscopy was demonstrated (Affolderbach *et al.* 2000). Soon after, the first miniature CPT clock prototype was demonstrated (Kitching *et al.* 2001a, Vanier *et al.* 2004). The idea to combine this CPT spectroscopy with fabrication methods developed for microelectromechanical systems (MEMS) into a chip-scale atomic clock (CSAC) was proposed (Kitching *et al.* 2002). MEMS fabrication techniques would allow for small size in an all-optical design and the use of a VCSEL in combination with small volume for correspondingly lower power requirements. An estimate of the fractional frequency instability of the clock stability at 1 s of integration as a function of cell size is shown in **Figure 2** for a 100-kPa N_2 buffer gas cell (red) and a paraffin wall coating (black) (Kitching *et al.* 2002). It can be seen that the fractional frequency stability of the clock degrades with smaller size, because of the more frequent collisions of the atoms with the cell walls. Nevertheless, stabilities below $1 \times 10^{-10}/\tau^{1/2}$ seem possible with a cell size of 1 mm (for an introduction to Allan deviation as a measure of frequency stability, see Section 3.18.3.2.1).

Since its proposal in 2002, the field of CSACs has rapidly progressed, largely due to the establishment of a CSAC program of the US Defense Advanced Research Projects Agency (DARPA). The goal of this program is to develop a MEMS atomic clock with a frequency instability of 1×10^{-11} at 1 h of integration in a package of volume 1 cm^3 consuming 30 mW of power. While this is still an ongoing project and the goals have not been reached yet, this chapter tries to outline some of the major developments so far. Since a majority of the work presented here was performed under the DARPA project with the goal of product development, many approaches cannot be reviewed here in detail, because no published information exists. Therefore, this review focuses mainly on MEMS clocks based on CPT, as most current approaches follow this route and a lot of published information exists. Nevertheless, other non-CPT approaches were successfully demonstrated and some of these are reviewed in Section 3.18.5.

3.18.1.2 Vapor Cell Atomic Clocks

The atoms in the gas phase are chosen for the best atomic clocks, because it is desirable to have distinct energy levels that are largely unperturbed by the

environment (as compared to the frequency bands of solids). The atoms in the first column of the periodic table, that is, alkali atoms, are favored in many atomic physics experiments because of their comparatively simple energy structure, determined largely by the single valence electron. The lowest energy electric dipole transitions in these atoms are called D-lines for historical reasons, and they correspond to changes in the distance between the valence electron and the nucleus, i.e., the transition $nS_{1/2} \leftrightarrow (n+1)P_{\mathcal{J}}$. The P state is split once again into two components of different total angular momentum $\mathcal{J}$ (**Figure 3(a)**). The atomic ground state ($S_{1/2}$) is split into two hyperfine energy components (F and F + 1), determined by the orientation of the electron spin relative to the spin of the nucleus. The clock frequency is determined by the energy difference between these hyperfine components divided by the Planck's constant h. Finally, the two hyperfine levels can be split into Zeeman sublevels in a magnetic field due to different orientations of the electron spin with respect to the magnetic field (m_F). Two of these Zeeman levels do not change their frequency to first order ($m_F = 0$ levels) in the presence of a magnetic field. These are usually chosen for the clock transition.

In an optically pumped vapor cell clock, one light field, e.g., with frequency ω_1, is present. It excites the atoms from state $|1\rangle$ into the excited state (**Figure 3(a)**). From there the atoms can decay into either of the two ground states. Eventually, a large fraction of atoms will accumulate in $|2\rangle$, a process called optical pumping (Happer 1972). The cell appears transparent because fewer atoms can absorb the light. When a microwave field with frequency $\omega_{\text{microwave}}$, equal to the clock transition frequency of the atom, is applied, the atoms can be repumped from $|2\rangle$ into $|1\rangle$. This microwave resonance can be detected through a change in the absorption of the light field.

Optical pumping in a RAFS, which are probably the most widely used atomic clocks in the world, is usually done with a rubidium discharge lamp (**Figure 3(b)**) (Vanier and Audoin 1989). It creates a broad spectrum of light, which is resonant with the transitions $5S_{1/2} \leftrightarrow 5P$. In order to enable efficient hyperfine pumping, the light needs to be spectrally filtered. This is done by using ^{85}Rb absorption, since the transition from one of the ground states in ^{85}Rb is very close to the one in ^{87}Rb. Therefore, RAFS usually have a ^{85}Rb filter cell in front of the ^{87}Rb clock cell (sometimes they are combined in the same cell though). After the filtered light passes through the ^{87}Rb cell, it is collected on a photodetector. A microwave cavity surrounds the ^{87}Rb cell to provide efficient coupling between the microwave field and the atoms and to ensure a uniform microwave phase over the entire volume of the cell. When the microwave frequency is exactly resonant with the atomic clock frequency of 6.8 GHz, the transmitted light decreases as atoms are pumped back into the depopulated hyperfine state. **Figure 3(c)** shows the transmitted light as a function of microwave frequency. Such a resonance can have Q factors of $\sim 10^8$.

RAFS can reach frequency stabilities in the range of 10^{-11} to $10^{-12}/\tau^{1/2}$ with centimeter cell sizes. At long times their frequency shows slow drifts around 10^{-14} per day; the detailed causes for this are still under investigation, but the diffusion of helium through the cell walls seems to be the one likely candidate

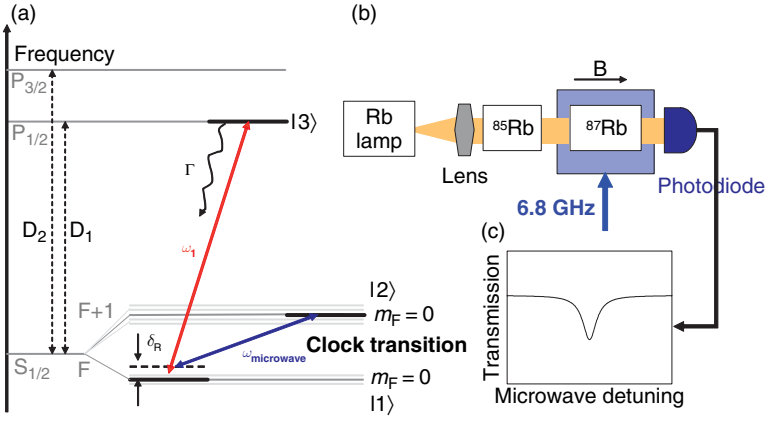

Figure 3 Schematic of the simplified atomic energy level configuration for the observation of (a) optically pumped microwave resonances, (b) spectroscopic setup, and (c) picture of a microwave resonance.

(Camparo 2004). The most power-consuming component in a RAFS is probably the Rb lamp. It has to be heated to high temperatures and usually consumes several hundred milliwatts to watts of power. The size of the RAFS physics package is largely determined by the size of the microwave cavity, since the clock frequency corresponds to ~4 cm. Therefore, it is challenging to miniaturize the current setup below the size of a deck of cards and to reduce the power consumption to below 1 W. In order to reduce the power consumption and the size of a vapor cell atomic clock, it would thus be useful to replace the lamp and the filter cell with a low-power laser and eliminate the microwave cavity.

3.18.1.3 Coherent Population Trapping

Heuristically, coherent population trapping (CPT) can be seen as a destructive quantum interference that happens, when the beat frequency between the two resonant light fields equals the ground state splitting frequency of the atoms. This destructive interference process largely reduces the probability that the atom can be excited by either of the light fields, so it appears dark, i.e., the resonance fluorescence is suppressed. CPT resonances have been studied for three decades. Alzetta *et al.* (1976) observed dark lines in the fluorescence emitted by a beam of sodium atoms. Simultaneously, the phenomenon was theoretically explained for a cascade system (Whitley and Stroud 1976) and for a Λ-System (Arimondo and Orriols 1976, Gray *et al.* 1978). Since then, the phenomenon of CPT and its related effect, electromagnetically induced transparency (EIT) (Fleischhauer *et al.* 2005, Harris 1997, Harris *et al.* 1990, Kasapi *et al.* 1995, Marangos 1998), have been suggested for a large number of applications such as optical bistability (Walls and Zoller 1980), laser cooling of atoms and ions (Aspect *et al.* 1988, Schmidt-Kaler *et al.* 2001), and lasing without inversion (Bentley Jr. and Liu 1999, Kocharovskaya 1992). The steep dispersion at CPT resonance at reduced absorption makes it attractive, for example, for the enhancement of nonlinear effects (Hemmer *et al.* 1995), slow light (Schmidt *et al.* 1996, Vestergaard Hau *et al.* 1999), optical data storage (Liu *et al.* 2001, Phillips *et al.* 2001), and gravitational wave detectors (Mueller *et al.* 1997). Finally, the narrow resonance linewidths (Brandt *et al.* 1997, Erhard *et al.* 2000, Merimaa *et al.* 2003) that can be achieved with CPT make it attractive for metrology applications (Tench *et al.* 1981, Thomas *et al.* 1982) where high-resolution laser spectroscopy can be applied to all-optical atomic clocks (Hemmer *et al.* 1983) and magnetometers (Bloom 1962, Scully and Fleischhauer 1992).

Although alkali atoms have a complicated structure of energy levels, the calculations for a simple system consisting of only three levels show surprisingly good agreement with the measurements (we will limit the introduction here to a very simplified picture for illustrative purposes only; for a review on CPT, see Arimondo 1996a). In these calculations, the so-called lambda system consists of two long-lived ground states $|1\rangle$ and $|2\rangle$, split by the clock frequency Δ_{HFS}, and an excited state $|3\rangle$ (**Figure 4(a)**, resembling the Greek letter Λ). Two light fields E_1 and E_2 with frequencies ω_1 and ω_2 and phases φ_1 and φ_2 can couple the electric dipole transitions $|1\rangle \leftrightarrow |3\rangle$ and $|2\rangle \leftrightarrow |3\rangle$. Both ground states have nearly equal populations in thermal

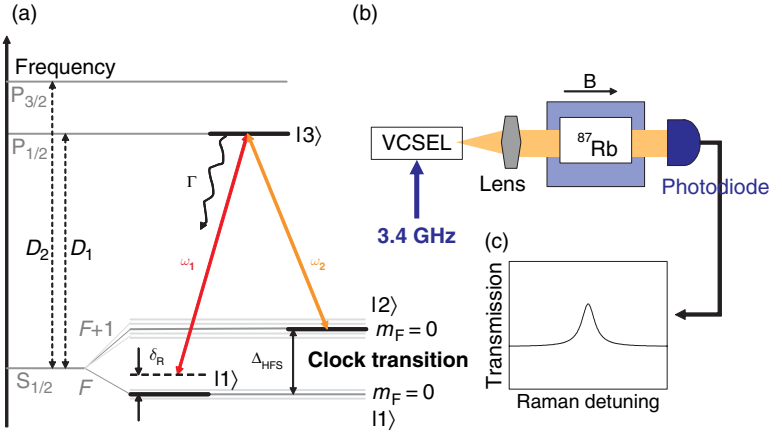

Figure 4 Schematic of the simplified atomic energy level configuration for the observation of (a) coherent population trapping (CPT) resonances (b) spectroscopic setup, and (c) picture of a CPT resonance.

equilibrium. A similar pumping as in microwave clocks can be performed between the ground states $|1\rangle$ and $|2\rangle$, when the two light fields E_1 and E_2 are resonant with the respective optical transitions (**Figure 4(a)**). If the beat frequency $\omega_1 - \omega_2$ is equal to the clock frequency Δ_{HFS} then the atoms can be pumped into a so-called coherent dark state $|NC\rangle$.

For very simplified illustration purposes, we can choose a new basis $\{|C\rangle, |NC\rangle, |3\rangle\}$, where the coupled state $|C\rangle$ and the noncoupled state $|NC\rangle$ are superpositions of the atomic ground states (with notations from **Figure 4(a)**):

$$|C\rangle(t) \propto g_1|1\rangle + g_2 \exp(-i\Delta_{HFS}t + i\phi)|2\rangle \quad [1]$$

$$|NC\rangle(t) \propto g_2|1\rangle - g_1 \exp(-i\Delta_{HFS}t + i\phi)|2\rangle \quad [2]$$

Here, g_1 and g_2 are the so-called Rabi frequencies, which determine the interaction strength of the transition, and they are proportional to the amplitude of the respective light fields combined with atomic parameters. Furthermore, the time-dependent states have a frequency of Δ_{HFS} and a phase of ϕ. It can be shown that if the difference frequency between the light fields $\omega_1 - \omega_2$ is equal to the ground-state splitting frequency Δ_{HFS}, and if the relative phase of the dark state ϕ is equal to the relative phase between the two light fields $\varphi_2 - \varphi_1$, then the probability for an atom to be excited from $|NC\rangle$ by the light fields is zero.

In this case, a ground-state coherence is created that is out of phase with the beat between the driving light fields. The relative phase between the two light fields has to be stable in order for the state to remain dark and not to get an admixture of the coupled state $|C\rangle$. At the same time this places a constraint on the stability of the relative phase only (i.e., the microwave phase), and not on the individual phases of the light fields φ_1 and φ_2.

While this approach gives an intuitive explanation of the existence of a coherent dark state, it does not include the population of this state by spontaneous emission. It also fails to predict detailed lineshapes, dephasing, and decay rates. In order to include these effects, the density matrix approach has proven useful (Arimondo 1996b, Orriols 1979, Vanier *et al.* 1998)) for a three-level (Arimondo 1996a) or a four-level (Vanier *et al.* 2003c) system. When the Raman detuning $\delta_R = \omega_1 - \omega_2 - \Delta_{HFS}$ is scanned around zero, the CPT resonance is detected as a bright line in the transmission of the light fields (see **Figure 4(c)** for the transmission ($\sim 1 -$ absorption)). Many of the features of CPT resonances are similar to the ones of microwave resonances used in RAFS.

Again, the width of the CPT resonance is inversely proportional to the lifetime of the coherence. Since the decay times of the ground-state hyperfine levels are several thousand years for stable alkali atoms, the decoherence is determined by external factors such as collisions, magnetic field inhomogeneities, power broadening, and relative phase instability of the light fields.

To reduce the last broadening mechanism, two phase-stable optical light fields are used with a frequency splitting of a few gigahertz, which is tuned to match the ground-state hyperfine splitting of the atoms. This has been demonstrated by actively phase-locking (Enloe and Rodda 1965, Schmidt *et al.* 1996) two diode lasers, external modulation of one laser (Bouyer *et al.* 1996, Hemmer *et al.* 1983), injection locking of two lasers (Simpson *et al.* 2003), or direct modulation of the diode laser injection current (Cyr *et al.* 1993, Hemmer *et al.* 1993, Levi *et al.* 1997, Myatt *et al.* 1993, Stähler *et al.* 2002). While the first two methods are difficult to implement in a small low-power device for field applications that require ease of use and robustness, the last methods seem to be suitable for this. It requires lasers with large modulation bandwidths for most alkali atoms. Recently, distributed feedback (DFB) lasers have become available at Rb and Cs D_1 and D_2 lines with modulation bandwidths around 10 GHz. A simple and cheap technique was demonstrated by Affolderbach *et al.* (2000), using a single-mode VCSEL modulated at 9.2 GHz, in order to create sidebands for Cs CPT. Despite their broad linewidths of a few tens of megahertz, narrow CPT resonances have been measured. As has been emphasized before, the relative phase stability (given by the modulation) is more important to the CPT resonance than is the overall frequency stability of the light fields. The low operating power of VCSELs, their large modulation bandwidths, and vertical design make them well suited for small, low-power MEMS devices.

When miniaturizing an atomic clock, CPT systems seemed suitable, mainly because of the simplicity of the setup. It is challenging to reduce the size of a microwave cavity very much below the size of the associated microwave wavelength, e.g., 4 cm for ^{87}Rb. In contrast, there is no such size restriction for CPT, since the microwave frequency is carried through the beat frequency of the optical light fields (at least at sizes much larger than the optical wavelength). Since then, small microwave clocks have been demonstrated as well without the microwave cavities (see Section 3.18.5).

3.18.1.4 CPT in Small Vapor Cells

Extensive studies have compared the advantages and disadvantages of CPT over the microwave approach (Lutwak *et al.* 2002, Vanier *et al.* 2003e). Despite many similarities, there are substantial differences between the properties of CPT and optically pumped microwave resonances. First, in optically pumped clocks, a population imbalance must be created between the hyperfine levels. This is usually done by a single light field resonant with one of the transitions, which does not require phase coherence but makes the system more susceptible to light field-induced frequency shifts (Camparo *et al.* 1983, Mileti *et al.* 1998, Orriols 1979, Vanier *et al.* 1998). At the same time CPT resonances tend to have lower contrast than microwave resonances, because background light fields are often present and destructive interference between multiple excited states can exist.

Finally, since the microwave transition is created by a single photon of spin 1, only ground states with magnetic quantum numbers differing by $\Delta m = 0, \pm 1$ can be coupled. In CPT two light fields are used to couple the ground states, which allows for $\Delta m = 0$, ± 1, ± 2 (see Section 3.18.3.2.3.(i)).

In the following section, we consider what happens when the size of the vapor cell is reduced. For simplicity, we assume that all the three dimensions are equal to L. As we reduce the size of the cell, fewer atoms will be interrogated and less light will be absorbed. It has been found that the maximum CPT signal is obtained when roughly 50% of the light gets absorbed by the atoms (Godone *et al.* 2002, Knappe *et al.* 2002). In order to stay close to this optimum condition, the temperature, and thus the vapor pressure of the alkali atoms, needs to be increased for smaller cells.

A major contribution to the CPT linewidth are collisions of the alkali atoms with the cell walls. To reduce this effect, a buffer gas is added to the vapor cell, which increases the time for an alkali atom to reach the cell wall and eliminates residual Doppler broadening through Lamb–Dicke narrowing (Dicke 1953, Vanier and Audoin 1989). Usually, inert gases or molecules such as nitrogen or methane are used as buffer gases, because they have small cross sections σ_{puff} for the ground-state decoherence (Beverini *et al.* 1971). This causes a diffusive motion of the alkali atoms through the cell, and the CPT linewidth contributions can be approximated in the lowest-order diffusion mode by the following equation

$$\Delta \nu_{\text{CPT}}^{\text{diff}} \propto \frac{D_0}{L^2 p} \quad \text{and} \quad \Delta \nu_{\text{CPT}}^{\text{puff}} \propto \sigma_{\text{buff}}\, p \qquad [3]$$

for the diffusion and the buffer gas collision as a function of buffer gas pressure p. Here D_0 is the diffusion constant (see, e.g., Vanier and Audoin 1989, 1992 for values of D_0 and σ_{buff} and various alkali–buffer gas combinations). Thus, the linewidth is determined at low buffer gas pressures by the collisions of the alkali atoms with the cell walls, and at high pressures by collisions with the buffer gas atoms. It is a standard method to choose the buffer gas pressure to operate at the sweet spot of lowest linewidth (Beverini *et al.* 1971, Brandt *et al.* 1997) (**Figure 5**). It has been experimentally shown that the CPT resonance width agrees well with these predictions even at very small cell sizes of 100 µm (Knappe *et al.* 2004a). At the same time it means that when the operation is at the sweet spot, the linewidth increases with cell size like L^{-1} (Kitching *et al.* 2002).

CPT resonances have also been measured in large, but extremely thin cells with thicknesses below the optical wavelength without buffer gases (Sargsyan *et al.* 2006). This was done in a different regime, where the dimensions perpendicular to the laser beam had to remain large so that the linewidth was determined mainly by atoms with a small velocity component in the direction of the laser beam.

Although the buffer gases usually have a small depolarization cross section of the ground state, they cause substantial depolarization in the excited state, causing the P-state to broaden homogeneously at a few megahertz per kilopascal of pressure (Allard and Kielkopf 1982). If the excited-state decoherence rate Γ increases, more laser intensity is required to obtain the same amplitude and linewidth of the CPT resonance.

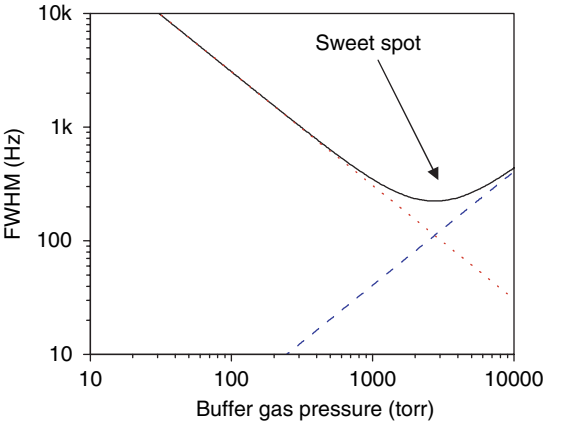

Figure 5 Coherent population trapping (CPT) linewidth as a function of buffer gas pressure in a 1-mm^3 cell filled with ^{87}Rb and N_2 as a result of diffusion to the walls (red dotted line), buffer gas collisions (dashed blue line), and the sum of both (black line).

At the same time, the absorption cross section of the atoms decreases so that the alkali vapor pressure, i.e., cell temperature, is increased to maintain a constant absorption. With an increase in alkali density, the rate of alkali–alkali spin-exchange collisions increases (Beverini *et al.* 1971, Happer 1972), i.e., rate is proportional to the alkali density. At sufficiently high pressures, spin-exchange collisions add a major contribution to the linewidth, rising proportional to the buffer gas pressure. In most vapor cells a molecular buffer gas, e.g., nitrogen, is included to quench the spontaneous emission and prevent radiation trapping (Copley and Krause 1969, Kibble *et al.* 1967).

Finally, the broadening of the excited state puts another constraint on very small CPT clocks. Since the bichromatic light field is usually produced by frequency-modulating a VCSEL at half the ground-state hyperfine frequency, the contrast of the CPT resonance is drastically reduced if the optical linewidth approaches the ground-state splitting frequency (Arimondo 1996a, Nikonov *et al.* 1994, Post *et al.* 2005). At these pressures the carrier and the second-order sidebands become resonant and can cause single-photon transitions out of the dark state (**Figure 6**). Furthermore, the beat frequency between the two first-order sidebands is out of phase with the ones between the carrier and the second-order sidebands. Since both beats have the same frequency, they could create dark states in the atoms, but with $\varphi_1 - \varphi_2$ having a difference of π, they cannot be dark simultaneously (eqns [1] and [2]). The phase relationships between the sidebands are symbolized in **Figure 6** by the direction of the arrows. Both effects reduce the lifetime of the coherence and degrade the stability of the clock.

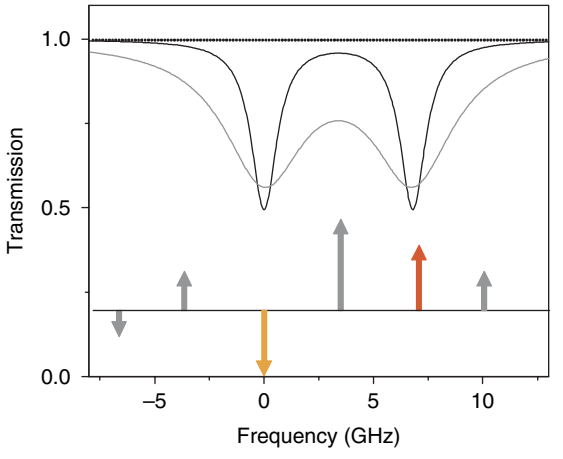

Figure 6 Transmission as a function of laser frequency relative to the transition of an atom with two ground states split by 6.8 GHz without buffer gas (black) and with homogeneously broadened lines (gray). The bottom arrows represent the sidebands created when the laser is modulated at 3.4 GHz and tuned such that the first-order sidebands (red and orange) are in resonance with the two atomic transitions. The direction of the arrows symbolizes the relative phase between them.

When frequency modulation (FM) of the VCSEL current is used, this places an upper limit on the buffer gas pressure. Thus, it is not necessarily favorable to operate at the sweet spot. The various parametric dependencies of the CPT clock resonance signals with cell parameters (such as buffer gas pressure, cell temperature, laser intensity, optical detuning, modulation frequency, and amplitude) have been characterized in detail (Knappe 2001, Knappe *et al.* 2001, Vanier 2001).

3.18.2 Design and Fabrication

3.18.2.1 Introduction

Passive CASCs in their simplest form consist of three parts: a local oscillator (LO) that generates the clock signal, a physics package that compares the frequency of the LO to the internal frequency of the atoms and outputs information about the difference frequency, and control electronics that tune the LO frequency such that the difference frequency is zero. Most CSACs use Cs or ^{87}Rb in their vapor cells, because of their relatively high ground-state splitting frequency (good Q factors), the availability of VCSELs at the right wavelengths, and relatively low vapor pressures.

In CPT-based CSACs, the LO usually produces a signal at half the ground-state hyperfine frequency of these atoms and modulates the injection current of a VCSEL. The frequency of the VCSEL is then tuned such that the two first-order modulation sidebands are in resonance with the two transitions from the ground-state hyperfine components to the excited state. Often, the buffer gas pressure is chosen to be above 5 kPa, so that the excited-state hyperfine structure is unresolved. The light is circularly polarized, attenuated, and sent through the alkali vapor cell. A photodiode detects the transmitted light. A small magnetic field parallel to the laser beam is applied to lift the degeneracy of the ground-state Zeeman levels and the cell is placed inside a magnetic shield to ensure a constant magnetic field strength. A schematic of this simple setup is depicted in **Figure 7**.

When the LO frequency is tuned to exactly half the ground-state frequency between the $m_F = 0$

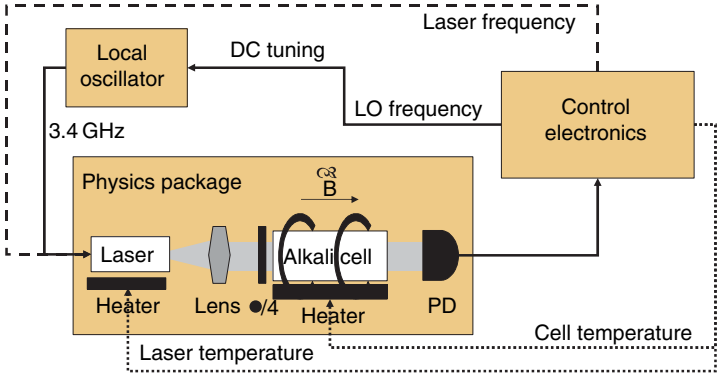

Figure 7 Schematic of a chip-scale atomic clock (CSAC) consisting of a local oscillator (LO), a physics package, and control electronics. The physics package consists of a laser with heater, lens, a quarter waveplate ($\lambda/4$), a vapor cell with heater, a magnetic offset field (B), and a photodetector (PD). The control electronics consist of servo loops for laser and cell temperature, as well as laser and LO frequency.

Zeeman components, the atoms are pumped into a coherent dark state and the transmitted light is reduced. To stabilize the LO frequency onto the top of the CPT resonance, its frequency is modulated at a few kilohertz. Phase-sensitive detection of the transmitted light at this frequency produces a dispersive error signal that can be used to lock the LO to the atomic resonance. A similar technique of phase-sensitive detection is used to lock the laser wavelength onto the center of the optical absorption by modulating the laser current at a low frequency. It is important that both of these modulation frequencies used for locking are well separated to avoid cross-talk between both loops. In addition to the two frequency-lock loops, two temperature servo loops are required to stabilize cell and laser temperatures. In some designs, the laser and the cell are in good thermal contact and one of the four feedback loops is eliminated (Lutwak *et al.* 2004).

3.18.2.2 Physics Package

3.18.2.2.1 Introduction

The physics package takes the instable 3.4-GHz signal from the LO and compares it with the internal frequency of the atoms. It generates an output signal that determines how much the LO frequency differs from the internal frequency of the atoms. In order to miniaturize a MEMS clock, various approaches have been investigated. Most of these, however, include the same general components and differ mostly in the engineered design. The first microfabricated physics package was reported in 2004 by the National Institute of Standards and Technology (NIST) (Knappe *et al.* 2004b). A picture is shown in Figure 8. It consisted of the VCSEL at the bottom, a micro-optical assembly, a vapor cell between two heaters, and a photodiode on the top. The electrical interconnects were wire bonds from the components in the stack to the pads on the baseplate.

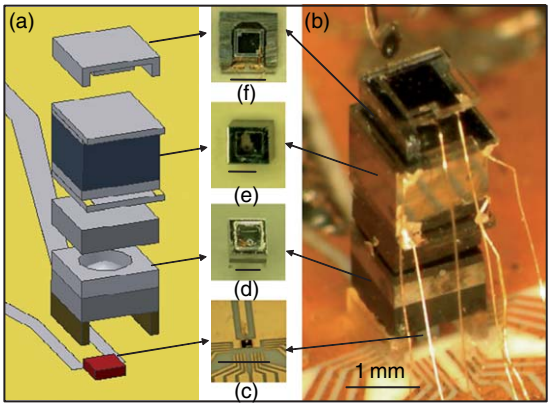

Figure 8 (a) Schematic and (b) photograph of a chip-scale atomic clock (CSAC) physics package consisting of (c) a vertical-cavity surface-emitting lasers (VCSEL), (d) an optics package, (e) a vapor cell with heaters, and (f) a photodetector.

In this approach, all the components were planar and in principle can be fabricated as arrays on individual wafers. While currently the wafers are diced first and the components stacked afterward, the design potentially allows for assembling the wafers first prior to dicing them into many individual physics packages, as indicated in Figure 9. This enables simple exchange of components and will potentially reduce fabrication costs.

Other groups have taken more complex approaches, where the laser beam is not just passed in a straight line to the photodetector. Lutwak *et al.*

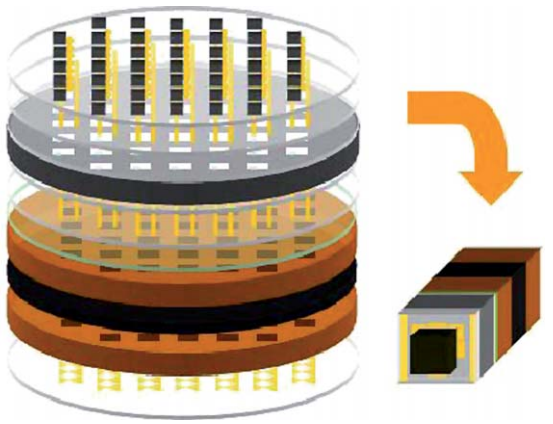

Figure 9 Wafer-level assembly of microelectromechanical systems (MEMS) clocks: wafers of baseplates with vertical-cavity surface-emitting lasers (VCSELs), spacers, neutral density (ND) filters with lenses, spacers, quarter waveplates, heaters, cells, and photodetectors are stacked and diced into individual chip-scale atomic clocks (CSACs) afterward.

(2004), for example, used a diverging beam and retro-reflected it back through the cell, where it was detected by a circular photodiode around the VCSEL die. One group explored a self-powered photon source as a low-power alternative to a VCSEL (Guo and Lal 2003). The kinetic energy of the electrons of 17.1 keV emitted from a radioactive ^{63}Ni film was used to generate photons through collisions with atoms. Photon generation in air, neon, and xenon was demonstrated with the goal to generate a low-power rubidium lamp for CSACs. Cesium, as well as rubidium, has been tried, and the fabrication of vapor cells differs. The cells vary in size between 250 µm and 1.5 mm. In the following sections as one example, we focus mainly on the approach taken by NIST, but there are other important ideas and approaches too.

3.18.2.2.2 Vertical-cavity surface-emitting laser

The VCSEL translates the electrical microwave signal from the LO into an optical beat signal. When the injection current of the VCSEL is modulated, a comb of modulation sidebands is created around the carrier in the optical spectrum spaced by the modulation frequency. The modulation properties of the VCSEL are therefore critical (see, e.g., Larsson *et al.* 2004). In order to interact with the atoms, the wavelength of the VCSEL has to be tuned such that some sidebands are resonant with optical atomic transitions.

VCSELs have been developed for telecom applications with high modulation bandwidths of up to 10 GHz (King *et al.* 1998, Lear *et al.* 1996). In contrast to traditional edge-emitting laser diodes, the light is reflected vertically through the thin layer of the active region, instead of along it. This creates a very short laser cavity of only a few micrometers between two stacks of Bragg mirrors, and only one longitudinal mode can be resonant with the gain medium (Jung *et al.* 1997). Nevertheless, many transverse modes could be resonating simultaneously (Chang-Hasnain *et al.* 1991, Degen *et al.* 2001). In oxide-confined VCSELs the physical restriction through a small aperture of about 3 µm diameter can limit oscillations to a single transverse TEM_{00} mode (Grabherr *et al.* 1997), reducing the output power of these single-mode devices to 5 mW (Jung *et al.* 1997, Seurin *et al.* 2002). Due to their vertical design, the beam profile is circular with a divergence angle of around 15°–25°. At the same time this design can allow two orthogonal polarization modes to be resonant. They can differ in frequency by many gigahertz and the polarization can flip back and forth between the two modes. Several approaches have been proposed to address this problem (Chavez-Pirson *et al.* 1993, Choquette and Leibenguth 1994, Debernardi and Gian Paolo 2003, Mukaihara *et al.* 1993, 1995a, Numai *et al.* 1995, Ostermann *et al.* 2005, Shimuzi *et al.* 1991). Nevertheless, these polarization jumps can still occur in single-mode VCSELs, and mode competition can cause amplitude noise in the single polarizations as well as in the total light power (Kaiser *et al.* 2002, Mukaihara *et al.* 1995b).

The vertical design makes it possible to fabricate large arrays of VCSELs, thus reducing the production costs (**Figure 10**). Their short cavities require Bragg mirrors of high reflectivity ($R > 99$ %), which reduce the sensitivity to optical feedback. Very low threshold currents below 1 mA (Choquette *et al.* 1994, Huffaker *et al.* 1994, Yang *et al.* 1995) have been reported, allowing small power consumption. At the same time, VCSELs have a large tuning of their output frequency with temperature ($\sim$30 GHz K^{-1}) and injection current ($\sim$300 GHz mA), which causes some problems for clock applications and places constraints on the current source and servo loops.

Even though laser linewidths of 3 MHz have been reported (di Sopra *et al.* 1999), most commercially available VCSELs have linewidths of around 50 MHz (Schmidt *et al.* 1996). While this can be a problem for many laser spectroscopy applications (Affolderbach *et al.* 2000), it does not substantially affect the CPT resonances. As mentioned in Section 3.18.1.3, the linewidth of the CPT resonance depends

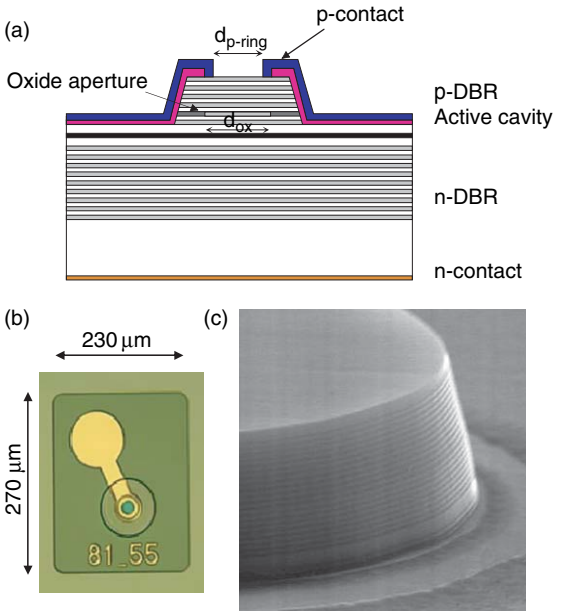

Figure 10 (a) Schematics and (b) photograph of a vertical-cavity surface-emitting laser (VCSEL). (c) Scanning electron microscope (SEM) picture of a VCSEL mesa after etching (before deposition of dielectrics and metal), the mesa height is about 3 µm. (Source: Avalon Photonics, Avalon Photonics Datacom VCSELs, http://www.avap.ch; reproduced with permission from Avalon Photonics Ltd.)

on the relative phase stability between the light fields, that is, the microwave phase, and not on the stability of the individual light fields (Dalton and Knight 1982). Nevertheless, a large VCSEL linewidth can reduce the CPT clock performance because of the large FM noise (Kitching *et al.* 2001c). The FM to amplitude modulation (AM) conversion process (Camparo 1998a) that occurs in the atoms adversely affects the CPT signal.

VCSELs have been developed for telecom applications since the 1980s (Fumio *et al.* 1989, Jewell *et al.* 1989), and reliable single-mode VCSELs have become available at the D_2 lines of Cs (852 nm). Lifetimes beyond one million hours have been reported (Avalon Photonics, Honeywell, Ulm Photonics, Mukoyama *et al.* 2006). Recently, VCSELs at the D_1 lines of Cs (895 nm) and Rb (795 nm), and D_2 lines of Rb (780 nm) and potassium (766 nm) have been produced.

Since their structure consists of more than 100 layers and their fabrication processes and designs vary from one manufacturer to another, the characteristics of single-mode VCSELs vary and directly impact the clock performance (see, e.g., Kwakernaak *et al.* 2004). It is therefore critical to choose the right VCSEL for the specific CSAC design. In order to get high yields, MEMS clocks must conform to stringent requirements regarding epitaxial growth accuracy and uniformity, which is much more demanding than is typically achieved in the best semiconductor fabrication facilities (Serkland *et al.* 2006). Some of the specifications are summarized here:

- Tunable to precise atomic wavelength (preferably 795 or 894 nm) at a given operating temperature, e.g., 75°C, ±5°C (Serkland *et al.* 2006).
- Single longitudinal, transverse, and polarization mode.
- Phase modulation index, >1.8 reachable with radio frequency (RF) powers of −6 dBm at 3.4 GHz (Brannon *et al.* 2005) or 0 dBm at 4.6 GHz (Serkland *et al.* 2006).
- Linewidth, <100 MHz (Serkland *et al.* 2006).
- Power consumption, <3 mW.
- Optical output power, 50 µW–1 mW.

3.18.2.2.3 Vapor cells

The vapor cell can be viewed as the heart of the clock, as it contains the atoms. Besides being a container that does not react with the atoms, the cell has to provide access to the light to and from the atoms. It needs to withstand elevated temperatures, should not be magnetic, and has to be hermetically sealed. For chip-scale vapor cells it should furthermore allow for wafer-level fabrication and filling, since fabrication cost as well as uniformity over an ensemble of cells is of concern. The interior size of the cell should be in millimeters and the exterior volume should be as small as possible. Finally, the geometry of the cell needs to be considered, when integrated with the rest of the physics package.

Several millimeter-sized glass vapor cells have been reported using conventional glass-blowing techniques (Balabas *et al.* 2006) or a focused CO_2 laser (Knappe *et al.* 2003a) (**Figure 11**). Glass alkali cells have been well studied for use in optically pumped clocks. This can make the wall effects due to higher surface-to-volume ratio and thinner walls more predictable. However, the high surface tension of glass, as well as the possibility of the alkali atoms reacting with the glass at high temperatures, makes size reduction to 1 mm challenging.

In an attempt to fulfill the above requirements for a miniature alkali vapor cell, a first fabrication process based on MEMS silicon wafers etching techniques was proposed (Kitching *et al.* 2002). At present, most fabrication techniques for microfabricated cells rely on these ideas, while the actual techniques for filling the

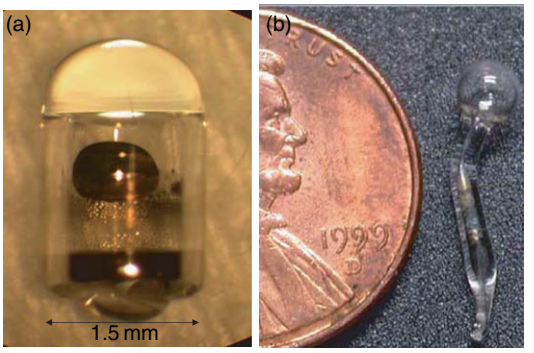

Figure 11 Photographs of small vapor cells: (a) made from a hollow-core glass fiber with a CO_2 laser; (b) made with conventional glass-blowing techniques.

cells with alkali atoms differ significantly. The first MEMS-fabricated vapor cells (Knappe *et al.* 2003b, Liew *et al.* 2004) used double-side polished ⟨100⟩ silicon wafers that were photolithographically patterned inside a clean room (**Figure 12**) and subsequently etched by means of silicon etching techniques (potassium hydroxide (KOH) or deep reactive ion etching (DRIE)) to produce arrays of holes. This allows for a very high level of miniaturization as well as regular arrays of cells with tight tolerances. Cells with holes of 1 mm in size were also successfully made by diamond drilling (Liew *et al.* 2004) or ultrasonic drilling. While surface roughness of the interior walls could be of concern for cells with antirelaxation wall coatings (Alexandrov *et al.* 2002, Bouchiat and Brossel 1966, Robinson *et al.* 1958), no evidence of effects due to rough silicon walls have been published so far for buffer gas cells.

Two early approaches for filling and sealing microcavities with alkali atoms have been demonstrated by NIST (Liew *et al.* 2004). Both used anodic bonding (Wallis and Pomerantz 1969) of Corning 7740 glass (Pyrex™)[1] or borosilicate glass to the etched silicon chips to create a cell preform. The cell was then sealed under a buffer gas atmosphere by anodically bonding a second piece of Pyrex over the top of the preform. In the first method, cesium was injected into the preform with a micropipette in an anaerobic chamber (**Figure 13**). While this is a very simple and inexpensive way to make cells, the chamber environment was difficult to control precisely. First, residual oxygen in the chamber limited the lifetime of cesium and produced large amounts of oxidized cesium inside the cell. Second, other background gases were present inside the chamber and thus inside the cell, which can cause

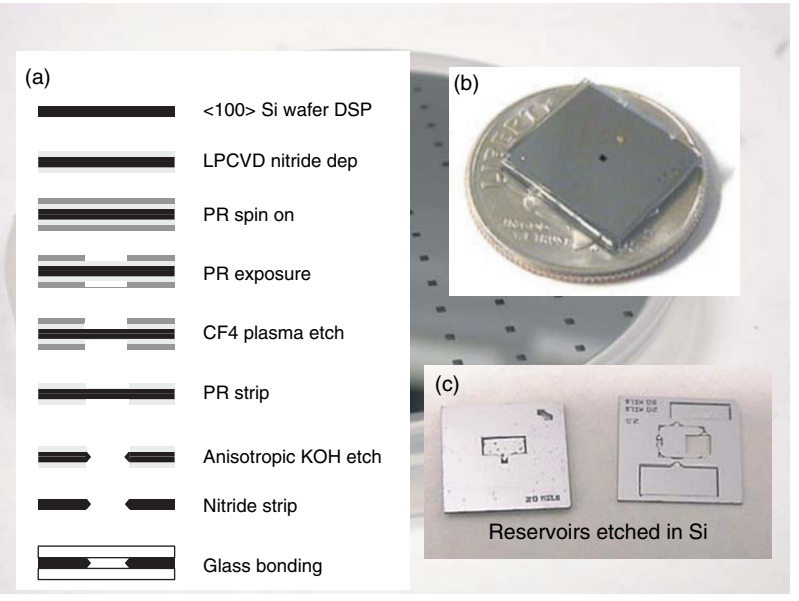

Figure 12 Microelectromechanical systems (MEMS) etching process of microfabricated vapor cells. (a) Steps of a typical potassium hydroxide (KOH) etching process. problems when trying to reduce the temperature coefficient of the clock by using controlled mixtures of different buffer gases (Vanier *et al.* 1982) (see Section 3.18.4.3 for a more detailed discussion). Very similar filling techniques have been reported subsequently by Kwakernaak *et al.* (2004) and Lutwak *et al.* (2005).

The second filling technique was successfully used in centimeter-sized buffer gas vapor cells before. A stable cesium compound was deposited into the cell and was reacted to produce pure cesium metal by using the following process (Espe 1966):

$$BaN_6 + CsCl \rightarrow BaCl + 3N_2 + Cs$$

The decomposition was initiated by heating the mixture to roughly 200°C inside a UHV chamber. The problem in a small cell arose from the difficulty of pumping off the excess nitrogen gas formed without having all the cesium metal leave the small cell volume at elevated temperatures. Furthermore, the BaCl and the free barium remained inside the cell where the chemical solution was deposited. In bigger cells, this can be desirable because barium can be used as a getter. However, in small cells that are heated to higher temperatures, the gettering rate of nitrogen by barium can cause pressure changes in the cells that result in frequency changes (Knappe *et al.* 2005a). Since the clock frequency of cesium is extremely sensitive to the nitrogen pressure ($45 \pm 2\,\text{Hz}\,\text{kPa}^{-1}$; Beverini *et al.* 1981), the pressure has to be stable at 2×10^{-3} kPa to support a frequency stability of 1×10^{-11}. When using barium inside small buffer gas cells, nitrogen must be completely avoided and instead atoms such as inert gases can be used. But even then it can be difficult to ensure that the chemical reaction has been completed and that no nitrogen is left inside the cell.

One advantage of chloride reduction through barium is that it is relatively easy and cheap to produce small quantities of isotopically enriched ^{87}Rb. Usually, isotopical purity of ^{87}Rb is preferred so that the light is not absorbed by the ^{85}Rb atoms (with 62% natural relative abundance), for which the CPT condition is not fulfilled. In order not to have any residues inside the cell cavity, the alkali atoms can be produced this way inside a glass ampoule and evaporated into the cell cavity through a small nozzle (Knappe *et al.* 2005a). The cell is then closed after filling the chamber with the desired buffer gas mixture. This is a versatile technique, and the cells with Cs, ^{87}Rb, and ^{85}Rb and a variety of buffer gases with pressures <1 torr to 1 atm have been produced this way.

Other approaches to insert the alkali atoms into MEMS cell cavities have also been reported on since then. Radhakrishnan and Lal (2005) encapsulated rubidium in wax micropackets as shown in **Figure 14**. The cell preforms were made by anodic bonding of bulk-micromachined silicon wafers to Pyrex under a xenon atmosphere. One side of the cavity array has a silicon

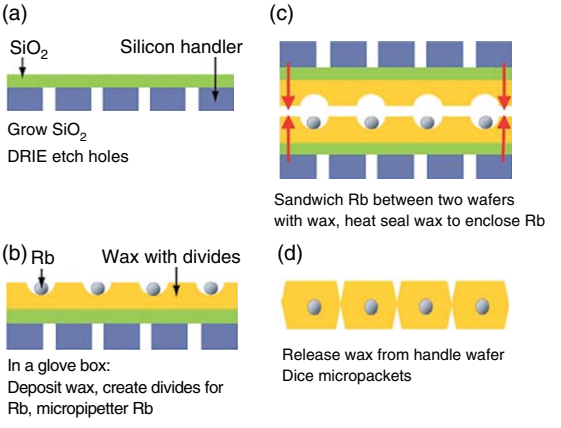

Figure 14 Process to enclose Rb in wax micropackets. (Source: Radhakrishnan S, Lal A 2005 Alkali metal-wax micropackets for chip-scale atomic clocks. *Dig. Tech. Papers – Int. Conf. Solid State Sensors and Actuators and Microsystems, Transducers '05*, pp. 23–6, © 2005; reproduced with permission from IEEE.)

nitride membrane that gets thermally bonded to the wax micropackets, as shown in **Figure 15**. The rubidium is released into the cavity by laser ablation of the silicon nitride membrane. Rubidium absorption was measured in these cells successfully, but the effect of the wax on the ground-state hyperfine coherence has not been studied yet.

A wafer-level process to make arrays of nitrogen buffer gas cells with cesium has been developed by Liew *et al.* (2006a, b). Here, cesium azide (CsN_3) is evaporated through an aluminum shadow mask into cell preforms made from silicon with borosilicate glass windows. The cavities are closed under vacuum by anodically bonding a wafer of borosilicate glass onto the top. The cesium azide is decomposed into cesium and nitrogen by exposing the cells to ultraviolet light. The decomposition is stopped when the nitrogen pressure reaches the desired value.

A technique demonstrated by Gong *et al.* (2006) uses cesium-enriched glass as a source for alkali atoms in microfabricated cells. The glass pieces are melted into a well on the bottom of an anodically bonded cell preform (**Figure 16**). The cell is closed by anodic bonding under the desired buffer gas atmosphere. Finally, the cesium atoms are released from the glass by passing an electrolytic current through the glass at 500°C and 1 kV between a $NaNO_3$ anode and the silicon (cathode).

Pieces of Cs-enriched glass (dark blue) are melted into the well. (b) Another Pyrex wafer is anodically bonded to the other free surface of the silicon wafer under an argon cover gas. (c) A copper stem, containing molten $NaNO_3$ salt in a basin at the top, is pressed against the Pyrex below the Cs glass well. The stem is attached to the copper base, resting on a hot plate at a temperature of 500°C. A potential of +700 V is applied for a few minutes between the molten $NaNO_3$ anode and the silicon cathode. (Source: Gong F, Jau Y Y, Jensen K, Happer W 2006 Electrolytic fabrication of atomic clock cells. *Rev. Sci. Instrum.* 77, 076101, © 2006; reproduced with permission from American Institute of Physics.)

A MEMS glass-blowing technique has been reported by Erklund and Shkel (2006). As the schematic in **Figure 17(a)** explains, cavities are etched into one side of a silicon wafer using DRIE. A 100-μm-thick piece of borosilicate glass is then anodically bonded over the top of the cavities enclosing the atmospheric pressure. When the wafer is heated to 850°C, that is, above the melting point of the glass, the air pressure inside the cavities deforms the glass into spherical shapes, as shown in **Figure 17(b)**. Afterward, the backside of the cavities is etched to allow for filling with alkali atoms. ^{87}Rb cells have been made this way by using the evaporative filling method described previously and by anodically bonding a second piece of borosilicate glass over the backside in the presence of a nitrogen and xenon atmosphere.

3.18.2.2.4 Optics

Even though the actual designs of the physics packages vary significantly, in almost all cases, there is an optics package that controls the size, intensity, and polarization of the laser beam. Most approaches use circular polarization by passing the beam through a low-order quarter waveplate. Neutral density (ND) filters are a simple way to attenuate the light to the desired power of around 10 μW. At the same time, these attenuators can reduce the optical feedback

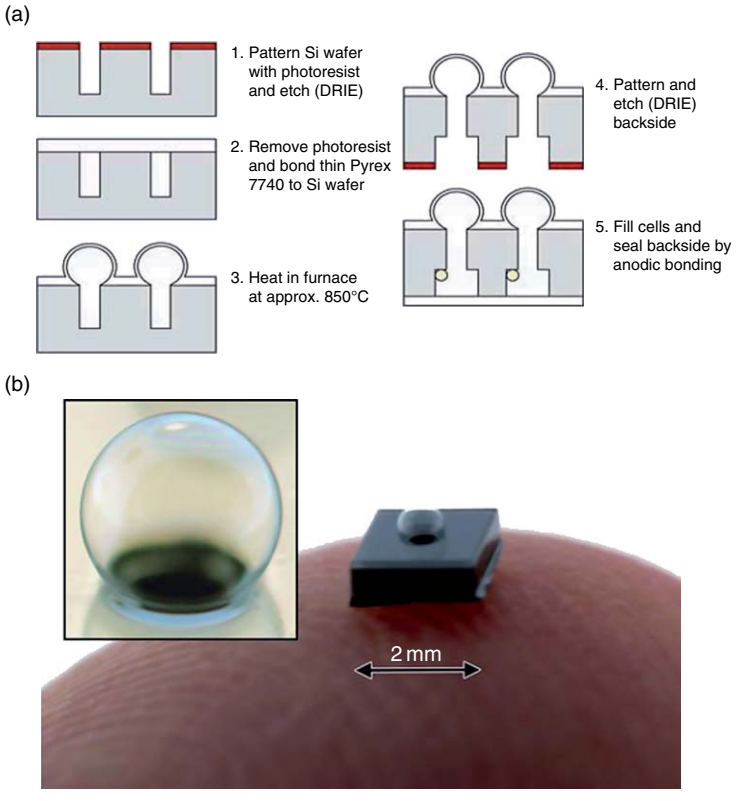

Figure 17 (a) Wafer-level fabrication of glass-blown vapor cells. (b) Photograph of a micro glass cell on top of a silicon wafer. (Courtesy of J. Erklund).

produced by light that gets reflected back into the VCSEL. Some optics packages also use antireflection-coated elements. In some setups, a polarizer is inserted to filter out the undesired polarization modes (Gerginov 2006). While in many designs the laser beam is collimated by a microlens, it has been shown that this is not necessary and a diverging beam can be used instead (Lutwak *et al.* 2004). **Figure 18** shows an example of an optics package consisting of a spacer, a ND filter, an inkjet-printed epoxy lens, and a quarter waveplate through which the beam passes. Other designs use more complicated beam paths by implementing micromirrors in the optics package.

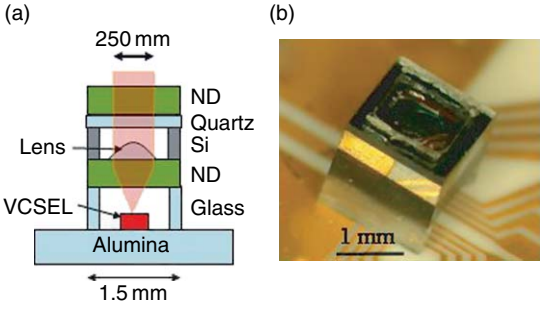

Figure 18 Schematic (a) and photo of a chip-scale atomic clock (CSAC) optics package.

3.18.2.2.5 Heating

In order to achieve sufficient absorption of the laser light over a 1 mm path length, the alkali vapor pressure has to be increased from its room temperature. Because most cells contain a liquid or a solid drop of alkali metal along with the vapor, this is usually done by simply heating the cell. The temperature for 50% absorption of the resonant light depends also on the buffer gas pressure, since buffer gas collisions change the lifetime of the P states (Allard and Kielkopf 1982). For higher pressures and low laser powers, the alkali density has to be increased proportional to the increase in buffer gas pressure to maintain the same absorption. For a 20-kPa nitrogen cell, for example, this temperature is around 75°C for cesium and 90°C for rubidium. Furthermore, it is advantageous to maintain the cell windows at a temperature slightly higher than the body of the cell to minimize the quantity of the alkali atoms that condense on the windows.

Microfabricated heaters are not a new technology (Lai *et al.* 1995, Nguyen and Howe 1993, Ruther *et al.* 2004) and approaches differ significantly. To reduce the magnetic fields produced by the currents flowing through the resistive heaters, patterned traces are often meandered and retraced and resistances are chosen such that only small currents flow. Traces can also be made from transparent materials or patterned such that the laser beam can pass through the center of the cell for better uniformity of heat distribution (Lutwak *et al.* 2004). Furthermore, thin substrate materials with low thermal conductivities are used for better thermal insulation. Substrates, heaters, and temperature sensor materials are chosen to be least magnetic, e.g., platinum, glass, polyimide, indium tin oxide (ITO).

Figure 19 shows an example of microfabricated transparent heaters (Schwindt *et al.* 2006) made from ITO. The heaters are glued directly onto the cell windows, and heat is produced when current flows through the conductive ITO layers. Two glass substrates with patterned ITO are glued together with a nonconductive epoxy to reduce the magnetic fields. The lighter color lines in the heater are where ITO has been removed through laser patterning. After the ITO patterning, gold pads are deposited for wire bonding, and a 2-μm insulating layer of benzocyclobutene is deposited over the remaining exposed ITO so that the electrical contact between the upper and the lower ITO layers is made only through the gold pads. The large arrows show where current enters and exits the heater. The electrically conductive epoxy provides the connection between the upper and the lower ITO. **Figure 20** shows a vapor cell with integrated heaters made from boron-doped silicon. The doped bifilar traces are bulk-micromachined into the silicon cell preform with a high aspect ratio (Liew *et al.* 2005, 2006b).

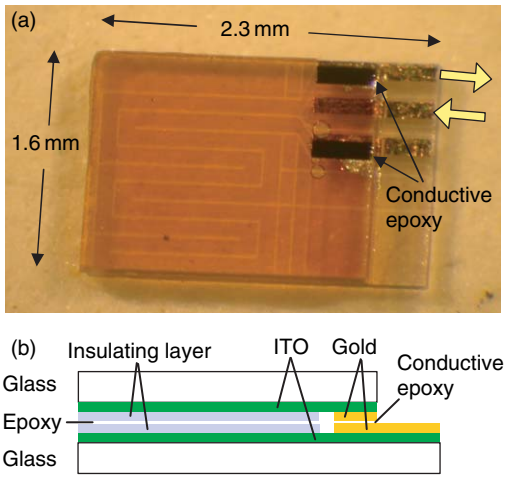

Figure 19 (a) Photograph and (b) schematic side view of laser-patterned indium tin oxide (ITO) heater. (Source: Schwindt P D D, Lindseth B, Knappe S, Shah V, Kitching J 2006 A chip-scale atomic magnetometer with improved sensitivity using the Mx technique. *Appl. Phys. Lett.*)

3.18.2.2.6 Magnetic field control

Most CSACs are operated on the $m_F = 0 \leftrightarrow m_F = 0$ hyperfine transition, to be insensitive to magnetic fields in first order. The magnetic field shifts the neighboring Zeeman sublevels apart with $\sim 7\,\text{kHz}\,\mu\text{T}^{-1}$ for ^{78}Rb and $\sim 3.5\,\text{kHz}\,\mu\text{T}^{-1}$ for Cs. Therefore, a field of a few microtesla in strength is sufficient to separate the neighboring CPT resonances of a few kilohertz linewidth. In order to couple the two 0–0 hyperfine components with circularly polarized light, a longitudinal magnetic field is required.

Until now, not much has been published about how to precisely control the magnetic field in the vicinity of the tiny vapor cell. Nevertheless, magnetic field strength, homogeneity, and direction can be of concern. The amplitude of the CPT 0–0 resonance is proportional to $\cos^2(\theta)$, where θ is the angle between the

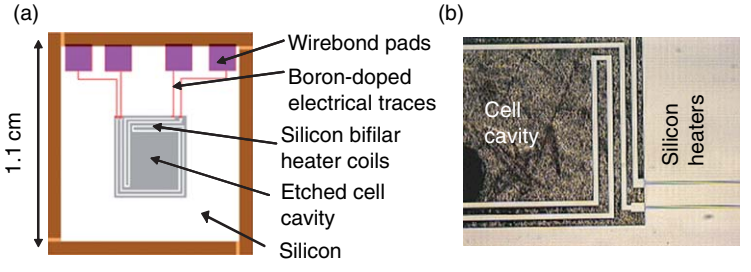

Figure 20 (a) Design of an advanced cell with integrated heaters. (b) Photograph of closeup of the cell cavity. (Source: Liew L, Moreland J, Knappe S, Shah V, Schwindt P, Gerginov V, Kitching J, Hollberg L 2005 Microfabricated alkali atom vapor cells with in-situ heating for atomic-based sensors. *Proc. 3rd Int. Symp. Sensor Science*, Juelich, Germany, pp. 181–3.)

direction of laser propagation and the magnetic field (Wynands and Nagel 1999). Also, because fairly high buffer gas pressures are used in most cells, the atoms can be considered stationary and sample the magnetic field at their location. The CPT resonance is then a convolution of all atoms interrogated and therefore broadens with magnetic field gradients across the cell. But again, if the 0–0 transition is used in buffer gas cells, this effect is reduced because the 0–0 resonance shifts with the magnetic field in second order only. It could be further reduced by using antirelaxation wall-coated cells (Robinson *et al.* 1958), where motional narrowing (Bloembergen *et al.* 1948, Kleppner *et al.* 1962) would suppress the gradient-induced broadening. Finally, the CPT 0–0 resonance frequency shifts with the total magnetic field at $57.5\,\mathrm{mHz}\,\mu\mathrm{T}^{-2}$ for cesium and $42.7\,\mathrm{mHz}\,\mu\mathrm{T}^{-2}$ for ^{87}Rb (see, e.g., Steck 1998, 2001, and references therein).

The externally applied offset field should therefore be made as small as possible to reduce frequency shifts and broadening due to ambient field changes (e.g., through heater currents), but big enough to lift the Zeeman degeneracy beyond the CPT linewidth and to ensure that ambient fields are not rotating the direction of the total field too much (e.g., earth's magnetic field). The external offset field is applied through either magnetic coils or permanent magnets. The latter method has the advantage of reducing the power consumption of the CSAC and the residual magnetic fields because the heater supply leads are not present. The disadvantage is that the CSAC frequency cannot be tuned through the C-field (as is most commonly used in Rb vapor clocks). The physics package is usually shielded from external magnetic fields, for example, the earth's magnetic field, by at least one layer of material with high permeability. It has been shown that shielding factors of around 1000 for one layer and greater than 4×10^6 (Hodby 2006) for three-layer shields of several millimeters in size can be reached.

3.18.2.3 Local Oscillator

3.18.2.3.1 Introduction

Most of the CSACs described so far are passive atomic clocks (see Section 3.18.2.1). The clock frequency is produced by a LO, which is locked to the atomic CPT resonance with a loop bandwidth $\mathrm{BW_{lock}}$. The clock frequency is determined by the atomic ground-state hyperfine frequency, i.e., 6.834 GHz for ^{87}Rb or 9.192 GHz for ^{133}Cs. Using CPT interrogation, a modulation of the VCSEL at half these frequencies is possible. Many applications, however, require a clock with an output frequency of 10 MHz, and frequencies up to 100 MHz can probably be used. Therefore, either the LO frequency has to be divided for the output or a low-frequency LO (10 MHz, for example) should be multiplied for VCSEL modulation. For reaching the goal of 30 mW total power consumption for the CSAC, the output frequency should most likely be the specific gigahertz frequency, determined by the atoms. In the following, we will mostly focus on LOs at microwave frequencies, which are developed for the chip-scale clocks. The list presented here is not complete but is rather a condensed overview.

As a passive standard, the CSAC frequency stability at times shorter than $(\mathrm{BW_{lock}})^{-1}$ is determined mostly by the phase noise of the LO. To reach a clock frequency stability of 1×10^{-11} at 1 h of integration, the single-sideband phase noise power spectral density of the LO needs to be between $-25\,\mathrm{dBc\,Hz^{-1}}$ at 100 Hz offset (Brannon *et al.* 2005, Kitching 2003) and $-43\,\mathrm{dBc\,Hz^{-1}}$ at 300 Hz offset (Römisch and Lutwak 2006) from the carrier. The required output power depends largely on the modulation efficiency of and the coupling efficiency to the VCSEL. It has been shown that for some VCSELs <-6 dBm output power at 3.4 GHz can be sufficient to transfer 60% of the light power into the desired first-order sidebands (Brannon *et al.* 2006b). At 4.6 GHz, the requirement was set to 0 dBm (Römisch and Lutwak 2006). In order to reach the goal of total power of 30 mW for the CSAC, it would be desirable if the DC power consumption of the LO was well below 10 mW and the footprint below $1\,\mathrm{cm^2}$.

A significant concern is the thermal frequency drift of the voltage-controlled oscillator (VCO). Since it is most likely not actively temperature-stabilized, its resonance frequency must not drift out of the tuning range provided by the servo when the ambient temperature varies over the entire operating range of the clock. A maximal thermal frequency shift of around $\pm 10\,\mathrm{ppm\,K^{-1}}$was therefore a goal with a tuning range of a few megahertz. At the same time, the tuning range of the VCO should be small for good resolution and frequency stability, but should be large enough to compensate for manufacturing tolerances. Finally, a supply voltage below 3.5 V is desired and all the components should be of low cost.

The best available oscillators at gigahertz frequencies are dielectric resonator oscillators (DROs) with Q factors of several thousand (Pozar 2001) and even 100 000 for cryogenically cooled sapphire devices (Ivanov and Tobar 2006, Ivanov *et al.* 1998). But their size, weight, and power make them unsuitable

for MEMS clocks. Crystal oscillators can be very good with similar Qs in the frequency range of up to hundreds of megahertz (Vig 1992). Oven-controlled devices (OCXOs) have very good stability, but require several hundred milliwatts of power, but TCXOs or microprocessor-controlled (MCXO) crystal oscillators can operate on a few milliwatts. Nevertheless, multiplying their frequencies into the gigahertz region may require too much power for CSACs. Therefore, considerable research is done on alternative approaches of small, low-power LOs at gigahertz frequencies.

3.18.2.3.2 Oscillator designs for CSAC

Even though the development of VCOs for MEMS clocks has advanced rapidly, not many devices have currently been tested together with CSAC physics packages. One reason is the requirement to operate exactly at the resonance frequency of the atoms.

Popović and coworkers implemented two oscillators at 4.596 GHz and 3.417 MHz (Brannon *et al.* 2005, 2006a) and demonstrated their applicability to a CSAC. The oscillators were based on quarter-wavelength ceramic-filled coaxial resonators. The phase noises of the oscillators were measured to be better than $-35\,\mathrm{dBc\,Hz^{-1}}$ at 100 Hz and $-94\,\mathrm{dBc\,Hz^{-1}}$ at 10 kHz. A weakly coupled varactor diode provides a tuning range of ~3 MHz to compensate for a temperature instability between 0 and $40\,\mathrm{ppm\,K^{-1}}$ over −5°C to +65°C. DC powers of 2.1 and 13.9 mW resulted in −6 dBm output power at 3.4 GHz and −4 dBm at 4.6 GHz. All components were of low cost and were commercially available.

A 3.417-MHz VCO was integrated with a CSAC ^{87}Rb physics package (Brannon *et al.* 2006b) onto a common baseplate. A power of −6 dBm was sufficient to modulate the VCSEL at its desired modulation depth. **Figure 21** is a photograph of the low-power 3.4-GHz oscillator (Brannon *et al.* 2006b) and the CSAC physics package.

Römisch and Lutwak (2006) recently demonstrated a 4.596-GHz oscillator based on a thin-film temperature-compensated resonator (Römisch and Lutwak 2006) using a very similar oscillator design. A single-sideband phase noise power spectral density of $-38\,\mathrm{dBc\,Hz^{-1}}$ at 300 Hz was measured when emitting the required 0 dBm output power, improving at lower powers. With a power consumption below 10 mW and a tunability of $2\,\mathrm{MHz\,V^{-1}}$, this resonator was designed for cesium CSAC.

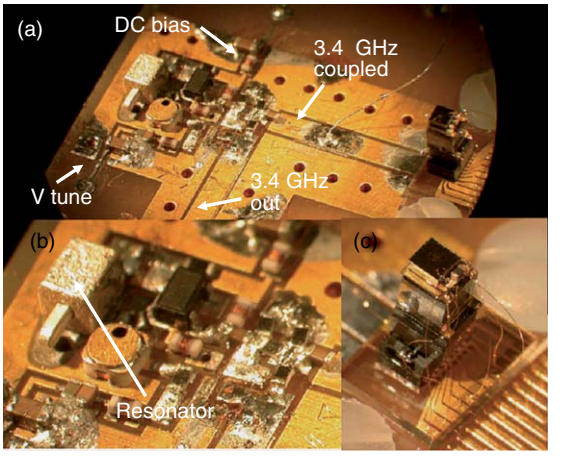

Figure 21 (a) Photograph of a 3.4-GHz voltage-controlled oscillator (VCO) integrated with a chip-scale atomic clock (CSAC) physics package. Inputs are DC bias and tune voltage for the VCO, and laser bias, photodetector bias, and heater currents for the physics package. Outputs are stabilized at 3.4 GHz and diagnostic signals. (b) Closeup view of the VCO and (c) the physics package.

3.18.2.3.3 Other MEMS resonators

The oscillators described so far were able to reach the goals set for the CSAC in terms of frequency stability, power consumption, and size. Nevertheless, fully integrated MEMS oscillators can be advantageous for mass fabrication and possibly advanced performance. A detailed noise analysis of MEMS oscillators was performed (Vig and Yoonkee 1999). In the following, we introduce a few approaches using other types of MEMS resonators.

Totally integrated complementary metal oxide semiconductor (CMOS)-type oscillators are probably the smallest devices, but do not presently fulfill the phase noise requirements (Gierkink *et al.* 2003, Mourant *et al.* 2000). Much progress has been made recently in the development of micromachined mechanical resonators (Nguyen 2005). Unloaded Qs greater than 10 000 have been demonstrated up to 1.5 GHz (Li *et al.* 2004) and temperature stabilities below 1.8×10^{-5} over 25–125°C (Hsu and Nguyen 2002). An advantage of these micromechanical resonators based on polysilicon (Li *et al.* 2004) or diamond (Wang *et al.* 2002) surface micromachining is that their resonance frequency can be defined by their lateral dimension, rather than by their thickness, which allows for easy specification through computer-aided design (CAD). Furthermore, arrays of mechanically coupled 15-MHz resonators have demonstrated an improvement in phase noise of 40 dB by locking all resonator frequencies to one

mode (Lee and Nguyen 2004). Nevertheless, no oscillator using one of these micromachined resonator tank has been demonstrated in the gigahertz region as at the time of this writing (2006).

MEMS techniques lend themselves to the making of gigahertz oscillators for CSACs, as small size allows for faster speed, lower power consumption, and lower cost. In the case of quartz resonators, MEMS fabrication enabled quartz on-chip resonators at 900 MHz with *Q*s greater than 10 000 and strong third overtone modes above 2.5 GHz and *Q*s greater than 7500 (Kubena *et al.* 2005, Stratton *et al.* 2004). Temperature coefficients around $-5\,\text{ppm}\,\text{K}^{-1}$ have been measured in shear strip designs. The fabrication process and a scanning electron microscope (SEM) photograph of a complete ultrahigh frequency (UHF) quartz resonator are shown in **Figure 22** as an example.

Other interesting candidates include thin-film bulk acoustic resonators (FBAR) and high-tone bulk acoustic resonators (HBAR). Frequency-tunable FBAR oscillators at 2 GHz showed a phase noise of $-112\,\text{dBc}\,\text{Hz}^{-1}$ at 10 kHz and an unloaded *Q* better than 500 (Khanna *et al.* 2003). With a supply voltage of 3.3 V, it uses 115 mW of power and had a tuning

Papers (Transducers '05)*, pp. 1100–1, © 2005; reproduced with permission from IEEE.)

sensitivity of 180–370 kHz V^{-1} (0–10 V tuning range). FBAR resonators generally have temperature stabilities of 20–30 ppm K^{-1}. Pang *et al.* (2005) have reduced the temperature coefficient of a tunable FBAR resonator at 2.8 GHz by 40 ppm K^{-1} by integrating a micromachined air-gap capacitor and Zhang *et al.* (2005) demonstrated a temperature stability of −8.7 ppm K^{-1} with a 5-GHz CMOS-compatible device. Care has to be taken in the design of FBAR oscillators to satisfy the resonance condition for the desired mode only, as they can have closely spaced series and parallel resonances. A schematic and a photograph of a 5-GHz FBAR oscillator are shown in **Figure 23**.

Resonators can be scaled even smaller with nanoelectromechanical systems (NEMS) to allow for Q factors in the range of 1000–100 000 with very low power consumption. Double-clamped beams made from SiC reach microwave frequencies (Ekinci and Roukes 2005).

3.18.2.4 Control Electronics

Besides the physics package and the LO, the CSAC needs miniaturized control electronics for operating the clock by providing the supply currents and voltages for the individual components and for controlling at least four servo loops for laser and cell temperature, laser frequency, and LO frequency. Sometimes, laser and cell are maintained at the same temperature and the two servos can be combined.

To reach the goal of 1 cm^3 total volume for the CSAC, an application-specific integrated circuit (ASIC) will most likely be required. Until now, prototypes of 10 cm^3 have been demonstrated (Gerginov *et al.* 2005, Lutwak *et al.* 2005) with control electronics

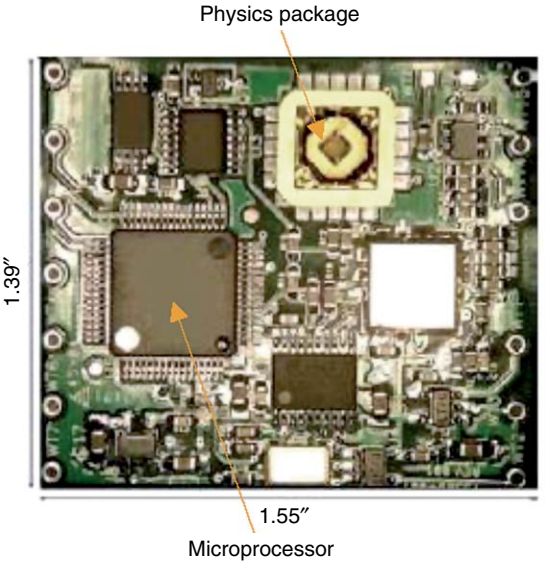

Figure 24 Prototype printed circuit (PC) board for a miniature atomic clock. (Source: Lutwak R, Vlitas P, Varghese M, Mescher M, Serkland D K, Peake G M 2005 The MAC – A miniature atomic clock. *Joint Meeting of the IEEE International Frequency Control Symposium and the Precise Time and Time Interval (PTTI) Systems and Applications Meeting*, Vancouver, BC, Canada, pp. 752–7.)

based on digital microprocessors. **Figure 24**, for example, shows a printed circuit (PC) board of footprint 14 cm^2 containing all the control electronics necessary to run a CSAC. As shown in the block diagram in **Figure 25**, the analog signals from the CSAC are converted into digital signals and processed by the microprocessor. The output is converted into analog signals again, which in turn drive the CSAC.

The temperatures are usually measured by thermistor temperature sensors. A proportional integrator (PI) servo is programmed into the microprocessor chip and the single-sided (heating only) output controls the heater currents. For low power consumption, the cell and the laser are operated above the maximum ambient temperatures, so that no cooling is required.

Since the laser and the LO have to be locked to the center of the optical and microwave resonance lines, respectively, phase-sensitive detection is implemented for these two servos. The laser current and the LO tuning voltage are modulated at a low frequency (500 Hz–30 kHz), and the photodetector voltage is demodulated at this frequency. To prevent cross-talk between the two loops, the two modulation frequencies are usually chosen to be different by an order of magnitude and the demodulation filters have to be tuned accordingly. The phase of the

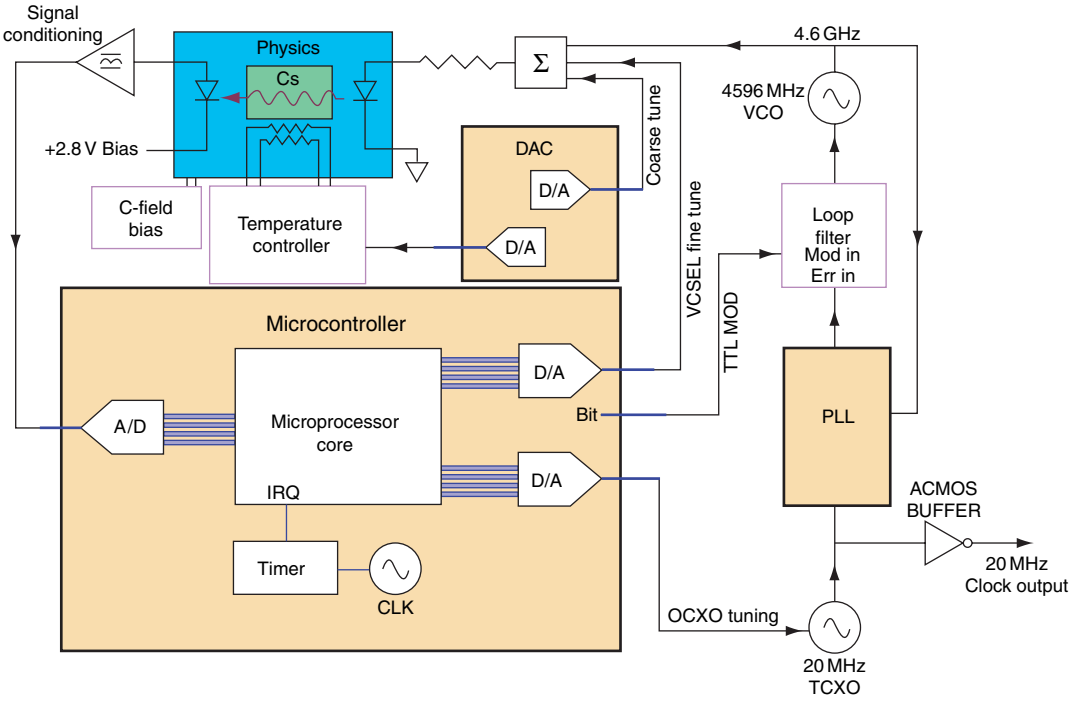

Figure 25 Block diagram of a miniature atomic clock. (Source: Lutwak R, Vlitas P, Varghese M, Mescher M, Serkland D K, Peake G M 2005 The MAC – A miniature atomic clock. *Joint Meeting of the IEEE International Frequency Control Symposium and the Precise Time and Time Interval (PTTI) Systems and Applications Meeting*, Vancouver, BC, Canada, pp. 752–7.)

demodulation has to be chosen precisely for best performance. Due to the high tunability of VCO ($\sim$2 MHz V^{-1}) and VCSEL ($\sim$300 GHz mA^{-1}), highly stable supply voltage and current are needed. In order to run the CSAC off a common voltage supply, for example, two AA batteries (3 V), heater resistances and current supplies have to be designed for minimum power consumption at this voltage.

3.18.2.5 Packaging

When power consumption is the concern, packaging, especially for the physics package, becomes a critical issue. Since laser and cell are heated above the ambient temperature, that is, to at least 75°C for many applications, thermal management and control need to be addressed. Without this control, physics packages will require 100–250 mW just to heat the small vapor cell and tiny laser die (Kitching *et al.* 2004). Most of the heating power is then lost thermally through conduction and convection.

Conduction can be tremendously reduced by increasing the thermal resistance between the physics package and the environment. **Figure 26** shows a CSAC physics package that consumes <10 mW of power at an ambient temperature of 25°C to heat the cell (Lutwak *et al.* 2004). The heat conduction has been reduced to 13 μW K^{-1} by suspending the physics package on a thin web of strained polyimide support tethers. Electrically conductive leads composed of gold and platinum are deposited on top with a titanium adhesive layer to supply the heating current.

Convection is minimized by vacuum packaging. Immersion has been suggested as a lower-cost alternative in some materials of low thermal conductivity. A different approach for a MEMS clock physics package has been proposed by Youngner *et al.* (2005), and also includes a thermal suspension system (**Figure 27**).

One of the major challenges in the thermal management is the requirement to maintain temperature control better than 100 mK over a wide range of ambient temperatures (−40 to +70°C) with a small power budget. This is further complicated by the heat dissipated by the VCSEL (Kitching *et al.* 2004). One solution can be a MEMS thermal conduction switch that can change the thermal resistance between the physics package and the environment (Laws *et al.* 2005). A schematic of a physics package that implements such a thermal switch is shown in **Figure 28**.

3.18.3 Performance

3.18.3.1 Introduction

The long-term goal for most CSAC projects, set by DARPA, is to reach a frequency instability below 10^{-11} at 1 h of integration in a 1 cm^3 package consuming <30 mW of power. Therefore, most CSACs have been characterized mostly by these three specifications: frequency stability at times <1 h, size, and power consumption. Nevertheless, for many applications, other specifications, such as frequency stability at times longer than a week, accuracy, acceleration sensitivity, magnetic field sensitivity, lifetime, no unlocks for long durations, might be at least as important. At the same time, which specifications will be set for the CSAC will strongly depend on the application. In the following sections, we nevertheless focus mostly on the three specifications set by DARPA.

3.18.3.2 Frequency Stability

3.18.3.2.1 Introduction

Atomic clocks are often characterized by their Allan deviation $\sigma_y(\tau)$ (for a review, see Allan 1987), which is a measure of the fractional frequency stability as a function of averaging time τ. Over short averaging times, the stability of many atomic clocks is characterized by white frequency noise. For this type of noise, the Allan deviation decreases as $\tau^{-1/2}$ (**Figure 29**, light gray dots) and can be expressed in

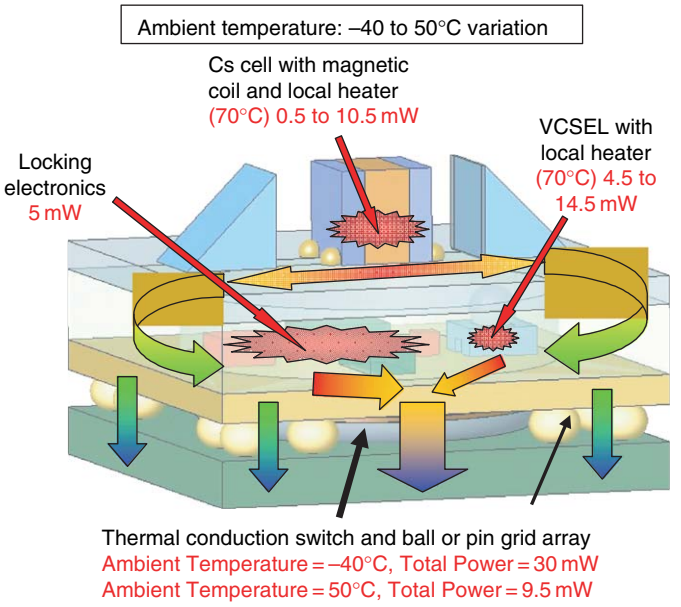

Figure 28 Illustration of heat transfer path through a chip-scale atomic clock (CSAC) design using a thermal conduction switch to reduce overall power consumption. Heat rates are estimated to meet clock power requirements of <30 mW. Radiation and conduction/convection are ignored. (Courtesy of V. Bright.)

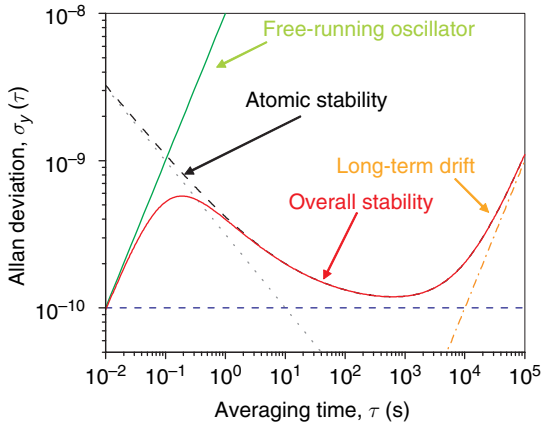

Figure 29 Fractional frequency stability: free-running oscillator (dashed green line), supported by the atoms (dashed black line), when locked to the atomic resonance. The atomic stability here is determined by white frequency noise (light gray dots), flicker noise floor (dashed blue dots), and frequency drift (orange dashes).

terms of signal-to-noise ratio S_{CPT}/N and resonance quality factor Q (Vanier 2001)

$$\sigma_y(\tau) = \frac{\chi}{QS_{\mathrm{CPT}}/N}\frac{1}{\sqrt{\tau}} \qquad [4]$$

Here, $Q = \nu_0/\Delta\nu_{\mathrm{CPT}}$ is defined as the ratio of resonance frequency over linewidth and χ is a parameter of the order of unity related to the method of interrogation. It is desirable to have a high signal-to-noise ratio and a narrow linewidth in order to reach good frequency stability. The fractional frequency stability of these clocks improves over measurement time until it reaches the flicker noise floor, $\sigma_y(\tau) \propto \mathrm{const}$ (**Figure 29**, blue dashes), or until the frequency starts drifting, $\sigma_y(\tau) \propto \tau$ (dashed orange dots). These drifts are usually caused by environmental variations that change the clock frequency over time. A typical Allan deviation determined by the atoms is shown in **Figure 29** (black dashes). In a passive CPT clock, an LO generates a signal close to the clock frequency. The physics package uses this signal as its input to create an output signal that carries information about the frequency difference between the LO frequency and the atomic frequency. This information can then be used to tune the LO frequency so that it always coincides with the one of the atoms (for a review on CPT clocks, see, e.g., Vanier 2005). Thus, the stability of the clock is determined by the LO stability at times shorter than the inverse loop bandwidth, and by the atoms at longer times (**Figure 29**, red line).

For a CSAC, the frequency stability can be predicted in the photon shot-noise limit to be on the order of $\sim 2 \times 10^{-13}/\tau^{1/2}$ for a 1-mm^3 cell and

typical experimental parameters (Vanier *et al.* 2003d). Unfortunately, in an experimental setup, this stability has not been reached, since other noise sources are dominant and the signals are small. For VCSELs, laser amplitude noise and laser frequency noise play a major role. Frequency noise gets converted into amplitude fluctuations through the atomic resonances (Camparo and Buell 1997, Coffer *et al.* 2002). In most CSACs, the VCSEL is locked to the center of a resonance, so that this effect is drastically reduced in comparison to when locked to the side of the resonance (Kitching *et al.* 2001b), but it nevertheless remains significant. Here it can be advantageous to use a high buffer gas pressure where the optical lines are very broad and have a shallow FM–AM conversion slope (Camparo 1998a). Furthermore, in some VCSELs, mode-competition noise (Kaiser *et al.* 2002, Mukaihara *et al.* 1995b) between different polarization modes causes large contributions to the noise on the detector, especially when transformed into amplitude noise by a polarizer. All of these noise sources reduce the frequency stability, so that the best short-term stability reported to date in a CSAC physics package is $4 \times 10^{-11}/\tau^{1/2}$ in a 1-mm^3 cell (Knappe *et al.* 2005b).

Besides the effects that limit the short-term stability of the CSAC, frequency shifts and line shape asymmetries can cause major problems at longer averaging times. They can result from magnetic fields, buffer gas pressure, temperature, light shifts, acceleration, or RF power. It is therefore critical to control these parameters carefully or to find a measurement scheme that reduces the frequency sensitivity to changes in these parameters.

While for many primary frequency standards the absolute clock frequency is critical (Quinn 2005), for most applications of chip-scale clocks this value is of minor interest, as long as it can be calibrated. Nevertheless, it is of great importance that the clock frequency does not change over time, i.e., it needs good stability, but not necessarily good accuracy.

3.18.3.2.2 Short-term frequency stability

The first CSAC physics package demonstrated used the D_2 line of cesium (Knappe *et al.* 2004b). Its short-term frequency stability of $6 \times 10^{-10}/\tau^{1/2}$ was limited by a CPT resonance contrast of 0.9% and a CPT linewidth of 7 kHz. The package had a volume of 9.5 mm^3 and required 75 mW of power at an external baseplate temperature of 46°C. The power budget did not include heating of the laser. A plot of the Allan deviation for this CSAC physics package is shown in **Figure 30** (black squares).

It has been shown for cesium (Lutwak *et al.* 2003) as well as for rubidium (Stähler *et al.* 2002) that the CPT resonance contrast is much higher on the D_1 line than on the D_2 line. The first CSAC physics package using the D_1 line of ^{87}Rb was demonstrated shortly after (Knappe *et al.* 2005b). The short-term frequency instability was $4 \times 10^{-11}/\tau^{1/2}$, the best short-term frequency instability reported so far for this simplest type of CPT CSAC with a 1-mm^3 vapor cell. A plot of the Allan deviation can be found in **Figure 30** (red dots). The improvement can be attributed to a higher CPT resonance contrast of 4.6% as well as to fewer Zeeman sublevels in ^{87}Rb when compared to Cs. Finally, a CSAC physics package using the D_1 line of cesium has also been presented with a short-term frequency instability of $1.4 \times 10^{-10}/\tau^{1/2}$ (Lutwak *et al.* 2005).

When the physics package is integrated with a miniature LO, the performance of the CSAC can change dramatically. In order to reach large tuning ranges, the tunability of the LOs often needs to be around 1 MHz V^{-1}, making them very sensitive to voltage fluctuations on the tuning input. Also, most small low-power LOs have phase noise around −40 dBc at 100 Hz at best, which puts tight constraints on the control system. Nevertheless, short-term stabilities of $2.4 \times 10^{-10}/\tau^{1/2}$ have been demonstrated with an integrated low-power LO physics package design (Brannon

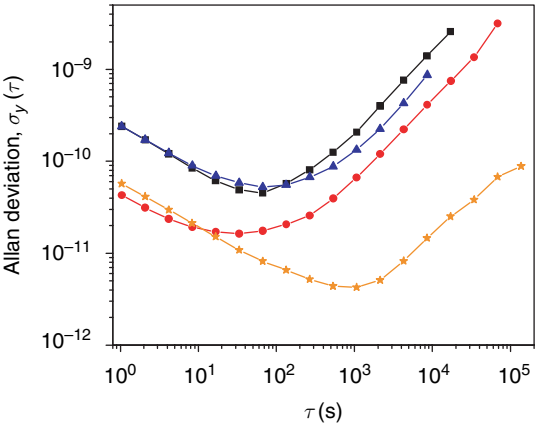

Figure 30 Fractional frequency stability as a function of averaging time for a Cs D_2 chip-scale atomic clock (CSAC) physics package (black squares), ^{87}Rb D_1 CSAC physics package (red dots), CSAC physics package with integrated local oscillator (LO) (blue triangles), and 1-mm^3 ^{87}Rb vapor cell (orange stars).

et al. 2006b) (**Figure 30**, blue triangles). Disciplining the VCO by the use of small control electronics can be challenging, as higher servo bandwidths are desired when compared to oscillators with better phase noise. This is worsened by the fact that several servo loops have to be controlled simultaneously. It has been shown that an integrated CSAC (matchbox size) can nevertheless support a fractional frequency stability of $6 \times 10^{-10}/\tau^{1/2}$ (Lutwak *et al.* 2005).

3.18.3.2.3 Long-term frequency stability

Until now, we have discussed only frequency stability for integration times <100 s. **Figure 30** shows that frequency drifts determine the stability of these CSACs at integration times >100–1000 s. Most drift is directly or indirectly caused by temperature fluctuations. The stabilities presented here were measured in a laboratory environment. It has been shown that under such conditions, MEMS cells can support frequency stabilities below 1×10^{-11} at 1 h and below 1×10^{-10} at one day (Knappe *et al.* 2005a) (see orange stars in **Figure 30**). Nevertheless, it can be expected that in a real-world environment, the frequency stabilities of these CSACs will degrade severely if the shifts are not addressed. In the following, we discuss different parameters that influence the long-term stability.

3.18.3.2.3.(i) Buffer gas pressure

As described in Section 3.18.1.4, a buffer gas is used to narrow the CPT linewidth. At the same time it shifts the hyperfine frequency. This shift is temperature-dependent. A standard way to reduce the temperature coefficient of the clock frequency in commercial optically pumped devices is to use combinations of buffer gases that shift in opposite directions (Arditi and Carver 1961, Vanier *et al.* 1982). The same technique works well for CPT clocks (Knappe *et al.* 2001). However, in small devices, the residual temperature coefficient is proportional to the total buffer gas pressure. Because the pressure in most approaches is nearly an order of magnitude higher than in centimeter-sized devices, coefficients worsen accordingly. Furthermore, the buffer gas combinations are harder to control in microfabricated cells, because the anodic bonding process with its high temperatures can create residual gases inside the cell. Therefore, the cell temperature has to be stabilized precisely. It has been shown, however, that the temperature stability of the cell (as well as the VCSEL) can be improved when direct absorption signals from the atoms are used to determine the temperatures, instead of temperature sensors in the vicinity of the cell (or VCSEL) (Gerginov *et al.* 2006b).

3.18.3.2.3.(ii) Light shifts

Compared to optically pumped clocks, light shifts can be reduced in CPT, because of the ability to create a more symmetric system (Levi *et al.* 2000, Orriols 1979, Vanier *et al.* 1998). Nevertheless, the frequency stability of most CSACs is still limited by light shifts at long averaging periods.

VCSELs have frequency tunabilities of roughly 300 GHz K^{-1} (see Section 3.18.3.2.3). Therefore, it is essential to stabilize their temperatures precisely. This is usually done with small temperature sensors, e.g., thermistors close to the VCSEL die. When temperature gradients between the sensor and the die change the VCSEL junction temperature, for example, due to ambient temperature fluctuations, its output frequency changes. The frequency servo then changes the DC current of VCSEL to pull it back onto resonance, but the output power as well as the VCSEL impedance, that is, modulation index of the light field, is usually different (Gerginov *et al.* 2006b). This in turn generally changes the clock frequency through altered light shifts (Arditi and Carver 1961, Barrat and Cohen-Tannoudji 1961, Mathur *et al.* 1968). It has been shown in a large cell (Levi *et al.* 2000, Vanier *et al.* 1999, Zhu and Cutler 2000, 2001) as well as in a CSAC (Gerginov *et al.* 2006b) that when the right RF modulation index is chosen, the total light shift from the laser carrier and all other sidebands vanishes. A similar technique has been implemented in a microwave clock as well (Affolderbach *et al.* 2006). Furthermore, an additional servo loop can be used to lock the RF power to this point, where no light shifts are present (Shah *et al.* 2006a).

3.18.3.2.3.(iii) Other frequency shifts

The field of MEMS clocks is very young when compared to that of lamp-pumped Rb standards. The use of new materials and components raises many uncertainties onto the performance of these new devices. Careful characterization and engineering over the coming years will be required to turn the current prototypes into reliable off-the shelf devices. In the following, a few of these parameters are summarized.

An important frequency shift is the RF output power of the LO. In an in-field environment where temperatures and coupling to metal objects can change dramatically, the RF power of the VCO is difficult to control. The clock frequency depends critically on the

power distributed over all modulation sidebands through light shifts. The modulation index therefore needs to be stabilized. Two methods have been demonstrated to do this. In a CSAC, the RF power can be locked to the point where the power in the first-order sidebands is maximized (Gerginov *et al.* 2006b). In a table-top CPT setup, the RF power is locked to the point where the total light shift vanishes (Shah *et al.* 2006a). Furthermore, the slow modulation of the LO frequency used for phase-sensitive detection of the CPT resonance can lead to shifts in the clock frequency (Phillips *et al.* 2006).

As mentioned in Section 3.18.2.2.6, the clock frequency is shifted as a function of total magnetic field. At the time of writing (2006), no measurements that characterize the residual shifts that occur after packaging and shielding have been published.

Since MEMS clocks are supposed to work in portable devices, acceleration insensitivity is of importance, and CSACs have not yet been characterized in this way. Nevertheless, two LOs have been specified with 0.2–0.3 ppm g^{-1} at 10 Hz (Brannon *et al.* 2006b) for these clocks.

Furthermore, in optically pumped clocks with their glass-blown vapor cells, diffusion of gases such as helium through the glass walls can cause problems (Bloch *et al.* 2000, Camparo *et al.* 2005). Chip-scale cells have not been characterized in this respect. But thin glass windows and new bonding mechanisms can be of concern. And finally, the reliability of the VCSELs with unknown behaviors in CSACs due to aging, sparks, radiation, etc., is yet to be determined. Nevertheless, initial performance results are encouraging, given the very short development time and the lack of any serious engineering.

3.18.3.3 Power Consumption

The power consumed by the first CSAC physics packages, which had essentially no thermal shielding, was 200 mW (Knappe *et al.* 2004b, 2005b). Nevertheless, their thermal properties have been modeled and characterized (Kitching *et al.* 2004). As discussed in Section 3.18.2.5, the main portion of the power was expended in heating the cell and the VCSEL. Therefore, it can be favorable to use cesium rather than rubidium, because of a higher vapor pressure. It has been convincingly demonstrated that it is possible to reduce heat conduction to below 13 μW K^{-1} in a CSAC physics package and therefore to heat a CSAC cell of volume 8.5 mm^3 to 75°C at an ambient temperature of 25°C with only ~6 mW of power (Lutwak *et al.* 2004). Since Rb has a slightly lower vapor pressure, with the same setup, it would require ~8.5 mW to reach a similar density at 90°C.

As discussed in Section 3.18.2.3, a VCO at 3.417 GHz is required for ^{87}Rb with an output power of at least −6 dBm and at 4.596 GHz for Cs with an output power of ~0 dBm. Two of these have been successfully demonstrated, requiring 2.1 mW (Brannon *et al.* 2006a) and 7.6–10 mW (Römisch and Lutwak 2006) for ^{87}Rb and Cs, respectively.

Control electronics have been developed using microcontrollers, resulting in packages around 10 cm^3 in size (see Section 3.18.2.4). For these, power budgets below 30 mW have been reported (Lutwak *et al.* 2005). For a complete miniature atomic clock package, including three such components, a total power budget of 108 mW was quoted (Lutwak *et al.* 2005). This included a commercial 4.6-GHz VCO. When this is replaced by one of the small low-power VCOs described here, the power budget is expected to be reduced further.

Finally, if an output frequency of 10 MHz is required, the odd output frequency in the gigahertz range has to be converted down. This can be done either by phase-locking a higher-power microwave VCO to a 10-MHz VCO (similar to **Figure 25**) or by adding an external frequency divider. The latter could consist of a fractional-*N* divider locked to a TCXO, for example. Such a device, as depicted in **Figure 31**, has been built on the same footprint as the

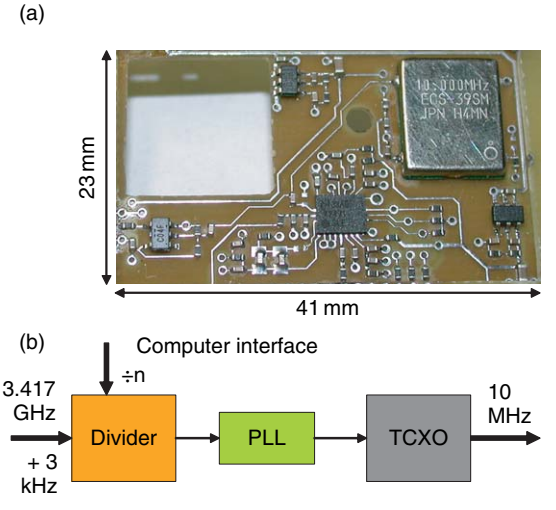

Figure 31 Photograph (a) and schematic (b) of a frequency divider for chip-scale atomic clock (CSAC). The fractional-*n* divider chip is programmed to divide 3.417 GHz down to 10 MHz. The output signal is then phase-locked to a 10-MHz temperature-compensated quartz crystal oscillators (TCXO).

NIST MEMS clock and consumes <30 mW of power (Waltman 2006). The TCXO acts as a cleanup oscillator that filters the modulation sidebands off the signal and reduces the phase noise at higher frequencies.

3.18.3.4 Size

The smallest CSAC physics package so far that consists of VCSEL, optics, cell, and photodiode has been demonstrated by Lutwak *et al.* (2005). It has a volume of 10 mm^3 without packaging. A picture is shown in **Figure 26**. The VCSEL is surrounded by a narrowband photodetector grown on the same substrate. After the diverging beam from the laser passes is attenuated and circularly polarized, it passes through the cesium vapor cell. Then it is retroreflected back through the cell onto the photodetector surrounding the VCSEL. The temperatures of the VCSEL and detector are stabilized together, so that their passbands are tuned simultaneously. When thermal packaging is included, it has a volume of ~1 cm^3. The smallest LO demonstrated to work with a CSAC physics package has a volume of ~0.15 cm^3 (Brannon *et al.* 2006a).

Finally, when integrating the control electronics with physics package and LO, a total volume of 10 cm^3 has been demonstrated (Lutwak *et al.* 2005). While this size is comparable to that of the smallest CPT vapor cell clock based on conventional technology (Vanier *et al.* 2004, 2005), its power is reduced by a factor of 5. With the CSAC technology demonstrated so far it is possible to reduce the volume of the control electronics to below 0.5 cm^3, allowing the CSACs to have volumes of around 1 cm^3.

3.18.4 Advanced Techniques

3.18.4.1 Introduction

Until now, we have mainly discussed the simplest approach to a CSAC: one VCSEL, one beam, one cell, and one photodetector, all in a straight line. The CPT resonance excited in this way couples the $m_F = 0$ ground states to either the $m_F = +1$ or the $m_F = -1$ excited state with circularly polarized light. The short-term performance of the CPT clock can then be characterized by the resonance contrast, defined as the amplitude of the CPT resonance over the background, the resonance width, and the noise. The performance at longer times is determined mostly by frequency shifts induced through time-dependent changes of external parameters. The progress of the CSAC project has triggered various new approaches that can potentially improve the clock performance. In the following section some of these more advanced techniques are discussed.

3.18.4.2 Resonance Contrast

It has been mentioned earlier that the resonance contrast (as well as the CPT width) is more favorable on the D_1 line as compared to the D_2 line. This has been experimentally (and theoretically) demonstrated for rubidium (Stähler *et al.* 2002) as well as for cesium (Lutwak *et al.* 2003). However, when using circularly polarized light on the D_1 line, a new problem arises due to the existence of a second dark state, the so-called stretched state or incoherent trapping state $|S_{1/2}: F = 2I + 1, m_F = \pm F\rangle$. This open system has been successfully modeled theoretically through a system with four levels, or with three levels and a trap (Vanier *et al.* 2003b). **Figure 32(a)** shows the level structure of the D_1 line of ^{87}Rb as an example. As the light intensity is increased, more atoms are pumped into the CPT state, but at the same time, more atoms are also lost into the stretched state, and the fraction of the atoms in the dark state drops again. **Figure 33(a)** shows the CPT absorption contrast (CPT amplitude divided by Doppler absorption) as a function of light intensity for a closed system (black) and a more realistic open system (red). **Figure 33(b)** and **33(c)** shows the CPT resonance width and the CPT resonance amplitude calculated for the same two systems, respectively (Shah *et al.* 2004).

A few different methods have been demonstrated in the past years to circumvent this problem of pumping. The simplest way would be to use linearly polarized light, as a combination of right-hand and left-hand circularly polarized light simultaneously. However, it has been shown (Wynands and Nagel 1999) that this forms a closed-loop system (Korsunsky *et al.* 1999, Kosachiov *et al.* 1992, Lukin *et al.* 1999, Shahriar and Hemmer 1990) on the 0–0 levels, which destructively interferes. A coherent dark state can be formed only in atoms that can couple simultaneously to more than one excited state from one pair of ground states (as in **Figure 32(b)**), if the following two conditions are fulfilled (Buckle *et al.* 1986, Kosachiov *et al.* 1991, 1992, Maichen *et al.* 1995, 1996):

$$\frac{g_1}{g_2} = \frac{g_3}{g_4} \quad \text{and} \quad \varphi_1 + \varphi_2 + \varphi_3 + \varphi_4 = 0 \qquad [5]$$

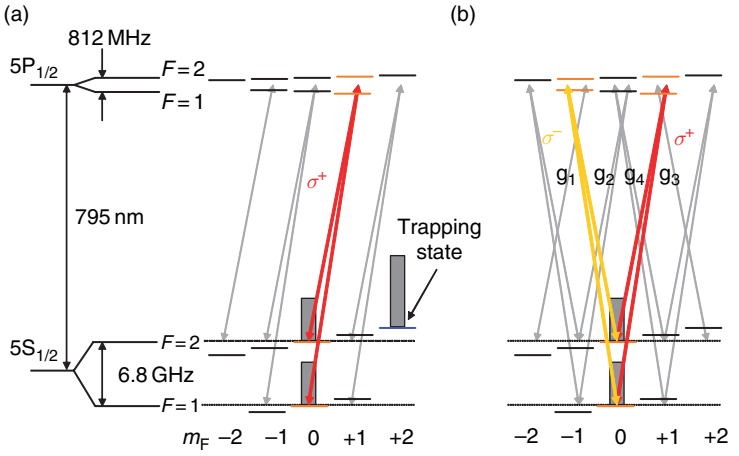

Figure 32 Atomic levels of the ^{87}Rb D_1 line. The levels involved in the coherent population trapping (CPT) coherence are shown in orange. (a) In this open system the circularly polarized light fields (red) optically pump atoms into the trapping state shown in blue. The gray columns indicate the atomic population distribution. (b) Adding an additional pair of light fields (yellow) with opposite circular polarization can eliminate the trapping state. The four optical transitions are coupled by the light fields E_j (with phases φ_j) and Rabi frequencies $g_j, j \in \{1\text{–}4\}$.

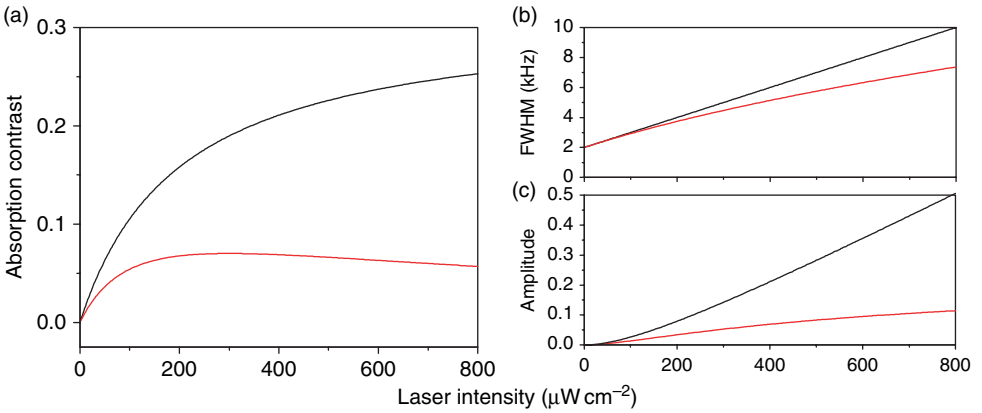

Figure 33 Calculations for a symmetric open (red) and a closed (black) Λ-system. Coherent population trapping (CPT) resonance absorption (a) contrast, (b) width, and (c) amplitude are plotted as a function of laser intensity. (Source: Shah V, Knappe S, Hollberg L, Kitching J 2004 On open Λ systems and the stability of coherent population trapping devices. Unpublished.)

Here, g_j is the Rabi frequency and φ_j is the phase associated with the jth light field, $j \in \{1\text{–}4\}$, as shown in **Figure 32(b)**. For linearly polarized light, on the two $m_F = 0$ ground-state levels $g_1/g_2 = -g_3/g_4$ so that no CPT resonance can be observed.

It has been shown that right-hand and left-hand circularly polarized light can nevertheless be used simultaneously to couple the same pair of ground states, if one beam is delayed by half a microwave wavelength (Affolderbach *et al.* 2002, Alzetta *et al.* 1999). This shifts the relative phase of one beam by π with respect to the other. Jau *et al.* (2004a) have nicely demonstrated that this can be used to increase the contrast of the CPT resonance by eliminating the incoherent trapping state. This transforms the open system back to a closed system (see **Figure 33**). A similar way to create this phase delay is by reflecting the circularly polarized beam back onto itself with opposite circular polarization and by placing the cell a quarter of a microwave wavelength away from the mirror (Affolderbach *et al.* 2002, Alzetta *et al.* 1999, Kargapoltsev *et al.* 2004, Taichenachev *et al.* 2004). It is difficult to integrate either of these methods into a small CSAC due to the delay of half a microwave

wavelength, which is 2 cm for ^{87}Rb. The trapping of atoms in the stretched state can also be circumvented by using two phase-locked single-frequency laser beams with linear orthogonal polarization separated in frequency by the ground-state splitting frequency (Nagel 1999, Zanon *et al.* 2005), but this is not convenient for a compact portable device. One way to implement these ideas into a CSAC physics package has been demonstrated by Shah *et al.* (2006b). They used two VCSEL dies with orthogonal polarizations. The linear light fields were converted into orthogonally circularly polarized fields before entering a microfabricated ^{87}Rb vapor cell. Instead of delaying one optical beam, the microwave phase was delayed by π.

The goal of these very similar techniques is to enhance the resonance contrast and therefore improve the frequency stability of the clock. However, in most cases, the clock is operated at a light intensity where the linewidth is roughly twice the zero-intensity linewidth only (for **Figure 33** this roughly correspond to $200\,\mu W\,cm^{-2}$). Since the linewidths for the open system and the closed system are roughly the same, it would correspond to an increase in CPT resonance amplitude roughly by a factor of 2. Assuming that the noise remains the same, it is questionable whether the more complicated setup justifies an increase in the frequency stability by a factor of 2 (Shah *et al.* 2006b), unless there is another advantage gained at the same time. Especially so, if the CPT amplitude can also be increased by a higher atomic density, until spin-exchange broadening counteracts the gain in frequency stability.

A different way to increase the contrast of CPT resonances has been investigated by Zhu (2003). Here, only a small amount of opposite circularly polarized light is added (without phase delay). While the medium becomes more transparent under CPT conditions for the strong polarization component, the weak one experiences enhanced absorption. Both components acquire opposite phase shifts. A polarization analyzer system is then adjusted such that only a small fraction of the strong polarization component is transmitted, and the relative phase delay in both polarization components is optimized to give a symmetric CPT signal with contrasts above 20%.

When limited to one laser, parallel linear polarizations can be used to couple a coherence between the ground states $|F,\ m_F = \pm 1\rangle$ and $|F+1,\ m_F = \Upsilon 1\rangle$ (Kazakov *et al.* 2005b, Knappe *et al.* 1999, Taichenachev *et al.* 2005, Zhu 2004). These resonances are also insensitive to magnetic fields in first order, but split at higher fields due to the contribution of the nuclear magnetic moment. Since this is a coherence between two states with $\Delta m_F = \pm 2$, it is suppressed at higher buffer gas pressures when the excited-state hyperfine structure is unresolved (Wynands and Nagel 1999).

A different way to accumulate atomic population in the 0–0 states has been demonstrated for optically pumped clocks (Bhaskar 1995) by using a series of microwave pulses. In a similar manner, a population can be optically pumped into one of the $m_F = 0$ states using π-polarized light that is resonant with the transition $|F\rangle \rightarrow |F\rangle$ (Kazakov *et al.* 2005a, Shah *et al.* 2004), where the transition between the $m_F = 0$ states is forbidden. The atoms will then accumulate in this state, while they are probed by circularly polarized light under CPT conditions. This technique also requires the excited-state hyperfine structure to be resolved for efficient pumping and two light fields from orthogonal directions.

3.18.4.3 Buffer Gas

We have seen in Section 3.18.2.3 that the CPT linewidth has a minimum at an optimum buffer gas pressure. From **Figure 5** it can be seen that for a 1-mm cell of ^{87}Rb and nitrogen, this optimum pressure is several atmospheres. At the same time, the buffer gas broadens the optical $S \rightarrow P$ transition. For a frequency-modulated light field, the CPT contrast dramatically reduces when this optical width approaches the ground-state splitting (Arimondo 1996a, Nikonov *et al.* 1994, Post *et al.* 2005), because the carrier and second-order light fields become resonant. They can cause single-photon transitions pumping atoms out of the dark state. They fulfill the dark-state condition as well, but their relative phase differs from the phase between the first-order sidebands. CPT resonances have nevertheless been observed in small cells with several atmospheres of buffer gas, where the ground states were unresolved, when the laser was amplitude-modulated with a $LiNbO_3$ Mach–Zehnder modulator (Jau *et al.* 2004a, Post *et al.* 2005). In most CSACs though, the buffer gas pressure is chosen such that the ground-state hyperfine structure is still resolved, and the linewidth is typically limited by wall collisions.

In table-top systems, antirelaxation wall-coated cells have proven to exhibit extremely narrow linewidths (Bouchiat and Brossel 1966, Robinson *et al.* 1958). Alkenes (C_nH_{2n+2}), such as tetracontane or paraflint, as well as silanes gave good results for Rb

and Cs Zeeman and hyperfine transitions (Budker *et al.* 2005, Frueholz *et al.* 1983, Risley *et al.* 1980, Robinson and Johnson 1982). However, accommodation coefficients (a measure of the average number of wall collisions before decoherence) for hyperfine transitions are found to be worse than for Zeeman transitions by about an order of magnitude (Robinson and Johnson 1982). Nevertheless, it could be advantageous to use wall coatings for small clocks, possibly in combination with low pressures of buffer gases. Advantages could include a reduced temperature dependence (Section 3.18.3.2.3.1), narrower linewidth, lower operating temperatures, or resolved excited-state hyperfine structure. The latter could allow for other interrogation schemes that couple ground states with $\Delta m_F = \pm 2$ (Kazakov *et al.* 2005b, Knappe *et al.* 1999, Taichenachev *et al.* 2005, Zhu 2004), which are suppressed at higher buffer gas pressures (Wynands and Nagel 1999). Research is progressing in this area to find new wall-coating materials that are amenable to microfabrication of vapor cells and that can withstand higher bonding and operating temperatures.

3.18.4.4 Spin Exchange

As cell length decreases, the alkali vapor density usually increases to maintain sufficient absorption through the cell (typically ~50%). At these densities, another broadening mechanism starts to dominate the CPT linewidth, caused by collisions between alkali atoms (Happer 1972, Walker and Happer 1997), as mentioned in Section 3.18.1.3. These so-called spin-exchange collisions conserve the total angular momentum of the pair of alkali atoms. By pumping the atoms into the stretched state with maximum angular momentum, the linewidth of the microwave resonance can be dramatically reduced (Jau *et al.* 2003, 2004b). However, this resonance frequency is strongly dependent on the magnetic field ($21\,\mathrm{kHz}\,\mu\mathrm{T}^{-1}$ for ^{87}Rb and $25\,\mathrm{kHz}\,\mu\mathrm{T}^{-1}$ for Cs), which has to be precisely controlled (see Section 3.18.5.2).

3.18.4.5 Noise Suppression

Most of the noise on the CPT resonance is from the VCSEL through frequency and/or intensity fluctuations (see Section 3.18.2.2.2). When locked to the top of the atomic resonance line, these contributions can be comparable to that of the photon shot noise (Kitching *et al.* 2001c). Furthermore, polarization mode-competition noise can be severe for some VCSELs, but negligible for others. They can be converted into intensity fluctuations when using a polarizer. To reduce the influence of laser-induced noise, two laser beams can be passed through the same vapor cell, inhibiting the same laser noise but different CPT signals.

Gerginov *et al.* (2006a) demonstrated a simple setup in a microfabricated vapor cell of area $2\,\mathrm{mm} \times 1\,\mathrm{mm}$ using two parallel beams, one with circular polarization and another with linear polarization. For the reasons described in Section 3.18.4.2, only the circularly polarized beam causes a CPT resonance. Subtracting the two photodiode signals cancels most of the laser-induced noise, but leaves the full CPT signal. It does not cancel the shot noise, but rather doubles it, so this technique improves the clock stability only if dominated by laser noise, e.g., when locked to the side of the resonance line. Additional noise caused by the CPT resonance itself cannot be reduced in this setup.

Additional noise reduction might be possible, however, with a differential detection technique, where the two beams have orthogonal circular polarization and propagate parallelly through the same region of the cell (Rosenbluh *et al.* 2006) in a similar manner as described in Section 3.18.4.2. The relative phase delay between the two beams here is $\pi/2$, as compared to π previously. This causes the CPT resonance not to have an absorptive Lorentzian lineshape, but rather a combination of absorptive and dispersive Lorentzians. The CPT signal in both beams has an opposite sign for the dispersive part of the signal, so that the difference signal is dispersive in shape. Because the laser noise on both signals is similar, it cancels. A noise suppression of 20 dB has been measured in a table-top setup.

3.18.5 Other CSAC Approaches

3.18.5.1 Introduction

Until now we have primarily discussed passive CSACs based on locking a VCO to a CPT transmission signal. There has been a series of other approaches, of which a few are introduced in the following sections. Unfortunately, not much has been published on these.

3.18.5.2 End-State CSAC

It has been mentioned in Section 3.18.4.4 that microwave resonance broadening due to spin-exchange

collisions between the alkali atoms can be largely reduced when the atoms are pumped into the stretched state (Jau *et al.* 2004b). This can lead to much narrower resonance lines and better stability of CSACs. A gain in sensitivity can be achieved by increasing the cell temperature into a region where spin-exchange collisions usually dominate the linewidth broadening, e.g., high buffer gas pressures. In general, this method works with CPT and microwave interrogation, but for CPT, a second laser beam would be required for optical pumping. Therefore, the scheme was implemented using microwave interrogation (Jau *et al.* 2006).

Since the end-state resonance frequency is very sensitive to magnetic fields, the magnetic field has to be stabilized precisely. This can be done by measuring the Lamor frequency and implementing an additional servo to stabilize the magnetic field (Jau *et al.* 2006) or by alternating between the two opposite stretched states to find the unshifted mean frequency. Furthermore, by choosing the right laser detuning, light shifts have been reduced simultaneously (Jau *et al.* 2006). Potentially, better stabilities could also be reached in microwave-interrogated CSACs, because no high FM is required and therefore lower noise VCSELs might be used.

3.18.5.3 Nanomechanically Regulated CSAC

An RF-interrogated CSAC that uses a mechanical motion to modulate the magnetic field at the location of the ^{87}Rb atoms has been proposed. This oscillation can be induced by using micromechanical choppers that attenuate the magnetic field depending on their position, oscillating at 6.8 GHz, for example (Lee *et al.* 2004).

Even though coupling of alkali atoms to the mechanical oscillation of a MEMS structure has not been demonstrated at gigahertz frequencies yet, it has been shown that double-resonance transitions can occur in ^{87}Rb atoms inside a MEMS vapor cell by using a magnetic cantilever oscillating at 15 kHz (Wang *et al.* 2006).

3.18.5.4 CPT Maser

Under CPT conditions, a coherence is created between the two ground states, oscillating at the difference frequency between them. As a result, the amount of light absorbed by the alkali vapor decreases. At the same time the oscillating magnetization can be detected through stimulated emission in a cavity (Vanier *et al.* 1998). This will happen when a microwave cavity surrounding the cell is tuned to the same ground-state hyperfine frequency. This signal can be used to lock the LO, which generates the modulation on the laser, by synchronous detection (**Figure 34**). While laser noise is not transmitted directly to the microwave signal, a change in sideband intensities and detunings can nevertheless change the output frequency through variations of the ground-state coherence (Godone *et al.* 2000, Levi *et al.* 2000). Using a method similar to the simple CPT clock, the modulation index can be chosen such that the overall light shift is reduced (Vanier *et al.* 1999).

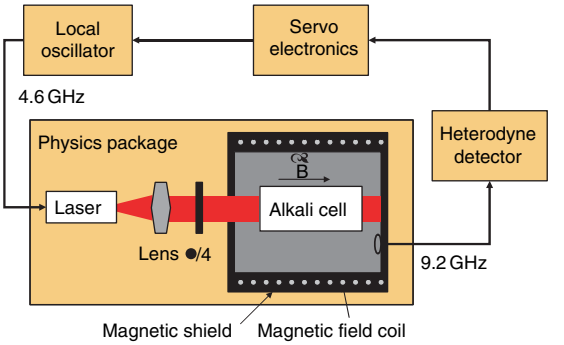

Figure 34 Conceptual setup of a coherent population trapping (CPT) maser.

Furthermore, effects such as cavity pulling, that is, detuning of the cavity with respect to the resonance and shifts due to finite microwave power and phase of the emitted field, can affect the frequency stability of the maser (Godone *et al.* 2000). Even though better stabilities can be potentially reached with a CPT maser (Vanier *et al.* 2003a), the size and the complication of the microwave cavity have prevented it from being used in chip-scale clocks.

3.18.5.5 Raman Oscillator

We have seen in Sections 3.18.1.3 and 3.18.1.4 that the ground-state coherence induced under CPT conditions can be detected in different ways: as a change in the transmission (or fluorescence) or through stimulated microwave emission. Yet another way of detecting the resonance is by detecting the light on a fast photodetector and by detecting the beat signal at the ground-state splitting frequency, e.g., 6.8 GHz for ^{87}Rb (Vukičević *et al.* 2000). No modulation of the VCSEL is necessary to detect this signal, since the second light field is created through stimulated

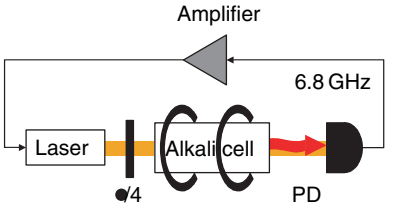

Figure 35 Closed-loop Raman oscillator. The 6.8-GHz signal is fed back to the injection current of the laser.

Raman scattering. However, the linewidth of this resonance can be fairly large in order to achieve enough Raman gain to detect the RF signal, and strong Stark shifts due to high laser intensities can limit the clock stability. This stimulated Raman oscillator design can provide better frequency insensitivity to accelerations when compared to the passive DC CPT clock, because the signal is derived from a purely atomic process.

To increase the signal-to-noise ratio, and allow for lower light intensity, a feedback loop can be included that feeds the amplified 6.8-GHz signal back onto the laser injection current (Vukičević *et al.* 2000) (**Figure 35**). The concept is similar to the one of optoelectronic oscillators as nonatomic systems (Yao and Maleki 1996). This setup requires a rigid structure and low loop delay times to reduce acceleration sensitivity, as changes in the RF phase are translated into frequency changes directly. Strekalov *et al.* (2006) demonstrated a fractional frequency instability of 5×10^{-10} at 1 s with this technique, when using a VCSEL and a 1-cm cell in zero magnetic field. One major problem with this setup is frequency tuning of the VCSEL as the RF power circulating in the loop varies.

Finally, a VCO can be inserted into the loop to modulate the laser (Vukičević *et al.* 2000). The 6.8-GHz signal detected on the photodetector can then be used to control the frequency of the VCO. Fractional frequency instabilities in the 10^{-11} range have been measured this way on the 0–0 transition in a centimeter-sized cell.

3.18.5.6 Ramsey-Type CPT Interrogation

In optically pumped clocks, narrower resonance lines can be achieved, when a (pulsed) Ramsey interrogation (Ramsey 1950, Thomas *et al.* 1982) is used rather than a continuous interrogation. Some of the first CPT resonances were measured in an atomic beam by using Ramsey-type interrogation. In a similar manner, a pulsed CPT clock has been proposed in a vapor cell (Zanon *et al.* 2005). The first pulse creates a ground-state coherence in the atoms followed by a precession in the dark. Coherence is then measured with a second pulse. One advantage of such a system is the reduction of power broadening. In the case of a pulsed technique, while continuous CPT resonances broaden linearly with light power, the width of the Ramsey fringes is given by the inverse time between pulses, e.g., the period during which the coherence precesses in the dark. Unfortunately, the decoherence time in a 1-mm cell is on the order of milliseconds.

3.18.5.7 N-Resonances

While CPT is a two-photon resonance, the so-called *N*-resonance is a three-photon process, which results in similar narrow lines (Phillips *et al.* 2005, Zibrov *et al.* 2005). **Figure 36(a)** shows a level diagram of this scheme. A two-photon resonance is created between the two ground states $|1\rangle$ and $|2\rangle$ by the two red-detuned light fields E_1 and E_2 if the Raman condition is fulfilled, i.e., the difference frequency between these two states is equal to the ground-state splitting frequency $\delta_R = \omega_1 - \omega_2 - \Delta_{HFS} = 0$. This condition is simultaneously probed by the field E_1 resonant with the transition $|2\rangle \rightarrow |3\rangle$. Off Raman resonance, E_1 pumps most of the atoms into the state $|1\rangle$. When tuned onto Raman resonance, however, atoms are pumped back into the state $|2\rangle$, increasing the absorption. This can be seen schematically in **Figure 36(b)**, where the transmission of E_1 is plotted as a function of Raman detuning. The experimental setup is fairly similar to the conventional CPT case with a laser modulated at the full hyperfine ground-state splitting frequency. The major difference is the use of a Fabry–Perot etalon to transmit only E_1 onto the detector in order to reach high resonance contrasts up to 30% (Phillips *et al.* 2005) (contrast is defined here as h_{Nres}/B_{GND}). It has been found that contrasts are higher on the D_2 line as compared to the D_1 line, the opposite of the case of CPT (Novikova *et al.* 2006a).

The shot noise in this system can be potentially lower than in the case of CPT, since the absorption is increased on resonance, and light shifts can be reduced in a way similar to that developed for CPT (Levi *et al.* 2000, Vanier *et al.* 1999, Zhu and Cutler 2000) by choosing a favorable modulation index (Novikova *et al.* 2006b).

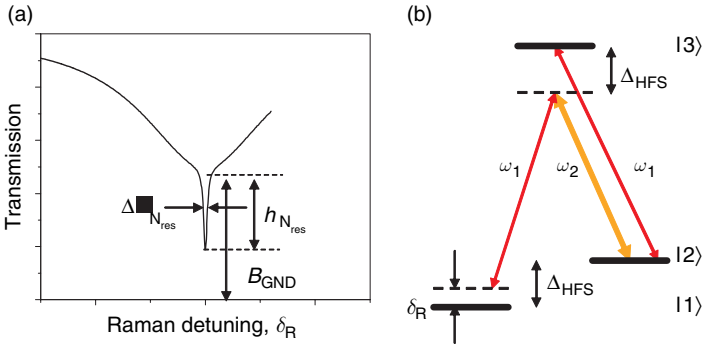

Figure 36 *N*-Resonance scheme. (a) Probe light transmission (ω_1) versus Raman detuning. (b) Three-level diagram showing probe (ω_1) and drive (ω_2) fields with their respective detunings.

3.18.5.8 Others

Recently, a miniature atomic clock was proposed in a solid-state system (White and Hajimiri 2005). The vanadium ion in magnesium oxide shows relatively narrow transitions around 1 MHz linewidth at 1.1 GHz. Such a solid-state atomic clock can be potentially very small and consumes very little power, with frequency instabilities around 10^{-8} to 10^{-9} at 1 s.

CPT spectroscopy is chosen as an all-optical interrogation technique in most approaches. One of the major arguments for this is the lack of a microwave cavity, which constrains the smallest possible size of the clock to a few centimeters. However, it has been shown that microwave resonances can nevertheless be seen in millimeter-sized cells without the use of a cavity, by the use of only small microwave power (Robinson 2003). **Figure 37(a)** shows a photograph of such a setup, where a 1-mm-diameter cell, made from an optical fiber with a CO_2 laser, is inside a copper microwave loop resonator. The magnetic RF field required to cause a clock transition can be roughly estimated to be 0.4 μT for a line of 3 kHz width. Creating this field in a current loop of 2 mm diameter would require roughly 0.6 mA of current, or 20 μW of power into 50 Ω. When using a tuned circuit cavity, the power could be reduced by the quality factor. Unloaded *Q*s around 200 seem possible with simple helical resonators like the one shown in **Figure 37(b)**. Even though these are only rough estimates, it can be seen that it does not necessarily require a high-*Q* large microwave cavity or a huge amount of power to excite a microwave clock resonance. One issue in such a lumped-parameter setup could arise from the stability of the microwave phase. The setup shown in **Figure 37** relies on the near-field and therefore has a decent confinement of the field over the dimension of the cell, but the setup nevertheless needs external shielding to ensure stability of the field.

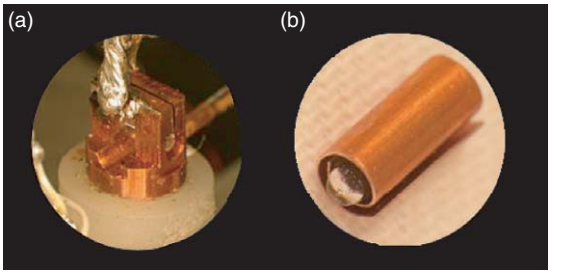

Figure 37 Photograph of a rubidium vapor cell of diameter 1 mm (a) inside a microwave loop and (b) inside a helical resonator (b) with a resonance frequency of 6.83 GHz and an unloaded *Q* of 200 (with and without cells).

3.18.6 Other MEMS Atomic Sensors

The technology discussed in this chapter is not limited to CSACs, but could rather open an avenue to a wide variety of chip-scale atomic sensors. Atomic and molecular transitions have proven useful in applications such as magnetometers (Allred *et al.* 2002, Bloom 1962), gyroscopes (Frazer 1963, Gustavson *et al.* 1997), accelerometers (Clauser 1988), gravimeters (Snadden *et al.* 1998), RF power meters (Camparo 1998b), and optical information storage (Fleischhauer and Lukin 2000, Liu *et al.* 2001). Furthermore, a stable frequency reference might be of value not only in the microwave regime, but in the optical regime as well. Stable optical wavelengths are used in devices such as interferometers, distance measurement, microscopy, and chemical trace detection. Combining wafer-level MEMS fabrication techniques with atomic stabilities and the ability to make absolute measurements without recalibration

could make these chip-scale atomic devices a viable technology for small, low-power applications.

Some chip-scale sensors based on these microfabrication techniques have already been demonstrated already. Two chip-scale atomic magnetometers (CSAMs) were constructed similar to the CASC physics package shown in **Figure 8**. One of them used CPT interrogation on a magnetically sensitive hyperfine transition (Schwindt *et al.* 2004) and reached a sensitivity of 50 pT $Hz^{-1/2}$ at 10 Hz in a 12-mm^3 package consuming 195 mW power. The so-called Mx magnetometer was based on the alignment of atoms in a magnetic field (Aleksandrov *et al.* 1995, Gröger *et al.* 2006). The precession frequency of the atoms was then used as a direct measure of the total magnetic field. The sensitivity was 6 pT $Hz^{-1/2}$ between 1 and 100 Hz bandwidth (Schwindt *et al.* 2006).

Furthermore, a microfabricated saturated absorption spectroscopy (Hänsch *et al.* 1971, Letokhov 1976) setup was demonstrated as an example of an optical wavelength reference with a MEMS cell and miniature optical components (**Figure 38**) (Knappe *et al.* 2006). It shows sub-Doppler linewidths on the order of 25 MHz at 795 nm optical wavelength and could be used to stabilize a diode laser to this transition. Frequency stabilities similar to those in table-top setups are expected.

These are just two examples of applications where microfabricated alkali cells are used in atomic sensors. While alkali atoms are often favored for spectroscopic applications, due to their relatively low vapor pressure and favorable transition frequencies, the technology introduced here is not necessarily limited to alkali atoms. We therefore expect chip-scale atomic devices to find applications in a wide variety of areas where size, cost, and power consumption need to be combined with high precision.

Acknowledgments

I thank John Kitching, Hugh Robinson, Zoya Popović, Leo Hollberg, and Robert Wynands for extensive reading of this manuscript as well as for their helpful and critical suggestions. Alan Brannon and Vishal Shah contributed through useful discussions.

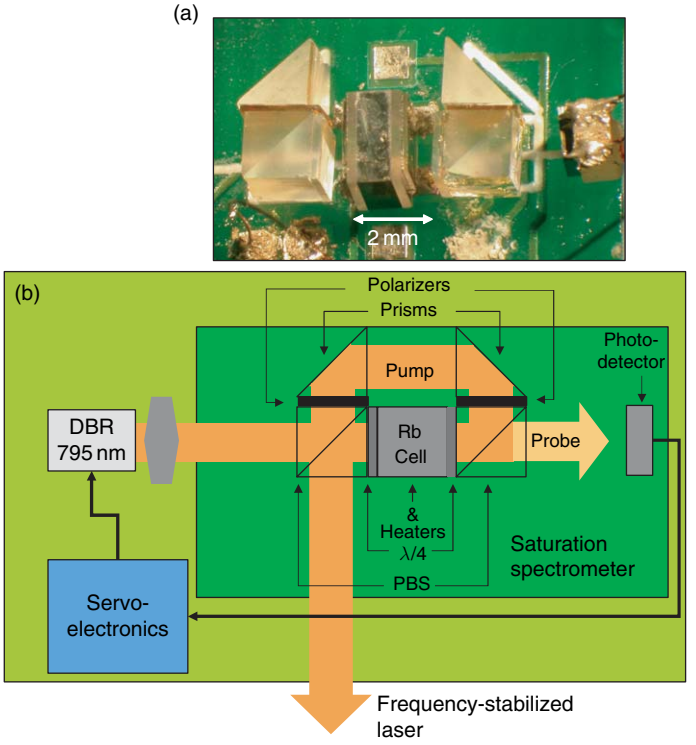

Figure 38 (a) Photograph of a microfabricated saturated absorption spectrometer setup. (b) Schematic of the microfabricated setup (dark green), which consists of a vapor cell with two heaters, two polarizing beamsplitters, two polarizers, two prisms, two quarter waveplates, and a photodetector. The light green shows a schematic of a stable wavelength reference including a laser locked to a stable sub-Doppler absorption resonance.

Commercial Rb standards: See, for example, Symmetricom X-72 Precision Rubidium Oscillator, Stanford Research Systems PRS10 Rubidium Frequency Standard, Accubeat AR-100B Rubidium Frequency Standard, Frequency Electronics FE-5658A Rubidium Atomic Frequency Standard, Temex LCR-900 Low Cost Rubidium; references are for technical clarity and do not imply endorsement by NIST.

Biography

Svenja Knappe received her diploma in Physics from the University of Bonn, Germany, in 1998. The topic for her diploma thesis was the investigation of single cesium atoms in a magneto-optical trap. She obtained her Ph.D. from the University of Bonn in 2001, with a thesis on "Dark resonance magnetometers and atomic clocks." Since 2001, she has been pursuing research in the Time and Frequency Division at NIST, Boulder, CO. Her research interests include precision laser spectroscopy, atomic clocks and atomic magnetometers, laser cooling, alkali vapor cell technology, applications of semiconductor lasers to problems in atomic physics and frequency control, and miniaturization of atomic spectroscopy.

3.19 Micro-Fuel Cells

Christopher Hebling, Lisbeth Rochlitz, and Thomas Aicher, Fraunhofer Institute for Solar Energy Systems, Freiburg, Germany

3.19.1 Introduction

Micro fuel cell systems have gained an increasing amount of attention as a potential power supply for portable and off-grid electronic applications due to some significant intrinsic advantages as compared with batteries. Depending on the application and the respective boundary conditions of its operation, small fuel cells can be considered both as a substitute and as a supplement to batteries. Fuel cell systems can be customized exactly according to the power demand of the respective electronic device and the geometrical design. The design of a micro fuel cell system has two degrees of freedom, power range and energy capacity, which means that both can be tailored exactly to the requirements of the various electronic devices and the operation time aimed at. However, many aspects, such as technical challenges due to the overall complexity of the fuel cell systems, cost, reliability, and safety issues, as well as the need for a different maintenance required by the customer as compared with that for batteries, should be addressed. In particular the management of the water generated by the electrochemical reaction is one of the major challenges for a reliable and long-term stable fuel cell system.

The advent of fuel cell systems took place when power sources with very sophisticated properties such as no toxic exhaust, low thermal signature, silent mode, variable power output, high energy density, instant refueling, and others were needed for very special applications (submarines, spacecrafts, and premium power). From the mid-1980s, the main emphasis was put on automotive and later on stationary applications with powerful statements about their upcoming market introduction and market penetration. After some disillusion in both areas, the portable and grid-independent fuel cell applications created fairly high expectations due to their intrinsic potential as an energy converter for battery-driven devices.

The major driver for fuel cells is the fact that improvements in battery technology have not kept pace with the growing power demands of particularly consumer data acquisition and communication devices, which again is a result of an increase in intelligence (computation), connectivity (band width), and the promotion of 'always on'. But as it seems now, niche applications with very special and well-defined boundary conditions, such as remote stationary systems (sensors, long-term data acquisition), decentralized microsystem networks, medical

appliances, security cameras, backup power and military systems, will be the first products that are powered by fuel cell systems either in addition to or instead of batteries.

The striking feature of small fuel cell systems is their inherent potential of achieving higher energy densities as compared to secondary batteries, which opens up the possibility to operate the respective devices much longer without recharging. This is due to the high energy density of a wide variety of hydrocarbons, alcohols, or just hydrogen, which can be used as fuel in fuel cell systems either directly or in conjunction with reformers. Unfortunately, in spite of the high specific energy of hydrogen ($32\,W\,h\,g^{-1}$), the use of pure hydrogen has hardly been pursued in micro fuel cell systems due to the challenges of hydrogen storage in high-pressure vessels or metal hydride containers. Liquid fuels such as alcohols are much easier to store and still have a very good energy density: $6.1\,W\,h\,g^{-1}$ ($4800\,W\,h\,l^{-1}$) and $8.6\,W\,h\,g^{-1}$ ($6800\,W\,h\,l^{-1}$) for methanol and ethanol, respectively (Coutanceau *et al.* 2006). Hydrocarbons with even higher energy densities (diesel and gasoline) have to undergo a reforming process in order to generate a hydrogen-rich reformate gas, which can be fed into a proton exchange membrane (PEM) fuel cell.

Due to the independence of the fuel cell system from the fuel container, the amount of energy can be tailored to a given application. In this context, the geometrical adaptability of the fuel cell form factor to a given cavity of the various devices is another important advantage. In addition to this, the system can be an integral part of the electronic device since only the container of fuel has to be refilled or replaced.

3.19.2 The Principles of Fuel Cell Systems

A fuel cell system is an electrochemical device that converts the chemical energy of a fuel directly into electrical and thermal energy with a high conversion efficiency. The fuel cell itself is the basic electrochemical unit where the electrochemical process takes place.

The chemical processes by which the electric current is generated are electrochemical, rather than thermochemical. Since no combustion reaction is involved, fuel cells do not produce any undesirable products normally associated with the oxidation of fossil fuels in conventional energy conversion systems. The fuel cell principle was first demonstrated by William Grove in 1839 but at that time, materials science was to no degree sufficiently developed to realize a functional device.

Generally, fuel cells are classified by their electrolyte: proton exchange membrane fuel cell (PEMFC), direct methanol fuel cell (DMFC) in which a polymer membrane serves as the electrolyte, alkaline fuel cell (AFC) in which the electrolyte is a base such as potassium hydroxide (KOH), phosphoric acid fuel cell (PAFC) in which the electrolyte is phosphoric acid (H_3PO_4), molten carbonate fuel cell (MCFC) in which molten carbonate $(Li,K)CO_3$ serves as the electrolyte transporting carbonate ions, and solid-oxide fuel cell (SOFC) in which the electrolyte is a solid such as yttria (Y_2O_3)-stabilized zirconia (ZrO_2) that transports oxygen ions (Hebling and Yu 2005).

The operation temperature is another way to classify fuel cells. Low-temperature fuel cells have an operation temperature lower than 100 °C. This type includes the PEMFC, the DMFC, and the AFC. The medium-temperature fuel cells have an operating temperature between 100 and 300 °C. This type includes the AFC and the PAFC. High-temperature fuel cells have an operating temperature between 600 and 1000 °C and include the MCFC and the SOFC. But with the advances in various fuel cells, there is a trend that the operating temperatures of fuel cell will be modified within given boundaries. For example, to avoid poisoning the PEMFC with CO, researchers are trying to raise the operating temperature above 100 °C. A higher operating temperature would also be advantageous for the DMFC. Meanwhile, researchers are making an effort to lower the operating temperature of SOFC to simplify the system.

Among the various types of fuel cells, the PEMFC and the DMFC are especially suitable for portable applications due to the low-temperature range and thus the quick-start capability. With the efforts made by research and development institutions and product manufacturers all over the world, micro fuel cells have without doubt a bright future.

On the technical side, the most important tasks are the increase of power and energy density while maintaining the reliability equivalent to the reliability of batteries. Micro fuel cells usually operate under ambient conditions. Reliable operation and simple system architecture are the contradictory requirements for these applications. Thus, to fulfill these requirements, the main technical challenges are to

realize a thermal and water management as passive as possible and to feed suitable reactants. These challenges can be solved for stationary fuel cell systems with active components such as compressors, heaters, cooler, or humidifier, whereas for portable systems only a minimum amount of peripheral elements should be used. The most important functions of the peripheral devices for portable fuel cell systems are to start, control, and stop the fuel supply for the fuel cell stack, to ensure an adequate hydrogen pressure or methanol feeding, and to provide the appropriate air supply for cathode feeding and system cooling. The necessary devices such as valves, pumps, fans, and pressure reducers have to be miniaturized in size and optimized in power consumption. Automatic operation of such a system requires several components that, in many cases, are not yet commercially available and thus need to be developed additionally. **Figure 1** shows a prototype of a 10 W PEM fuel cell system for a digital video recorder, which was developed from the Fraunhofer Alliance Micro Fuel Cells.

Finally, the interaction of all system components with respect to a high efficiency and reliable system performance needs to be controlled in a sophisticated way. This includes the total power management and voltage control with respect to the adaptation of the fuel cell system to the respective electronic device. Since the profile of the electrical load of electronic devices varies during operation, the fuel cell system must be accommodated to the needs of the respective system. Mobile phones, for example, need only some milliwatts in the stand-by mode, short pulses of higher power demand for contacting the next transmitter station, and several watts during the talk time again with additional pulses. Such profiles are a significant challenge for the system architecture of a fuel cell system. A hybrid system combining a fuel cell with a battery or with a super capacitor is considered as an ideal solution for such challenging boundary conditions. If the fuel cell system is to be used as a battery supplement in electronic consumer devices, the same safety standards as for batteries have to be obeyed. Even under abuse, no dangerous situation should occur, as is the case with the common types of batteries such as Ni/Cd, Ni/MH_x, or Li ion. Any kind of maintenance is excluded; however, recharging the fuel cell system by simply replacing an empty storage container by a full one is the change the customer has to accept in his behavior.

In a PEMFC, the reactant and the oxidant are fed into two compartments, which are separated by the membrane electrode assembly (MEA) where electricity is generated due to the electrochemical reaction. A fuel cell consists of reactant gas suppliers (gas diffusion layer), electrochemical active sites (MEA), and the fuel supplier out for the fuel cell (reformer or hydrogen storage). **Figure 2** shows the principle

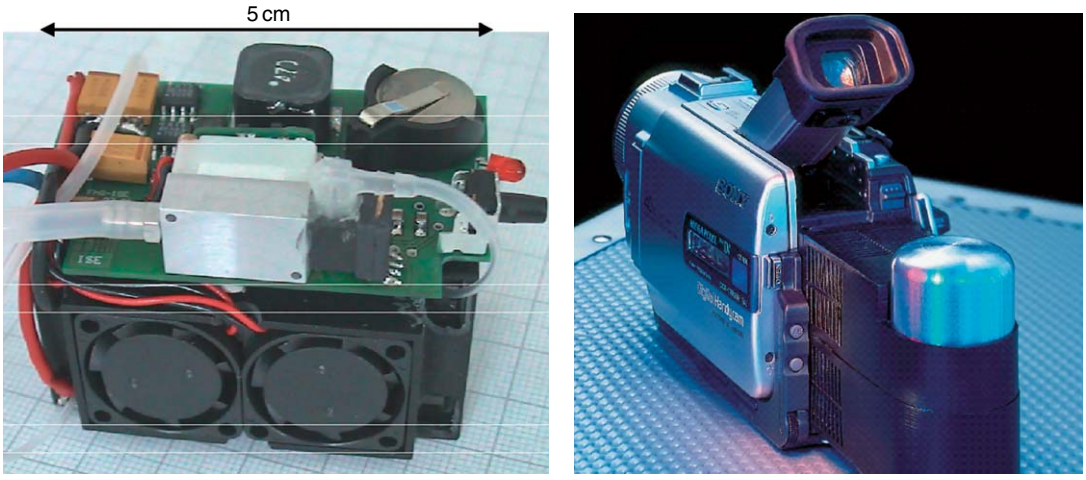

Figure 1 Miniaturized 10 W_p PEM fuel cell system (*left*) integrated into the battery housing of a digital camcorder (*right*). The hydrogen is stored in a metal hydride container located in the back of the fuel cell system. The peripheral components, for example, for microfluidic fuel processing (valves, fans, etc.), define the limits of conventional macroscopic production technology. Further miniaturization requires silicon-based microelectronic fabrication techniques such as microelectromechanical systems (MEMS) technology. (Source: Litterst C, Eccarius S, Hebling C, Zengerle R, Koltay P 2006 *J. Micromech. Microeng.* **16**, 248–53.)

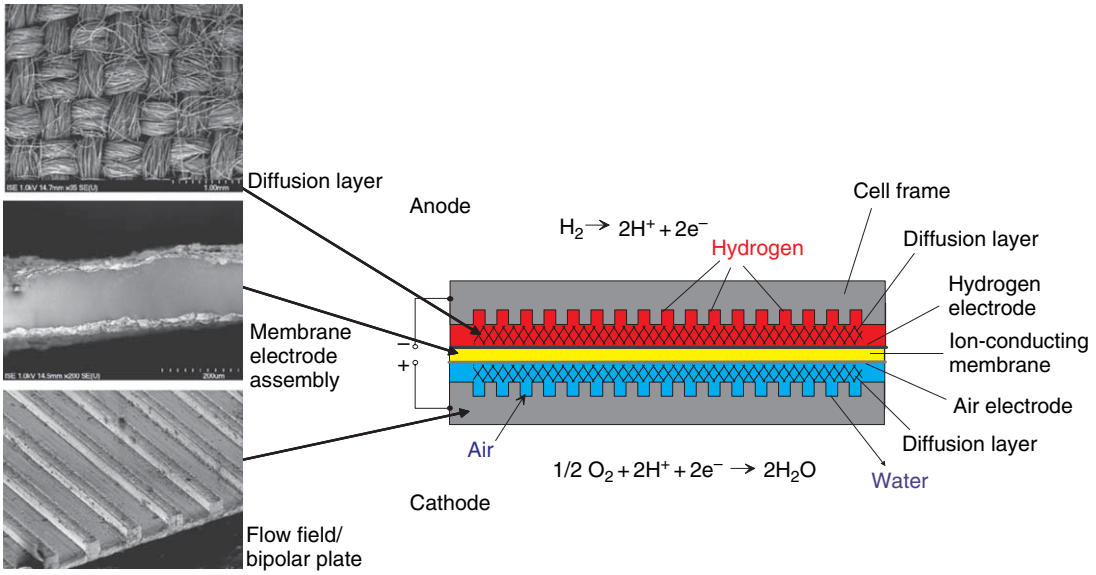

Figure 2 Design of a PEM single fuel cell including the functional units gas diffusion media (GDM), membrane electrode assembly (MEA), and bipolar plate containing the flowfield for the reactants.

setup of a single fuel cell, typically a large number of single cells are stacked on top of each other in order to connect the voltage in series.

The basic electrochemical reactions that take place in a PEMFC are as follows:

At the anode $\varphi_o = 0$ V, at the cathode $\varphi_o = 1.229$ V, which results in a total reaction $E_o = 1.229$ V.

At the anode, in a typical fuel cell design, the hydrogen is broken down into two components: the hydrogen nucleus (proton) and an electron. The electron is transferred from the anode to the cathode through the electric circuit. The proton migrates from the anode to the cathode through the electrolyte. At the cathode, the proton reacts with the electron coming from the load and with the oxygen molecule. They recombine to form water, which is the only chemical product of the fuel cell. The membranes are commonly made of proton-conducting polymers such as perfluorinated ionomers.

The electrochemical reactions that take place at the electrodes need to be facilitated by an electrocatalyst such as platinum or ruthenium. At the two electrodes, the electrochemical reactions occur on the catalyst surface where the electrolyte and the fuel (or oxidant) meet. This interface is often referred to as the triple or three-phase interface, since in some fuel cell designs the fuel (or oxidizer) is gas, the electrolyte is liquid, and the electrode/catalyst surface is solid. The state of this three-phase interface plays a critical role in determining the electrochemical performance of a fuel cell; hence, this triple interface has been the focus of much research in improving the fuel cells.

For the DMFC, the cathode reaction is the same as for the PEMFC cathode, oxygen electrochemical reduction is $\varphi_o = 1.229$ V. While at the DMFC anode, the CH_3OH electrochemical oxidation reaction is $\varphi_o = 0.046$ V, the total reaction is $E_o = 1.183$ V.

Methanol is a liquid fuel that can be oxidized electrochemically in the presence of water. Methanol has a high energy density, is easy to handle, and is completely water-soluble. However, methanol is toxic and the crossover of methanol through the polymer electrolyte membrane results in the poisoning of the cathode catalyst by the formation of a mixed potential. Another problem is the slow anode electrocatalysis of methanol, which requires significantly more noble metal catalyst than the hydrogen PEMFC. As a result, the power density of the DMFC stack at room temperature is currently at least a factor of 5 smaller than that of hydrogen-fed PEMFC.

3.19.3 Micro Fuel Cell Systems Based on MEMS Technologies

Micro fuel cell systems below 10 W and even more in the subwatt range are microchemical systems that offer inherent advantages, such as increased heat

and mass transfer rates, increased safety as a result of smaller volume, enhanced temperature control, on-demand consumption of the reactants, and reduced volume waste streams and thus a very high dynamics for electric load variations, over macrosystems (Kelley *et al.* 2002). Furthermore, integrated microsystems on a chip enable sensing, computing, actuation, control, and communication on a single chip (Lu 2004). Silicon-based micro fuel cell systems are predominantly based on micro direct methanol fuel cells (μDMFC) due to the easy storage and easy handling of liquid fuel as compared to gaseous hydrogen. The anode and the cathode flowfields, usually having channel and rib width on the order of 500 μm and below, are fabricated on Si wafers using the microelectromechanical system (MEMS) technology (Liu *et al.* 2006). Microfabrication permits fine feature resolution, geometry optimization, porosity control in the gas diffusion media (GDM), and the ability to manage the wetting characteristics that are needed to engineer optimal micro fuel cell components (Modroukas *et al.* 2005).

A major target for MEMS-based μDMFCs is to realize a system that is as passive as possible in operation. This means reducing the complexity of the fuel cell stack, methanol sensors, CO_2 separators, electronic controls, methanol feed pump, circulation pump, and pump drivers for the dilution of pure methanol to aqueous methanol solution (usually 2–6 vol.% methanol) to a minimum. In addition to the complexity of such an overall system, the system components add considerable cost to the overall system and consume parasitic electricity, which in turn significantly reduces the net power output. Guo and Faghri (2006) has given an excellent overview of the technologies used by selected developers in order to realize sophisticated μDMFC systems. While some approaches rely on the miniaturization of active components, the major trends pursue passive techniques for driving miniature DMFCs, in particular the cathodic air supply, fuel delivery by capillary forces, and passive CO_2 removal. Fuel storage, CO_2 release, water and thermal management, and orientation-independent operation belong to the main unresolved issues in such systems. In **Figure 3**, a concept that enables fully passive CO_2 gas bubble removal in μDMFC is depicted. The concept is based on a microchannel flowfield with a T-shaped cross section and well-defined tapering angles along the cross section. The tapered channel design creates an intrinsic transport mechanism that removes the gas bubbles from the electrodes by capillary forces only (Litterst *et al.* 2006).

3.19.3.1 Water Management in PEMFC

An excellent stability of the fuel cell operation as well as a high level of miniaturization of the fuel cell system volume is absolutely required for portable electronic applications. These constraints are accompanied by operating conditions that change over time. System start-up, system shut down, and changes in the power demand of the electronic load during operation require an excellent understanding of the transient behavior of fuel cells. In particular, the understanding of the dynamic accumulation and transport of liquid water in the PEMFC is a precondition for a stable operation under varying loads and ambient conditions. Two-phase, dynamic fuel cell models provide insight into the physical phenomena that govern the dynamic operating behavior of a PEMFC.

The complexity of water management in PEMFC systems is due to the fact that the proton exchange membrane is based on cross-linked, sulfonated fluorocarbon membranes and that the electron conductivity of the membrane is strongly affected by the water content. Thus, the membrane

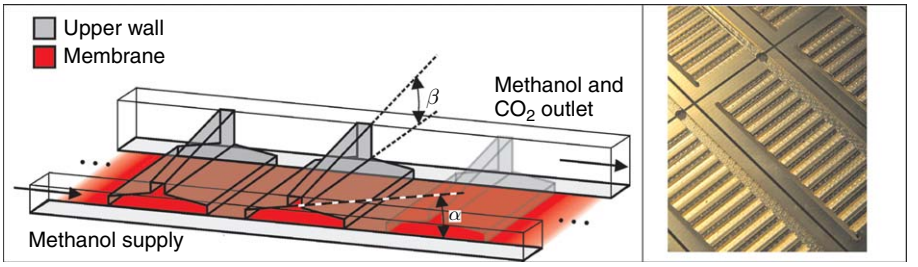

Figure 3 Tapered channel design allowing passive CO_2 gas bubble movement driven by different capillary pressures. (Source: Litterst C, Eccarius S, Hebling C, Zengerle R, Koltay P 2006 *J. Micromech. Microeng.* **16**, 248–53.)

performance will directly follow the water content change, and insufficient water content will lead to a very poor performance and fuel utilization. Since the water content depends both on the local temperature distribution and on the air and hydrogen flow rate, the mathematical description and physical quantification of the time- and spatially-resolved parameters is a demanding challenge, which is being pursued by means of multiphysics and multiscale simulations.

3.19.3.2 Hydrogen Generation and Storage

PEMFCs require hydrogen as feed for their electrochemical energy conversion. The hydrogen can be supplied either in pure form or as a hydrogen-rich gas, containing other compounds as long as they are not harmful to the fuel cell. Pure hydrogen can be provided from either hydrogen storage systems or from reformer systems with subsequent hydrogen separation. A hydrogen-rich gas can be supplied from a fuel processor. Other compounds in the reformer product gas can be nitrogen (if an autothermal reforming (ATR) process is used), carbon dioxide, water, carbon monoxide, and trace amounts of methane and higher hydrocarbons.

The fuel choice is limited by several factors such as the volumetric and gravimetric energy density of the fuel, the weight and lifetime of the fuel container, the conversion efficiency of the chemical energy to electricity, the safety of the fuel and fuel container during refueling and transportation, and finally the fuel distribution infrastructure. In the small-power range, both hydrogen and methanol are very attractive fuels, and also chemical hydrides and even the microreforming of hydrocarbons are moving more and more into the focus of research activities. PEMFCs possess by far higher potential in terms of power density whereas methanol fuel cells dominate from the energy density point of view.

There are several techniques for storing pure hydrogen: as liquid at $-253\,^{\circ}C$ in appropriately isolated vessels, in gaseous form at high pressure, and chemically bound in either metal hydrides or chemical hydrides. Furthermore, the development of carbonaceous materials as another weight-efficient medium for hydrogen storage for fuel cell applications shows promise in the long term. A good overview on hydrogen storage technologies is given by Züttel (2003).

With respect to hydrides, there are two choices:

(1) Metal alloys, which are able to adsorb and desorb hydrogen upon changes in pressure and temperature
(2) Chemical or complex hydrides like $NaBH_4$, which release hydrogen upon heat input or addition of water.

Metal hydride materials, which can be charged and discharged reversibly, are metallic alloys. Hydrogen reacts at elevated temperatures with many transition metals and their alloys to form hydrides. Metal hydrides can absorb large amounts of hydrogen at a constant pressure because of the phase transition. The composition of the alloy determines the temperature and pressure levels for the desorption and the adsorption process. For portable applications, the temperature and the pressure for the desorption process must be close to ambient conditions. These types of alloys, such as AB5, have been under development for many years. The typical hydrogen storage density of these hydride materials is 1.3–1.5 wt.%, corresponding to 150 l of hydrogen per kilogram of hydride material or $450\,W\,h\,kg^{-1}$ or $1050\,W\,h\,l^{-1}$ based on the lower heating value for hydrogen. Some companies have announced that hydrides with 2 wt.% hydrogen will be available in a few years. In addition to the hydride material, there is a container, a filter, and a valve to complete the storage system. These also contribute to the weight and the size of the system, indicating a lower limit for a reasonable size of the container. These hydride materials are considered to be the safest way to store hydrogen since the temperature decreases during discharging and the hydrogen release is decelerated accordingly. The alloys can be charged and discharged several thousands of times with moderate degradation, depending on the purity of the hydrogen used for charging.

Compounds such as chemical or complex hydrides can be used only once. The main difference between complex and metallic hydrides is the transition to an ionic or covalent compound upon hydrogen absorption. The hydrogen in the complex hydrides is often located in the corners of a tetrahedron with B or Al in the center. The negative charge of the anion, $[BH_4]^-$ and $[AlH_4]^-$, is compensated by a cation, e.g., Li or Na. The hydride complexes of borane, the tetrahydroborates $M(BH_4)$, and the tetrahydroaluminates $M(AlH_4)$ are nonflammable and stable in air. They

decompose only at elevated temperatures, often above the melting point of the complex.

Small-scale reformers offer the use of hydrocarbons with their high energy density at reasonable fuel costs. The striking feature is the worldwide availability of fuels such as LPG, gasoline, diesel, or kerosene.

Reformers are used to produce hydrogen from hydrocarbons or alcohols for fuel cells. They consist of the actual reforming reactor, where the fuel is reacted to hydrogen, water, carbon monoxide, and carbon dioxide, with small amounts of methane and other hydrocarbons as by-products. The reforming reaction requires elevated temperatures between 250 °C for methanol and up to 900 °C for liquid hydrocarbons such as kerosene and diesel. In addition, catalysts are used to increase reaction rates and hydrogen yields. In principle there are three reforming processes that can be distinguished by the oxidant. If water is the oxidant the reaction is the so-called steam-reforming (SRF) reaction, which is endothermic. If, on the other hand, oxygen is used as an oxidant, then the reaction is exothermic and is called catalytic partial oxidation (CPOX). If both oxygen and steam are mixed in such a ratio that no heat input is required and no heat release occurs, then the reaction is called autothermal reforming (ATR).

Depending on the fuel cell used in the system, the reformer product gas has to be treated. If PEM fuel cells, which can tolerate up to 20 ppm carbon monoxide only, are utilized, the reformer system also has to comprise shift reactors and further unit operations for removal of carbon monoxide (fine purification) down to the level tolerated by the PEM fuel cell. In **Figure 4** a schematic process flow diagram of a reformer system including gas treatment and fuel cell is depicted.

The feed streams are preheated, evaporated, and superheated up to the operating temperature of the reformer; the heat duty is provided by the gas streams after the reformer and the shift reactors. The reformer also possesses an integrated burner for the fuel cell anode off-gas. In case of a steam reformer, this burner provides the reaction enthalpy, and in the case of CPOX or ATR, this burner provides additional heat duty to preheat the feed streams.

The reformer product is then supplied to one or several shift reactors operating at temperatures between 200 and 350 °C, where the carbon monoxide content of the gas stream is reduced to concentrations of about 0.5–1 vol.% (dry gas). In the subsequent fine purification, the carbon monoxide content is further reduced by either preferential CO oxidation (PROX) or selective CO methanation. Both processes are explained in more detail in the Section 3.19.4. The treated reformate enters the anode of the fuel cell where the electrochemical oxidation of hydrogen occurs under the release of electrical energy and heat. The anode off-gas still contains unreacted hydrogen

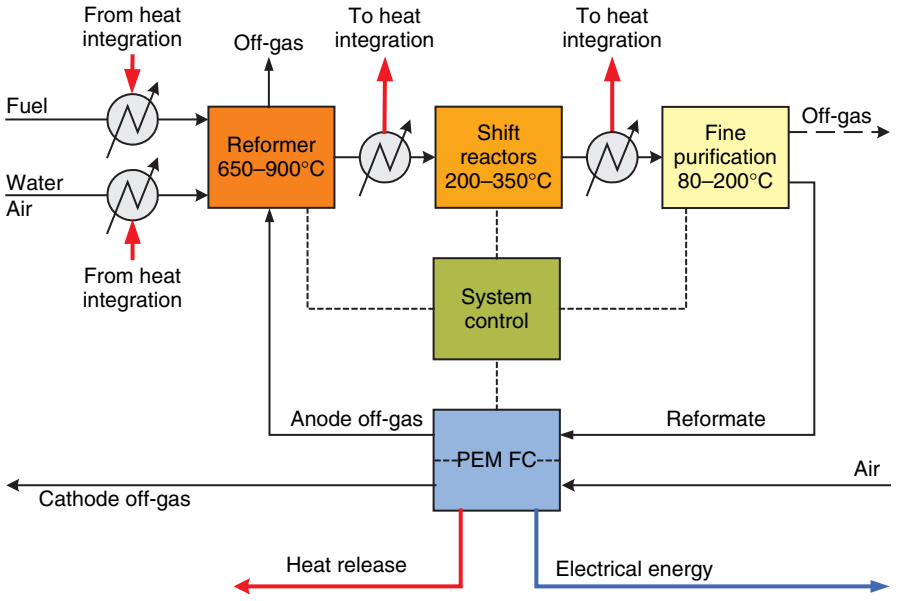

Figure 4 Process flow diagram of a reformer system with PEM fuel cell.

along with traces of methane and is, therefore, combusted in the reformer to increase system efficiency.

The entire reformer/fuel cell system is controlled by a control system that controls operating parameters in the reformer system and the fuel cell. System control for such a system is very complex and is the objective of numerous R&D activities.

Microreformers for hydrogen supply to PEMFCs for portable electronic devices and off-grid power supply are well investigated and have been developed at numerous academic and industrial research centers. They are viewed as replacement for batteries.

Typical applications range from military soldier power supply, where high energy densities are of foremost importance (Palo *et al.* 2002, Patil *et al.* 2004), to portable electronic devices such as cell phones, handhelds, or laptop computers (Hallmark *et al.* 2006, Kawamura *et al.* 2006, Kundu *et al.* 2006). Auxiliary power units (APU) are also designed based on microreforming technologies (Edlund 2005). The PEMFC is the fuel cell of choice for these applications due to low temperatures and fast dynamic operation. However, it requires hydrogen supply from a microreformer.

Some authors predict a significant potential for high energy densities. Palo *et al.* (2002) predict methanol SRF/PEMFC systems to have the potential to reach $1500\,\mathrm{W\,h\,kg^{-1}}$ by 2005 and up to $3000\,\mathrm{W\,h\,kg^{-1}}$ by 2008 for $15\,\mathrm{W_e}$ power output. However, these numbers have to be taken with care, because they always depend on the tank size, or in other words on the amount of stored energy.

3.19.4 Introduction to Reforming Technologies

Ahmed and Krumpelt (2001) give a brief overview of fuel processing for hydrogen generation. The conversion of fuels to hydrogen is carried out by one of the three major techniques – steam reforming (SR), partial oxidation (POX) reforming, and autothermal reforming (ATR).

SRF is probably the most common method for producing hydrogen in the chemical process industry:

$$\mathrm{fuel}\left(\mathrm{C}_n\mathrm{H}_m\mathrm{O}_p\right) + \mathrm{steam} \rightarrow \mathrm{carbon\ oxides} + \mathrm{hydrogen},\ \Delta H_\mathrm{R} > 0 \qquad [\mathrm{I}]$$

In this process, steam reacts with the fuel in the presence of a catalyst at elevated temperatures producing hydrogen, carbon monoxide, and carbon dioxide. Steam reformers are well suited for long periods of steady-state operation and can deliver relatively high concentrations of hydrogen (>70% on a dry basis). The primary SRF reaction is strongly endothermic, and the reactor performance is typically limited by heat transfer rather than by reaction kinetics.

POX reformers process the fuel with a substoichiometric amount of oxygen. The oxidation reaction yields heat generation causing high temperatures of the product gas:

$$\mathrm{fuel}\left(\mathrm{C}_n\mathrm{H}_m\mathrm{O}_p\right) + \mathrm{air} \rightarrow \mathrm{carbon\ oxides} + \mathrm{hydrogen} + \mathrm{nitrogen},\ \Delta H_\mathrm{R} < 0 \qquad [\mathrm{II}]$$

The heat generated from the oxidation reaction increases the gas temperature to above 1000°C. The oxidation step may be conducted with or without a catalyst.

Autothermal reformers combine the heat effects of the POX and the SRF reactions by feeding the fuel, water, and air together into the reactor:

$$\mathrm{fuel}\left(\mathrm{C}_n\mathrm{H}_m\mathrm{O}_p\right) + \mathrm{air} + \mathrm{steam} \rightarrow \mathrm{carbon\ oxides} + \mathrm{hydrogen} + \mathrm{nitrogen},\ \Delta H_R \approx 0 \qquad [\mathrm{III}]$$

This process is carried out in the presence of a catalyst, which controls the reaction pathways and thereby determines the relative extents of the oxidation reforming and SRF reactions. The SRF reaction absorbs part of the heat generated by the oxidation reaction, limiting the maximum temperature in the reactor. The net result is a process that is slightly exothermic to compensate for heat losses. In order to achieve the desired conversion and product selectivity, an appropriate catalyst is essential. **Figure 5** below gives a simplified overview of the three reforming technologies presented.

The three different technologies result in different product gases, as shown in **Table 1**. Depending on the downstream energy conversion device (fuel cell, internal combustion engine, turbine, and burner), the dilution of product gases with nitrogen is not favored, for the fuel cell then has a higher gas throughput to achieve the same electrical output. Therefore, the advantage of the faster start-up in ATR over SRF is negated, so most of the microreformer fuel cell systems apply SRF technology.

Of the three reforming pathways, the SRF process yields the highest hydrogen concentration in the

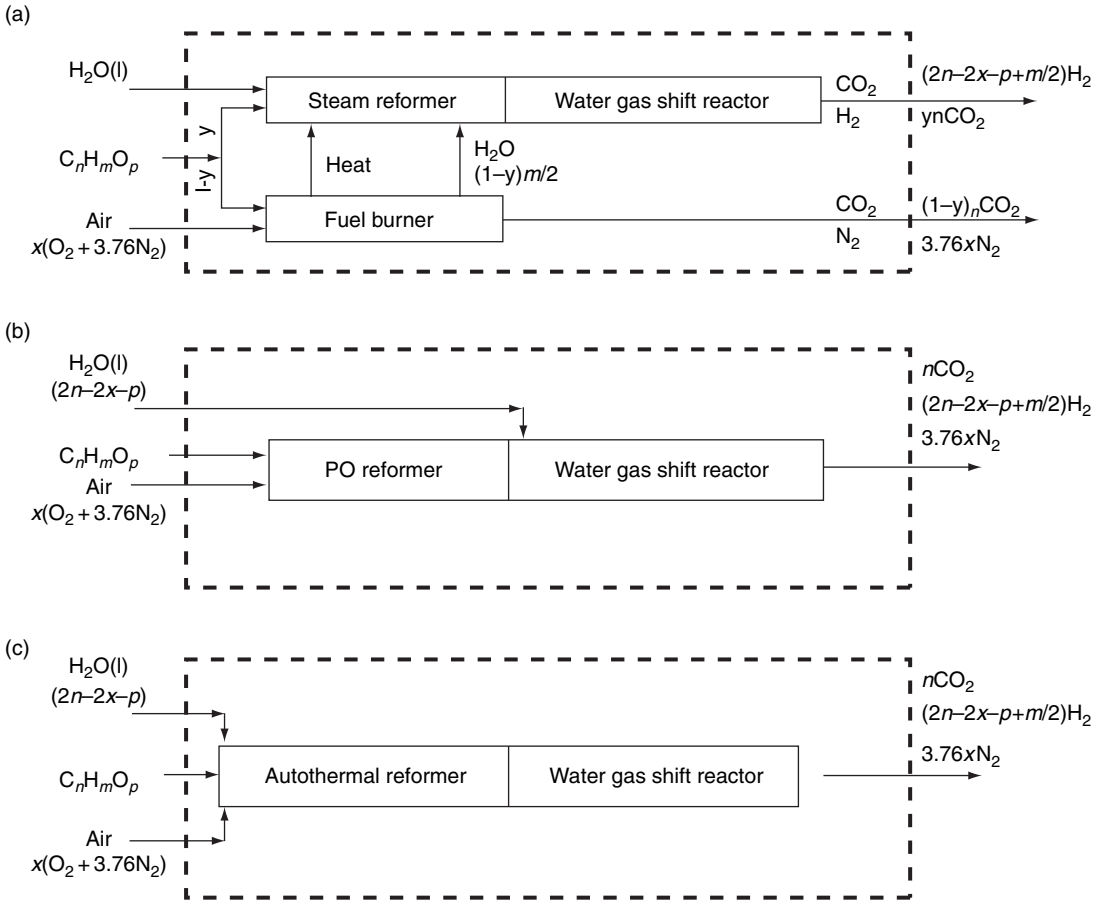

Figure 5 Schematics of idealized fuel processors, showing feeds and products from (a) steam reforming (SRF), (b) partial oxidation (POX) reforming, and (c) autothermal reforming (ATR). (Source: Ahmed S, Krumpelt M 2001 Hydrogen from hydrocarbon fuels for fuel cells. *Int. J. Hydrogen Energy* **26**, 291–301.)

Table 1 Comparison of dry product gases (vol.%) from the three different processes

Gas	*SRF*	*POX with air*	*ATR*
H_2	75–78	24–30	32–35
CO	8–10	14–18	9–11
CO_2	10–13	0.6–2	8–10
CH_4	2–5		0.2–1
N_2	–	43–52	44–48

product. However, for practical applications, POX and ATR processes are more attractive, according to Ahmed and Krumpelt, because they possess the potential to be more energy-efficient and the hardware can be smaller and lighter (Ahmed and Krumpelt 2001). In ATR technology, no extra burner is needed theoretically but then the anode off-gas from the fuel cell needs to be treated in an after burner to prevent combustible gases from being set free.

The carbon monoxide and, if necessary, carbon dioxide are removed from the reformate gas by a variety of reactions and scrubbing techniques, such as the water gas shift (WGS) reaction:

$$CO + H_2O \leftrightarrow CO_2 + H_2, \quad \Delta H_R < 0 \qquad [IV]$$

methanation:

$$CO + 3H_2 \rightarrow CH_4 + H_2O, \quad \Delta H_R < 0 \qquad [V]$$

PROX:

$$CO + 1/2\,O_2 \rightarrow CO_2, \quad \Delta H_R < 0 \qquad [VI]$$

and CO_2 absorption in amine solutions, and pressure swing adsorption.

Apart from reforming technologies, there is also the pyrolysis process in which no oxygen is provided

to the fuel, so it splits directly into hydrogen and carbon when heated to temperatures above 800 °C.

$$C_xH_y \Leftrightarrow xC + \frac{y}{2}H_2, \quad \Delta H_R < 0 \qquad [VII]$$

Up to now pyrolysis is considered to be economically feasible for large-scale plants only. The disadvantages lie in the formation of carbon, which has to be removed in a batch process, and also the efficiency, which lies below that of SRF (Ledjeff-Hey *et al.* 2000). A disadvantage in propane pyrolysis is that 30–50% of the energy content of the fuel are discarded with the carbon.

To choose the appropriate hydrogen generation process, the pros and cons in size, product gas purity, manufacturing process with respect to the size, weight, and complexity of the system, power density, total system efficiency, and cost need to be evaluated. For example, methanol reformer PEM fuel cell systems can reach higher power densities than DMFC stacks. Thus, building larger PEM fuel cell stacks with a greater electrical power output and still achieving acceptable costs instead of using a larger DMFC is favored for systems in which power density is the key criterion (Edlund 2005).

3.19.4.1 Differences Between the Micro- and Macroworlds

In this overview the word microsystem is used for a miniaturized integrated system with integrated sensors, controllers, and actors whose characteristic dimensions are on the micrometer scale (Kasper 1999). The word macrosystem is used for systems with characteristic dimensions >1 cm. A general comparison between micro- and macroworlds is given for instance by Hessel *et al.* (2005).

Advantages due to smaller size. With decreasing dimensions the gradients of physical parameters such as temperature, pressure, and density, which represent the driving force for heat and mass transfer and diffusion, increase. This results in improved heat and mass transfer, as evidenced in higher heat transfer coefficients in micro heat exchangers and shorter mixing times in micromixers. Thus, in microapplications with exothermal reactions, local hotspots are avoided through improved heat transfer.

Larger surface area-to-volume ratio. The maximum surface area-to-volume ratio in macroreactors from the production industry is $100\,m^2\,m^{-3}$, whereas in microchannels, values as high as $50\,000\,m^2\,m^{-3}$ can be achieved. This is an advantage for all catalytic reactions, for the active area increases noticeably. The change in surface area-to-volume ratio results in a limit for small-dimensional combustion (Peterson 2003). This is due to the surface area decreasing to the square and the volume decreasing to the cube with decreasing length. Fast thermal losses of a forming nucleus of combustion require a minimum surface area-to-volume ratio. These correlations are also found in nature in the limits in the size of warm-blooded animals. On the other hand, the increase of surface area-to-volume ratio also leads to an increase of heat losses (Kawamura 2006).

Analogies in the micro- and macroworlds. To calculate the behavior of gases and liquids in microchannels, the Navier–Stokes equations seem to be applicable. Calculated friction coefficients in laminar flows show good accordance with those of the macroworld. Small deviations can result from measurement errors that occur when experiments are carried out in this small scale (Amador *et al.* 2004).

Generally speaking, it can be stated that there will almost always be laminar flow conditions in microchannels. Although in the microworld the critical Reynolds numbers for laminar flow lie between 200 and 900, i.e., lower than in the macroworld, occurring Reynolds numbers mostly lie far below this limit. The critical Reynolds number changes due to a higher sensitivity towards surface roughness (Ducrée 2005).

Differences between the micro- and macroworlds. When placing a solid-state body in a cooler or a hotter environment, it cools down or heats up, resulting in an inner temperature gradient, represented by the dimensionless Biot number:

$$Bi = \frac{\alpha L}{\lambda} \qquad [1]$$

which describes the ratio of heat transfer α on the outer surface to inner heat conduction λ over a certain characteristic length L.

As L decreases, the Biot number decreases. For $Bi << 1$ the internal temperature gradient becomes very small, so homogeneous temperatures can be assumed. Therefore, smaller reactors are less affected by thermal tension and can tolerate faster temperature changes (Madou 1997).

3.19.5 Microchannel Reformer

Most conventional microreformers are manufactured using conventional welding techniques, the catalysts being inserted as pellets, honeycombs, or sometimes directly applied onto the reactor surface of heat exchangers, if they are used as reactors. These microreformers produce power in the range of 1–100 W_e. Another concept is the use of microchannel reactors for microreformers. In these reformers, dimensions of flow channels and other reactor internals, such as packed beds of catalyst particles, flow distributors, and mixing devices, are on the order of hundreds of micrometers or even below. They are called microchannel reformers. This overview of microreformers concentrates on microchannel reformers.

Numerous developments of small-scale reformers with internal microstructures are reported in the literature. Key players in microchannel reforming research and development are companies such as Motorola Labs (USA), Samsung (Korea), Matsushita Electric Works (Japan), Casio (Japan), research institutes such as Battelle (USA), Korea Institute of Energy Research (Korea), IMM GmbH (Germany), FZK-IMVT (Germany), EPFL (Switzerland), and universities such as University of Michigan (Dept. Chem. Eng.), Lehigh University (USA), Dalian Institute of Chemical Physics (China), Yonsei University (Korea), Korea University (Korea), Sungkyunkwan University (Korea), Seoul National University (Korea), Kyoto University (Japan), Tohoku University (Japan), Kogakuin University (Japan). This list is by no means comprehensive.

The published papers reflect a fraction of the activities going on in academia and especially in industry in the field of microreformers. A good overview of the literature on microchannel reformer development up to 2002 is given by Gariilidis *et al.* (2002). More current developments are summarized in a book by Hessel *et al.* (2005) where the authors describe various kinds of microchannel reformers, gas cleanup concepts, catalytic combustor design, and fully integrated systems.

Microchannel reformer capacities range from several hundred milliwatts (**Figure 6**) to one hundred watts (**Figure 7**) based on the electric power output a fuel cell could generate with the reformer product gas flow. With parallel installation of several microchannel reformers, capacities can reach the several kilowatt range (Tonkovich *et al.* 2004). Fuels commonly used in microreformers are liquid fuels such as methanol, ethanol, gasoline, isooctane, diesel, diesel surrogates, and gaseous fuels like LPG, and natural gas (methane).

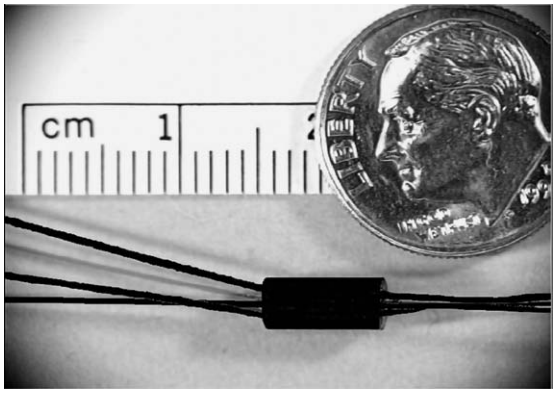

Figure 6 Battelle's 100 mW_e fully integrated methanol steam reformer including vaporizer, and catalytic combustor. (Source: Holladay J D, Jones E O, Phelps M, Hu J 2002 *J. Power Sources* **108**, 21–7.)

Over the past five years, the majority of research and development teams have concentrated on steam reformers for methanol for several reasons:

(1) Methanol can be reformed at relatively low temperatures between 250 and 350°C, which allows the use of silicon and ceramics as reactor material
(2) It reduces the requirements for insulation.
(3) Due to the low reforming temperature the carbon monoxide content of a methanol steam reformer product gas is on the order of 0.5–2 vol.%. Therefore, a subsequent shift reactor is not required.

In case of using PBI-membrane PEMFC that operates at elevated temperatures, no further gas cleanup is necessary, because they tolerate carbon monoxide concentrations up to 2 vol.%. In the case of standard low-temperature PEMFC, the carbon monoxide content has to be reduced down to 20 ppm by PROX, methanation, or Pd membranes. A few researchers report work on microchannel reforming using ATR or CPOX and on fuels other than methanol (Aartun *et al.* 2004, Hu *et al.* 2003, Kolb *et al.* 2007, Ryi *et al.* 2005, 2006, Tadd *et al.* 2005, Thormann *et al.* 2006, Tonkovich *et al.* 2004).

Aside from the key components of any reformer system, the actual reformer reactor, one or several WGS reactors, a carbon monoxide-reducing step (methanation, PROX, or Pd membrane), a vaporizer, a catalytic combustor, and various peripheral components, e.g., pumps, valves, pressure/temperature sensors, electrical heaters, and system controls, are required.

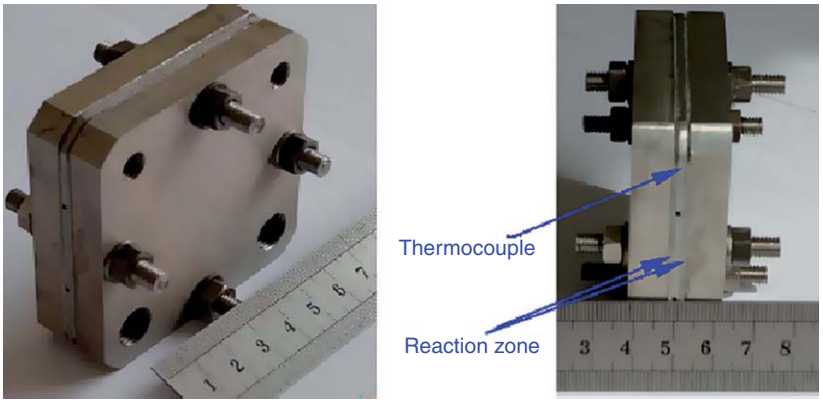

Figure 7 Microchannel methanol autothermal reformer (100 W_e) by Chen and coworkers. Combustor and vaporizer are not integrated. (Source: Chen G, Li S, Yuan Q 2007 *Catal. Today* **120**, 63–70.)

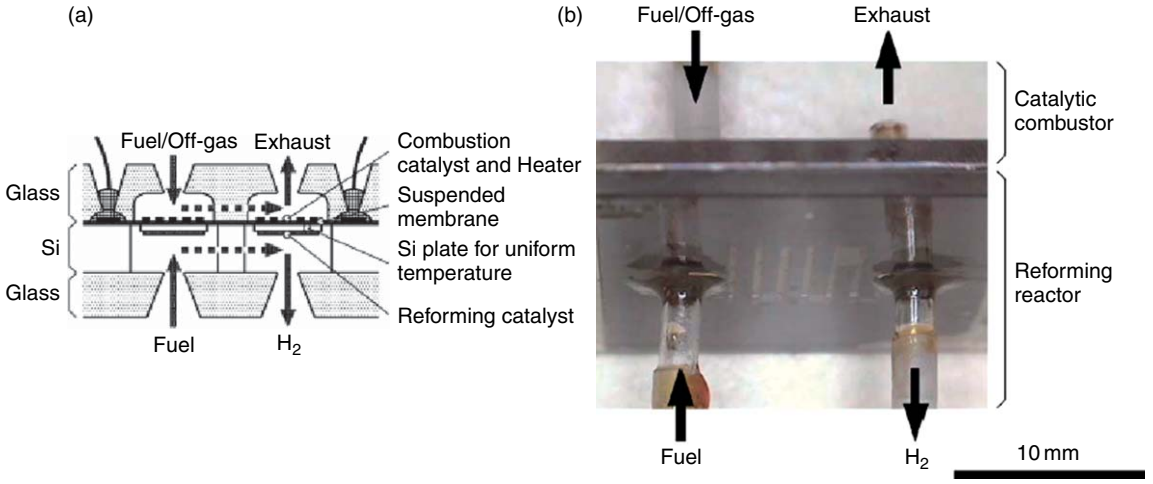

Figure 8 Microchannel reactor (a) with integrated catalytic combustor (b). (Source: Tanaka S, Chang K S, Min K B, Satoh D, Yoshida K, Esashi M 2004 MEMS-based components of a miniature fuel cell/fuel reformer system. *Chem. Eng. J.* **101**, 143–9.)

Most researchers focus on the design, fabrication, and testing of the microchannel reactors only, with integrated catalytic burners (**Figure 8**) or electric heaters (**Figure 9**) for heat supply to vaporizer and endothermic SRF reactor. A few teams, mainly with a more industrial background, develop complete integrated reformer systems with heat exchangers, preheaters, vaporizers, and catalytic combustors (Hallmark *et al.* 2006, Holladay *et al.* 2002, Holladay et al. 2004a, b, Kwon *et al.* 2006, 2007, Shin *et al.* 2006) – see **Figures 6** and **10**.

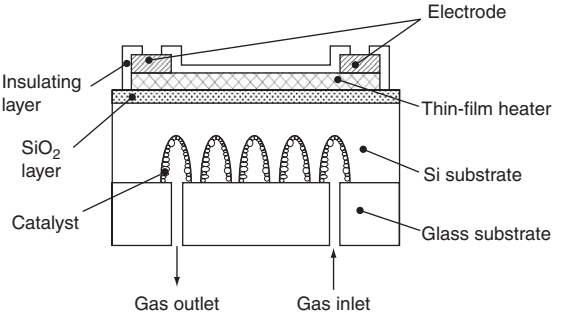

Figure 9 Microchannel reformer with electric film heater. (Source: Kawamura Y, Ogura N, Yamamoto T, Igarashi A 2006 *Chem. Eng. Sci.* **61**, 1092–101.)

3.19.5.1 Overview

Table 2 gives on overview of the developments reported in most recent papers. It provides

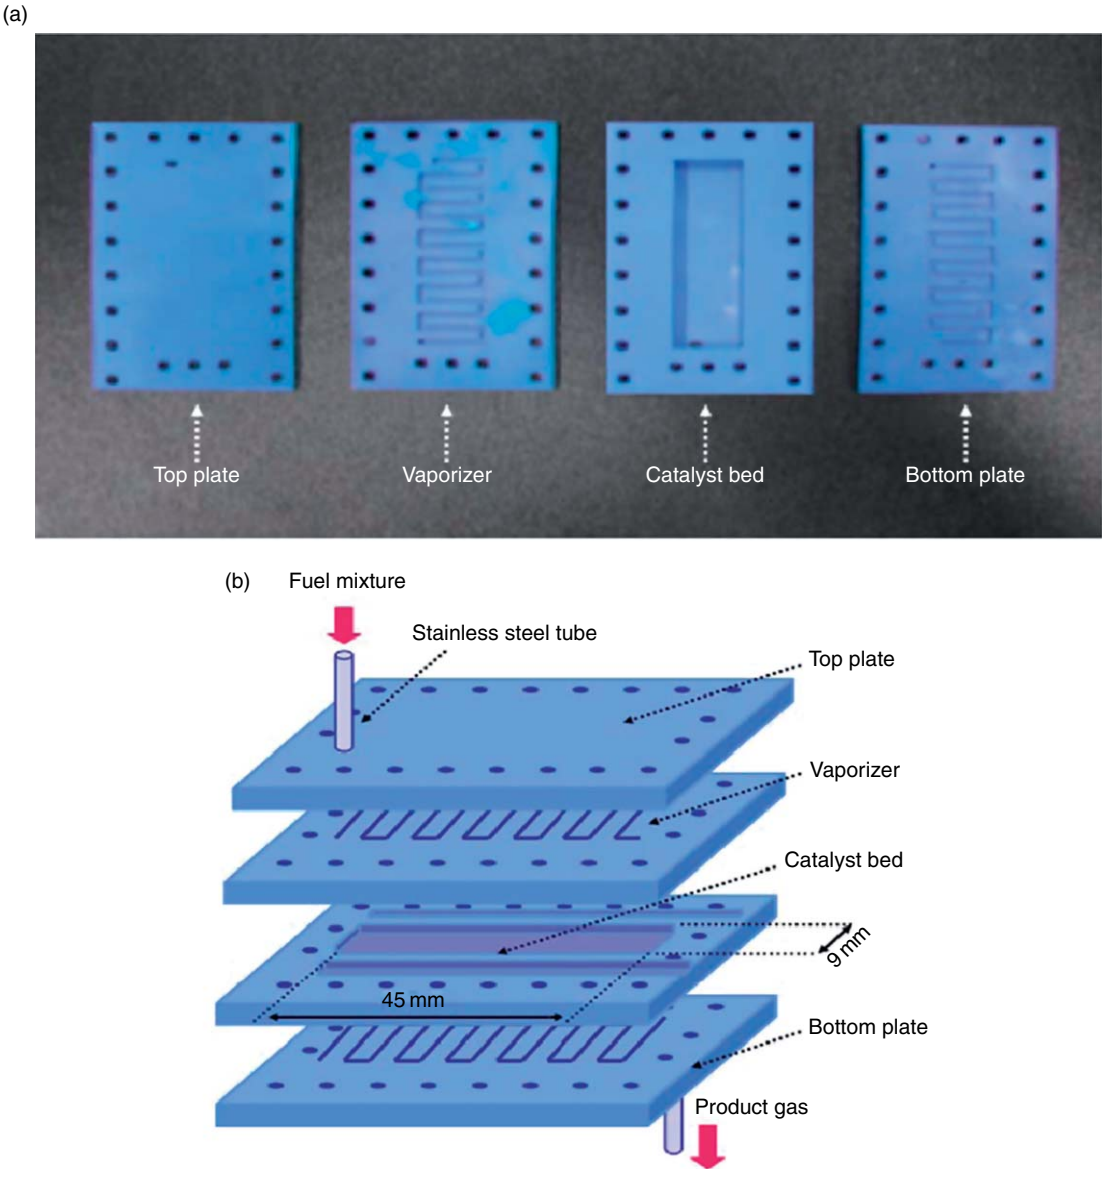

Figure 10 Methanol microchannel reformer with integrated vaporizer and electrical heaters. (Source: Shin Y, Kim O, Hong J-C, Oh J-H, Kim W-J, Haam S, Chung C-H 2006 *Int. J. Hydrogen Energy* **31**, 1925–33.)

information about the power output of the reformer, the fuel used, the reforming process (SRF, ATR, and CPOX), the type of gas cleanup (if any), peripheral components, reactor material (metal, silicon, and ceramic), and the source of the catalyst (proprietary development or commercial supplier). At the bottom of the table, references that deal with gas cleanup only, such as WGS, PROX, methanation (meth.), and Pd membranes (Pd) are cited. A question mark denotes that the particular information is not provided in the reference.

3.19.5.2 Catalyst and Fabrication

Many groups develop proprietary catalysts for reforming, PROX, WGS, and methanation. They all deal with the coating of reactor walls (adhesion problems) and catalyst distribution on the wash coat. Commercial catalyst suppliers are BASF AG, Süd-Chemie AG, and Johnson Matthey Plc.

A few studies have been published that include comparisons of packed bed and microchannels for microreforming reactors (Kundu *et al.* 2006, Park *et al.* 2005, Tadd *et al.* 2005) and PROX (Srinivas *et al.*

Reforming process: SRF, steam reforming; ATR, autothermal reforming; CPOX, catalytic partial oxidation. Gas cleanup: WGS, water gas shift; meth., methanation; Pd, palladium membrane. Periphery: eject., ejector; T sens, temperature sensor on chip. Material: SS, stainless steel; Incon., Inconel; FeCrA., FeCr alloy; Si, silicon; LTCC, low-temperature cofired ceramic; silica cap., silica capillaries; por Si, porous silicon. Catalyst development: prop, proprietary; comm., commercial; p. bed, packed bed.

2004). Packed beds supposedly have high-pressure drops, even despite new designs that lead to radial geometries (Pattekar and Kothare 2005). However, other sources do not state significant differences between both reactor concepts, as reported, for example, for the PROX reaction by Srinivas *et al.* (2004). Holladay *et al.* (2002) investigated different supports for methanol SRF catalysts. They looked into foams from pure metals, alloys, or ceramics. Kundu and coworkers used a packed powder (packed bed) in a microchannel reactor, as can be seen in **Figure 11**.

Palladium membrane fabrication in microchannel reactors is described by Karnik *et al.* (2003), Presting *et al.* (2004), and Kothare (2006). These membranes are used for separation of hydrogen from a reformate gas, with the copper support acting as a WGS catalyst.

For SRF of methanol, Cu/ZnO on an alumina substrate (Al_2O_3) is commonly used and is described

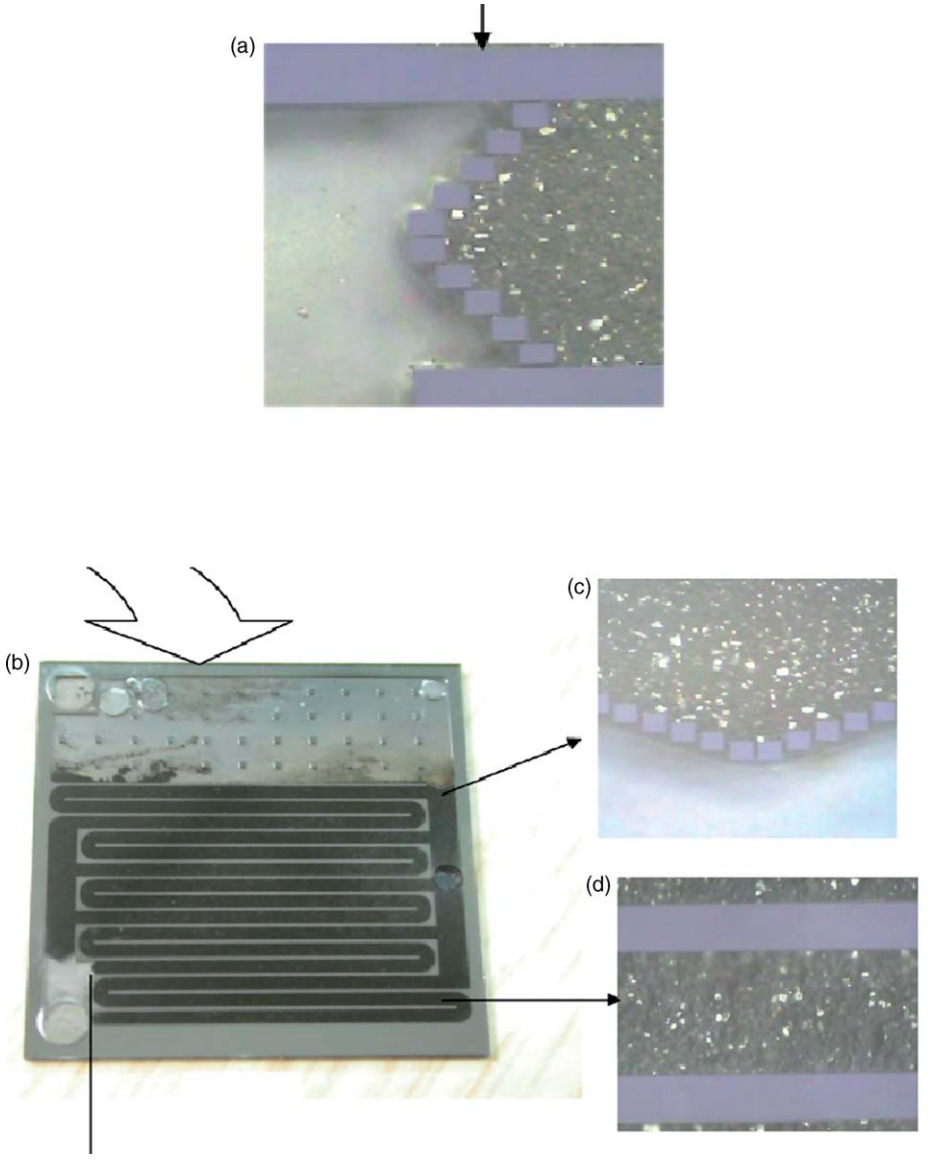

Figure 11 Packed powder in microchannel reactor. (Source: Kundu A, Jang J H, Lee H R, Kim S H, Gil J H, Jung C R, Oh Y S 2006 *J. Power Sources* **162**, 572–8.) (a) Photograph of serpentine patterned silicon wafer with catalyst. (b) Microscopic imaging of filter at the inlet point of the reactor part. (c) Microscopic image of catalyst packing inside the channels. (d) Microscopic image of filter at the outlet of the reactor part.

as a good catalyst with high activity and high carbon dioxide selectivity. Unfortunately, the catalyst does not tolerate hot spots, liquid water, and exposure to air while warm. All of these restrictions pose difficulties in the design, fabrication, and operation of reformers with that catalyst. According to Hallmark *et al.* (2006) the temperature limitations of the Co/ZnO-based catalyst probably pose the greatest challenges, because manufacturing of metal and ceramic reactor typically requires at least one high-temperature step (welding, brazing or diffusion bonding for metal, and cofiring for ceramic). However, these high temperatures significantly reduce the activity of the Cu/ZnO catalyst. Therefore, the catalyst coating of the reactor must take place after the high-temperature fabrication step for this catalyst. This is achieved by coating the reactor walls after reactor fabrication and impregnating the wash coat with catalyst solution afterwards. Depending on the wall material, wash coating faces severe adhesion problems. In this context, Hallmark *et al.* (2006) teamed up with BASF AG to develop a novel palladium catalyst that can withstand the high temperatures of the cofiring production step. This allows the catalyst to be applied to green tape prior to cofiring and, thereby, facilitates the production process.

3.19.5.3 Microchannel Design

Typical dimensions of microchannels reported are on the order of 100–500 μm wide, 100–300 μm deep, and 20–60 mm long. Many times the reformer and gas cleanup reactors are integrated in plate heat exchangers with counter current, cocurrent, and cross flow. Also, single–flow, meandric-shaped channels are investigated (Kawamura *et al.* 2006, Shin *et al.* 2006). Double meanders of reformer and vaporizer with catalytic combustor on the backside of the plate have been reported as well (Park *et al.* 2006). For more fundamental investigations some authors use electric heaters on the back side of the patterned microchannel plates for defined heat input (Kawamura *et al.* 2006, Kundu *et al.* 2006, 2007, Kwon *et al.* 2006, 2007, Shin *et al.* 2006, Tadd *et al.* 2005). **Figure 9** shows a typical example.

Special precautions are taken to achieve even flow distribution over a large number of parallel microchannels. This results in inlet ports (**Figure 12** shows two typical examples), as described by the majority of authors, and staggered rod bundles (Srinivas *et al.* 2004).

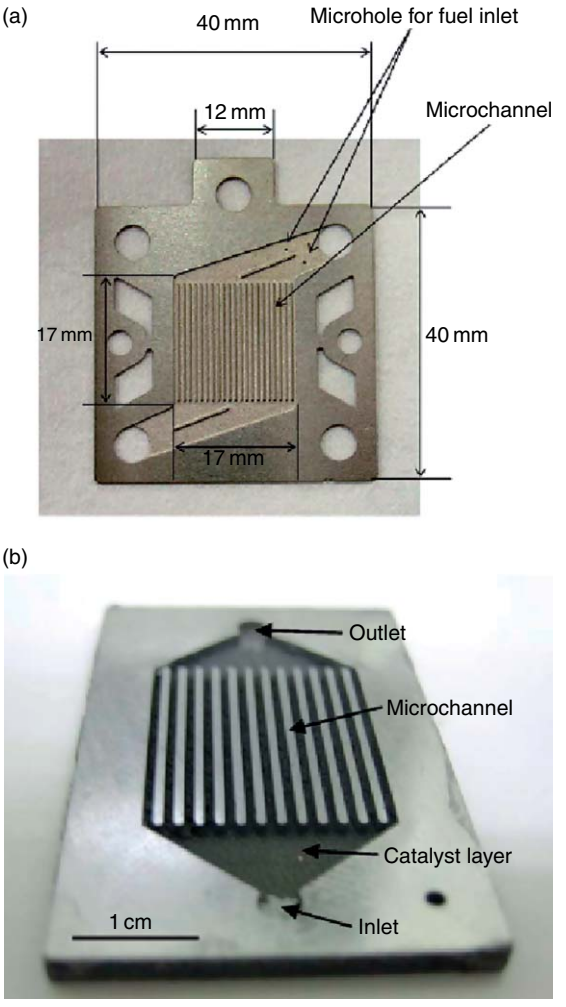

Figure 12 Two examples for an inlet port design to achieve even flow distribution to parallel microchannels. (a) (Source: Ryi S K, Park J S, Choi S H, Cho S H, Kim S H 2005 *Chem. Eng. J.* **113**, 47–53.) (b) The microchannel width is 500 μm and reactor chamber size is 1.5 cm × 2.0 cm × 0.1 cm. (Sources: Kim T, Kwon S 2006a *Chem. Eng. J.* **123**, 93–102; Kim T, Kwon S 2006b *Micromech. Microeng.* **16**, 1760–68.)

Some authors have worked with microtubes, reactors filled with catalyst powder (packed bed) (Shin *et al.* 2006), or foams with microcavities instead of microchannels (Bravo *et al.* 2004, Conant *et al.* 2006, Presting *et al.* 2004). One team even designed a radial flow reactor to minimize pressure drop in the packed bed for the volume increasing the reforming reaction (Pattekar and Kothare 2004, 2005). Simulation tools are used to predict flow regimes inside the microchannels and temperature distribution throughout the microchannel reactors (Kawamura *et al.* 2006, Mukherjee *et al.* 2007).

3.19.5.4 Materials and Fabrication

Materials typically used for microchannel reactors are metal foils and plates (stainless steel, Inconel, FeCrAlloy), silicon in combination with Pyrex glass, and ceramic (low-temperature cofired ceramic, LTCC). Different materials require different microreactor fabrication procedures.

3.19.5.4.1 Metal

(1) In metal sheets, microchannels can be created by wet chemical etching all the way through and then placing manifold sheets between the microchannel sheets. Finally, cover sheets at the bottom and the top allow tight assembly by use of screws (Park *et al.* 2004, 2005). This is depicted schematically in **Figure 13**.

(2) Another way is to create microchannels in metal plates by wet chemical etching, only partly into the metal material. The microchannel sheets are then placed between end plates and screwed together (Chen *et al.* 2002, 2007, Kundu *et al.* 2007, Ryi *et al.* 2005, 2006) (**Figure 14**).

(3) Some authors use wet chemical etching of microchannels in metal foils and subsequent laser

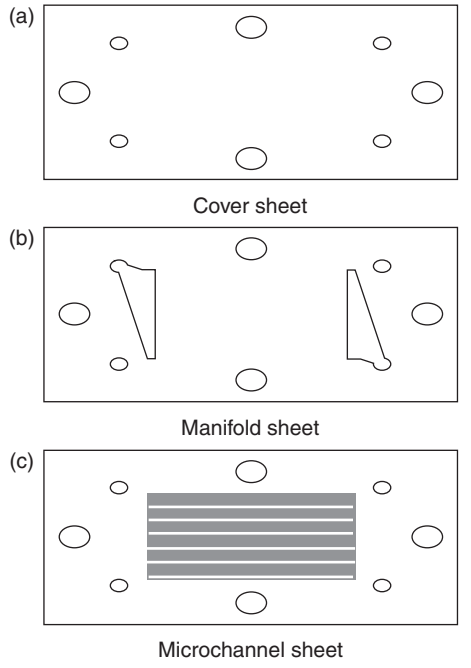

Figure 13 Microchannels created by wet etching all the way through metal sheets. (Source: Park G-G, Seo D J, Park S-H, Yoon Y-G, Kim C-S, Yoon W-L 2004 *Chem. Eng. J.* **101**, 87–92.)

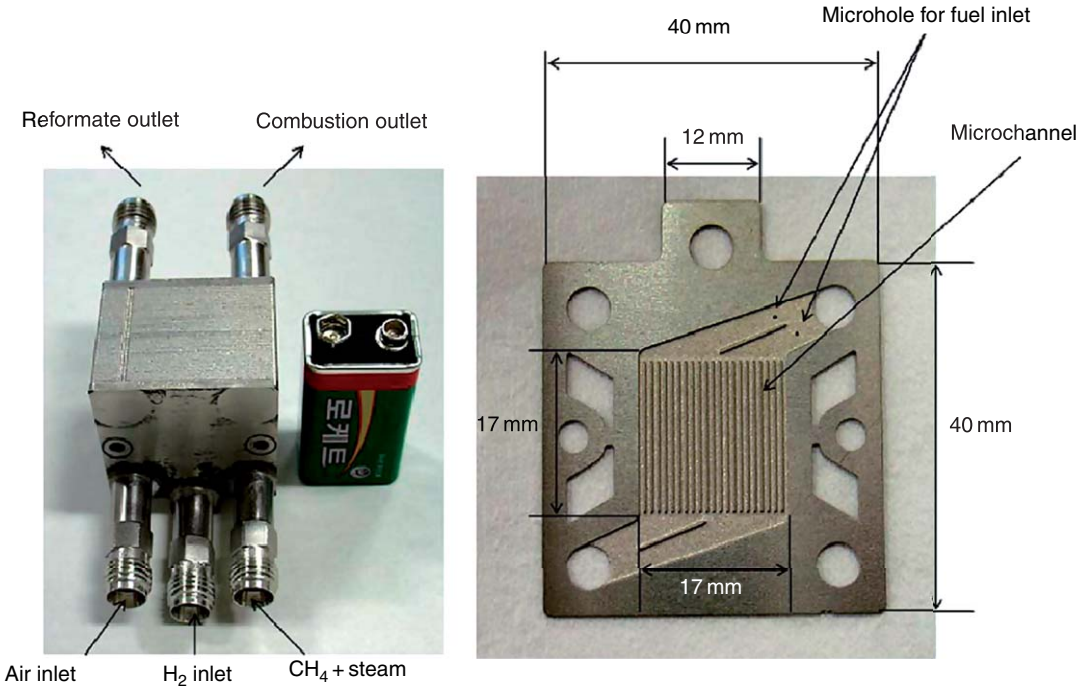

Figure 14 Example for microchannel plates and their assembly. (Source: Ryi S K, Park J S, Choi S H, Cho S H, Kim S H 2005 *Chem. Eng. J.* **113**, 47–53.)

welding as sealing technique (Kolb *et al.* 2007, Tonkovich *et al.* 2004).

(4) Other groups fabricate microchannel plates as described in (2) or by micromachining, then the plates are stacked together in a housing, and closed hermetically, for instance, by use of clamps (Aartun *et al.* 2004, Görke *et al.* 2005, Reuse *et al.* 2004) (**Figure 15**).

(5) Another approach is to use microreactor structures (for instance, foams) surrounded by a gasket and placed inside a metal gasket retainer sheet. This assembly is placed between separation sheets, with cover sheets on top and bottom. The whole array is finally screwed together (Tadd *et al.* 2005).

3.19.5.4.2 Silicon

(1) Microchannels in silicon wafer can be created by standard photolithography followed by deep reactive ion etching (DRIE). The channeled side of the wafer is then bonded with Pyrex glass by anodic bonding (Kawamura *et al.* 2006, Kundu *et al.* 2006, Park *et al.* 2006, Pattekar and Kothare 2005, Srinivas *et al.* 2004, Tanaka *et al.* 2004).

(2) Another method is wet etching of microchannels into a silicon wafer by KOH solution and subsequent anodic bonding with Pyrex glass (Kwon *et al.* 2006).

3.19.5.4.3 Ceramic (LTCC)

(1) Green tape is processed, with the microchannel structure created by mechanical punching, stacked, and laminated under elevated temperature and pressure (110–120 °C, 137–150 bar); LTCC stack can be sintered on a quartz glass plate to maintain uniform shape (Shin *et al.* 2006).

(2) According to Hallmark *et al.* (2006), a novel catalyst paste is applied to green tape using standard filling or screen printing techniques without any change to the ceramic tape process used in high-volume commercial foundries. In addition,

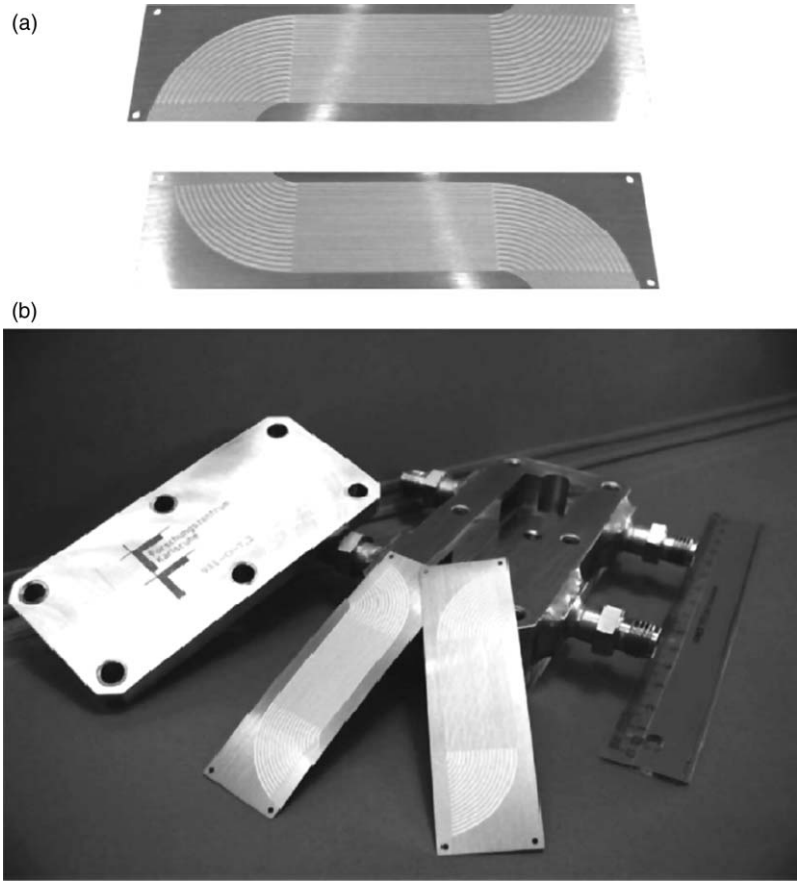

Figure 15 (a) Microstructured plates. (b) Housing of the two-passage microstructured reactor. (Source: Reuse P, Renken A, Haas-Santo K, Görke O, Schubert K 2004 *Chem. Eng. J.* **101**, 133–41.)

this process eliminates the coating fraction limitations inherent in slurry coating (Hallmark *et al.* 2006).

3.19.5.5 Balance of Plant

The balance of plant components were developed by many researchers during the development of microchannel reformers: catalytic burners (Park *et al.* 2005, Ryi *et al.* 2005), microheat exchangers (Ryi *et al.* 2006), evaporators (Yoshida *et al.* 2006), and microejectors (Tanaka *et al.* 2004). Also system insulation is of importance (Kawamura *et al.* 2006, Tanaka *et al.* 2004). Furthermore, system control is a topic that a few researchers address. According to Kothare (2006), new hardware architecture and high-performance control algorithms that can be embedded and integrated with microchemical systems need to be developed.

Thomas Aicher obtained his M.Sc. and Ph.D. in Chemical Engineering from University of Karlsruhe, Germany. His dissertation deals with free and forced convection heat transfer in tube bundle heat exchangers and was completed in 1997. For the next four-and-a-half years he worked for the American Engineering, Procurement and Contracting (EPC) company, Fluor Daniel, Inc. in Aliso Viejo, CA, USA. His assignments included process studies, as well as front end and detail engineering for refineries, power plants, and gas treatment plants. In the beginning of 2002 he joined Fraunhofer ISE in Freiburg, Germany, where he is head of the group Hydrogen Production and Storage. He has published 25 technical and scientific papers on heat transfer, drying technology, gas processing, and reforming technology.

Lisbeth Rochlitz studied Environmental Engineering and Process Engineering with a focus on energy technology and water and sewage-water technology at the Brandenburg Technical University in Cottbus, Germany, and the Beijing Institute of Technology, P.R. China. She obtained her M.Sc. in 2002, and in 2003 she started working at Fraunhofer ISE in Freiburg, Germany. From 2004 through 2006 she held a scholarship from the German Federal Environmental Foundation to carry out her Ph.D. research in the field of microreforming during which she gave several oral presentations at conferences.

Christopher Hebling studied physics at the University of Freiburg with a focus on elementary particle physics. The Ph.D. dissertation, carried out at the Fraunhofer Institute for Solar Energy Systems ISE, dealt with the simulation, realization and characterization of crystalline silicon thin-film solar cells on insulating substrates. The Ph.D. degree in physics was received with summa cum laude in 1998 from the department of physics at the University of Konstanz.

In January 1999 Christopher Hebling founded the Micro Energy Technology group at Fraunhofer ISE which is investigating small energy converters as a supplement or a substitute to batteries. The technologies are device-integrated high efficiency solar cell modules, organic solar cells as well as fuel cells in the low power range. The target market are portable and remotely located electronic appliances with a power demand from some mW to some 100 W.

Since 2001 he is head of the department 'Energy Technology' which is mainly involved in hydrogen generation technologies such as reforming and electrolysis as well as fuel cell technology. The department employs about 70 engineers, scientists and students. He has published about 25 reviewed scientific papers in the field of crystalline silicon solar cells and micro fuel cell systems. Dr. Christopher Hebling is 44 years old, is married and has three children.

3.20 Molecular Machine-Based NEMS

Tony Jun Huang, Department of Engineering Science and Mechanics, The Pennsylvania State University, University Park, PA, USA

3.20.1 Introduction

Machines are extensively used in our daily lives. The *Oxford English Dictionary* defines a machine as an apparatus for applying mechanical power, having several parts each with a definite function (Hawkins 1979). The concept of a machine can be extended to the molecular level. Although there are many chemical compounds whose structure and/or shape can be modified by an external stimulus, the term molecular machine will only be used for systems whose component parts undergo movements of relatively large amplitudes. Furthermore, systems in which the molecular movements are not controlled by some easily identifiable and well-characterized external stimulus will not be considered to be molecular-level machines. For example, due to thermal energy, molecules in solution are almost never stationary and are consequently not considered to be molecular machines because such thermal movement is not controllable. Therefore, a molecular machine can be defined as an assembly of a discrete number of molecular components designed to perform mechanical-like movements (output) as a consequence of appropriate external stimuli (input) (Balzani *et al.* 2000, 2003).

The concept of a machine at the molecular level is not new. Our bodies can be viewed as very complex ensembles of molecular-level machines (Boyer 2002, Goodsell 1996). Natural molecular machines are individual protein molecules that are ultimately responsible for essentially all active biological motions. Important examples of natural molecular machines are myosin, kinesin, and ATPase. They perform vital, life-sustaining tasks, some of which include muscle contraction, cell division, intracellular transport, and genomic transcription. The idea of constructing artificial molecular-level machines, however, is quite a recent one. In 1959, Richard Feynman, one of the greatest physicists and teachers of the 20th century, originated the idea of artificial molecular machines in his historic address to the American Physical Society, "There is plenty of room at the bottom" (Feynman 1960). The Nobel laureate contemplated, "What are the possibilities of constructing molecular-scale mechanical machines ··· What would be the utility of such machines? Who knows? I cannot see exactly what would happen, but I can hardly doubt that when we have some control of the arrangement of things on a molecular scale we will get an enormously greater range of possible properties that substances can have, and of the different things we can do." In the early 1980s, the earliest examples of synthetic molecular-level machines were reported and they were based on the

photoisomerization of azobenzene (Shinkai and Manabe 1984). Since then, the development of artificial molecular machines has become one of the most intriguing topics in the field of nanoscience and nanotechnology.

This chapter commences with a review of biological molecular machines and their applications in nanoelectromechanical systems (NEMS). Subsequently, various artificial molecular machines will be introduced. Next, the author will describe the research he and his colleagues have conducted in the past few years on moving artificial molecular machines from solution to solid supports to NEMS device settings. Finally, the chapter concludes with a perspective for future developments.

3.20.2 Biological Molecular Machines and Their Applications in NEMS

Biological molecular machines are molecular proteins that convert the chemical energy released by hydrolysis of adenosine 5′-triphosphate (ATP) into mechanical energy. Ubiquitous in biological systems, molecular machines are responsible for the directed transport of macromolecules, membranes, or chromosomes within the cytoplasm, thus playing a critical role in cell behavior and architecture (Boyer 2002, Goodsell 1996, Howard 1997, Vall and Milligan 2000). Over the past decade, interest in motor molecules has blossomed. Atomic structures of various motors have been solved by X-ray crystallography; new motors have been discovered; forces, steps, and speeds have been measured at the molecular level; hybrid devices integrating bottom-up-based biomolecular motors and top-down-based nanoengineered structures have been realized. These scientific breakthroughs have not only led to a much improved understanding of cell motility but have also profound impact in the field of nanoscience and nanotechnology.

3.20.2.1 Myosin and Kinesin

Enzymes such as myosin, kinesin, and their relatives are linear motors that convert the energy of ATP hydrolysis into mechanical work along polymer substrates – myosin along actin filaments in muscles and cells and kinesin along microtubules (**Figure 1**) (Cross and Duncan 1996, Howard *et al.* 1989, Kull *et al.* 1996). In a kinesin molecule, two heads, each about 8 nm long, are joined at the coiled-coil neck. The neck then connects to a long coiled coil that terminates in the tail region and binds to the organelle cargo. Myosin's heads are about twice the size of kinesin's and are composed of two major domains: the motor domain that binds to actin and nucleotides and the regulatory domain that is an 8-nm-long α-helix stabilized by two calmodulin-like light chains. A long coiled-coil rod connects to the regulatory domain and oligomerizes to form the thick filament in muscle.

The developments in DNA/RNA sequences have helped reveal the similarities between myosin and kinesin (Kull *et al.* 1996). The core 180 amino acids within the myosin and kinesin head structures have the same fold. Furthermore, the preserved

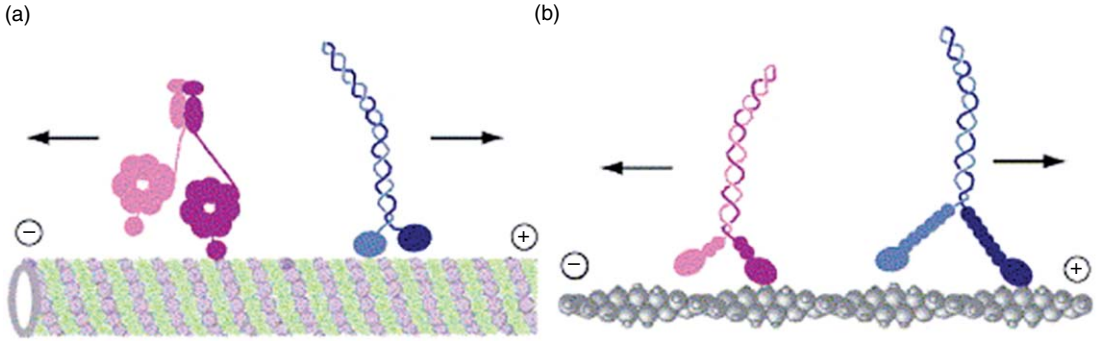

Figure 1 Linear motors that walk along cytoskeletal filaments: (a) kinesin and dynein motor that move to the plus and minus end, respectively, of a microtubule; and (b) myosin V and myosin VI that move to the plus (barbed) and minus (pointed) end, respectively, of an actin filament. (Source: Lipowsky R, Klumpp S 2005 Life is motion: Multiscale motility of molecular motors. *Physica A* **352**, 53–112.)

sequence direction and order of the α-helices and β-sheets within the core suggest that these two biomotors evolved from a common ancestor. Yet despite these structural similarities, there are profound functional differences between kinesin and myosin. Conventional kinesin operates alone or in small numbers to transport membrane-bound organelles over large distances (up to a millimeter) along microtubules, whereas muscle myosin operates in huge arrays of up to a billion molecules in a large muscle fiber and moves relatively short distances (up to about 1 μm) along actin filaments (**Figure 2**) (Hackney 1996, Lipowsky and Klumpp 2005). Myosin provides the power for all of our voluntary motions (running, walking, lifting, etc.) as well as for involuntary muscles (e.g., a beating heart).

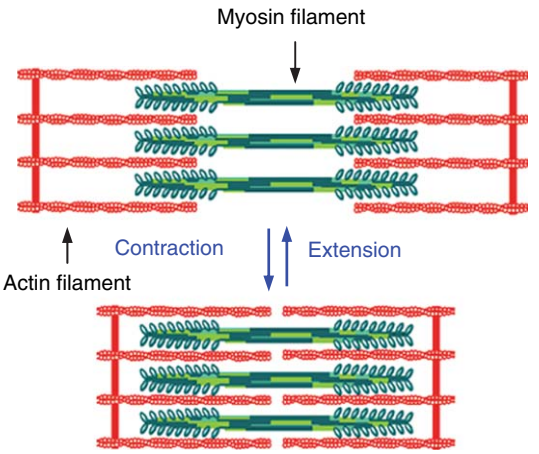

Figure 2 The sliding of myosin along actin filaments causes muscle contraction and extension.

Recent years have witnessed a strong interest in the exploration of biological molecular machines for NEMS applications. Limberis and Stewart (2000) demonstrated that kinesin can be engineered and used to transport silicon microchips along microtubules. Negatively charged microtubules bound electrostatically to a positively charged coverslip and were aligned in a microfluidic channel. Next, genetically modified kinesin motors attached with silicon microchips were added into the microfluidic channel. The microchips were observed to move in various ways (**Figure 3**), depending on how they were bound to microtubules. If a microchip moved along parallel microtubules, it traveled along linearly, with a maximum speed of approximately 0.8 μm s^{-1} (**Figure 3a**). When it interacted with antiparallel microtubules, it rotated (**Figure 3b**). A microchip with one end fixed flipped over (**Figure 3c**). This work proved that kinesin motors had enough force to transport cargo, such as silicon microchips that are much larger than kinesin molecules, thus paving the way for future development of biomotor-based NEMS.

To improve the efficiency of kinesin-based NEMS, the direction of the microtubules must be controlled and aligned. Hiratsuka *et al.* (2001) developed a lithographic process to restrict the microtubules onto fabricated tracks and control the direction of kinesin's mechanical motion. The experiment used two concentric circles with arrowhead patterns facing opposite directions (**Figure 4**). Without the arrowheads in the pattern, the microtubules would travel either clockwise or counterclockwise in either circle. However, once

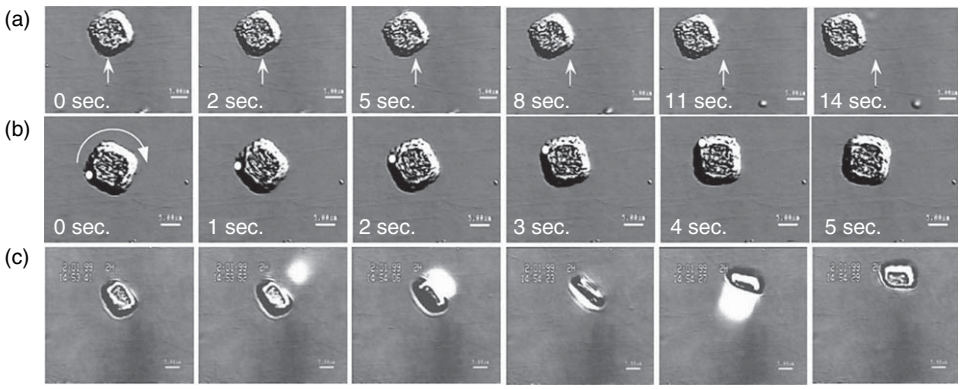

Figure 3 Kinesin-powered silicon microchips. Bar, 5 μm. (a) The chip moves on parallel microtubules at 0.8 μm s^{-1}. The arrow is a fixed reference point. (b) The chip rotates clockwise on antiparallel microtubules. A reference dot was placed on one corner of the chip. (c) The chip flips perpendicular to the surface. (Source: Limberis L, Stewart R J 2000 Toward kinesin-powered microdevices. *Nanotechnology* **11**, 47–51.)

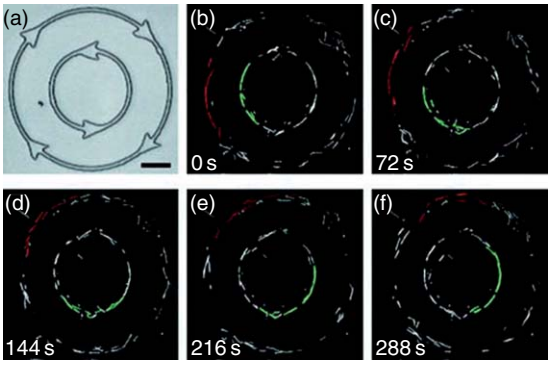

Figure 4 Unidirectional movement of microtubules along circular tracks. (a) Image of the arrowhead pattern. (b–f) Photographs demonstrating the microtubule rotational movement were taken at 72-s intervals beginning 20 min after the addition of adenosine 5′-triphosphate (ATP). Some filaments were dyed to facilitate the tracking of microtubules: the red microtubules are moving clockwise and the green microtubules are moving counterclockwise. (Source: Hiratsuka Y, Tada T, Oiwa K, Kanayama T, Uyeda T Q P 2001 Controlling the direction of kinesin-driven microtubule movements along microlitho-graphic tracks. *Biophys. J.* **81**, 1555–61.)

the pattern of arrowheads was added, within a few minutes the microtubules would travel in the same direction that the arrows pointed toward. As microtubules enter the arrowhead from the correct direction, they could easily pass through; however, if microtubules entered from the reverse direction, they would usually bump against the wall at the base of the arrow and turn around. Four different versions of the arrowhead pattern were tested; the most efficient pattern had a probability of a 73% chance of reversing microtubules in the wrong direction.

The alignment of microtubules for guiding the long-range transportation of kinesin motors has also been investigated. Platt *et al.* reported the alignment of magnetic nanoparticle functionalized microtubules in magnetic fields (**Figure 5**). In their study, microtubules were labeled with cobalt ferrite ($CoFe_2O_4$) nanoparticles through the biotin–neutravidin binding. When placed above a magnet, magnetized microtubules were aligned to match the orientation of magnetic line. It was also shown that microtubules could respond to the changing of magnetic orientation and reorient them within several seconds.

Recently, Van den Heuvel *et al.* (2006) reconstituted the kinesin–microtubule transport system in enclosed fluidic channels and realized active electrical control of the direction of individual kinesin-propelled microtubule filaments at Y-junctions. Using this technique, they demonstrated molecular sorting of differently labeled microtubules (**Figure 6**). The steering of microtubules is attributed to electric field-induced bending of the leading tip. From measurements of the orientation-dependent electrophoretic motion of individual, freely suspended microtubules, they estimate the net applied force on the tip to be in the range of piconewtons.

Transportation is not the only attribute of biological molecular machines. Hess *et al.* (2002) have developed a forcemeter assembled from kinesin and microtubules (**Figure 7**). One microtubule with

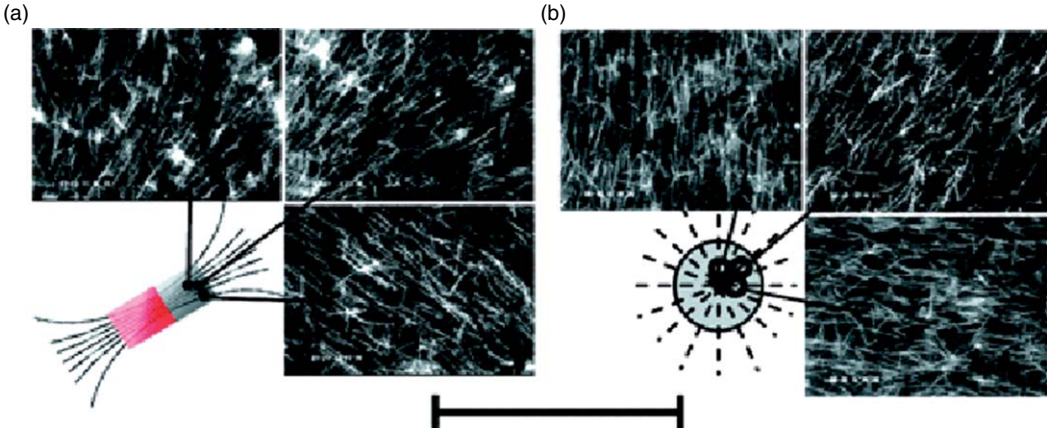

Figure 5 Fluorescence microscopy images of 37% biotinylated microtubules aligned with (a) a bar magnet for 3 min and (b) a cone magnet for 10 min. Scale bar = 116 μm. Figure 7 The cantilevered microtubule (MT) is attached on one end to a clump of beads, whereas the other end is suspended above the surface. Swiveling due to Brownian motion causes the smeared-out appearance of the free end. The moving microtubule is propelled by kinesin motor proteins adsorbed to the surface and carries a clump of beads. The snapshots show how the moving microtubule approaches (0 s), makes contact (10 s), bends (20 and 30 s), and releases (40 s) the cantilevered microtubule. (Source: Hess H, Howard J, Vogel V 2002 A piconewton forcemeter assembled from microtubules and kinesins. *Nano Lett.* **2**, 1113–15.)

known stiffness serves as a cantilever. Force is applied by another microtubule propelled by kinesin motor proteins adsorbed to a surface. The two microtubules are attached by a link whose strength is to be determined. The moving microtubule continues to travel while bending the molecular cantilever until the link ruptures. The force on the link can be calculated based on the bending of the cantilevered microtubule, the distance traveled by the second microtubule, and the angle between the two microtubules. Since this forcemeter measures forces at the range of piconewtons, it is ideal for measuring the strength of biological receptor/ligand pairs, such as streptavidin/biotin.

3.20.2.2 ATPase

ATP synthase (ATPase) is a ubiquitous protein that functions as a proton pump and the primary source of ATP for most eukaryotic cells (Allison 1998, Block 1997, Elston *et al.* 1998, Uptain *et al.* 1997, Yin *et al.* 1995). It manufactures ATP from ADP and phosphate by using the energy derived from a transmembrane protonmotive gradient. It can also reverse itself and hydrolyze ATP to pump protons against an electrochemical gradient. ATPase carries out both its synthetic and its hydrolytic cycles by a rotary mechanism. The general structure of an F_0F_1-ATPase is shown in **Figure 8**. It consists of two portions: a soluble component, F_1, containing the catalytic sites, and a transmembrane component, F_0, comprising the proton channel. The entire F_0F_1 structure is arranged as a counterrotating rotor and stator assembly. The stator portion consists of the

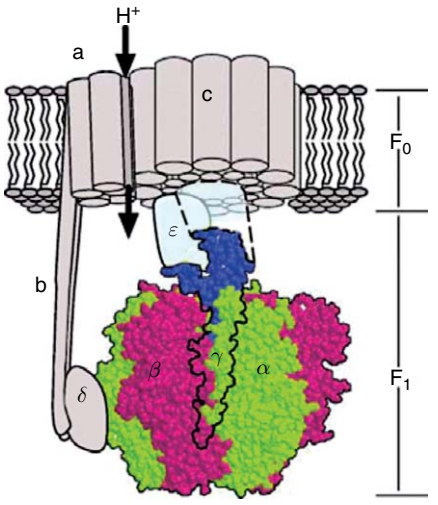

Figure 8 Schematic drawing of an F_0F_1-ATP synthase. (Source: Allison W S 1998 F_1-ATPase: A molecular motor that hydrolyzes ATP with sequential opening and closing of catalytic sites coupled to rotation of its subunit. *Acc. Chem. Res.* **31**, 819–26.)

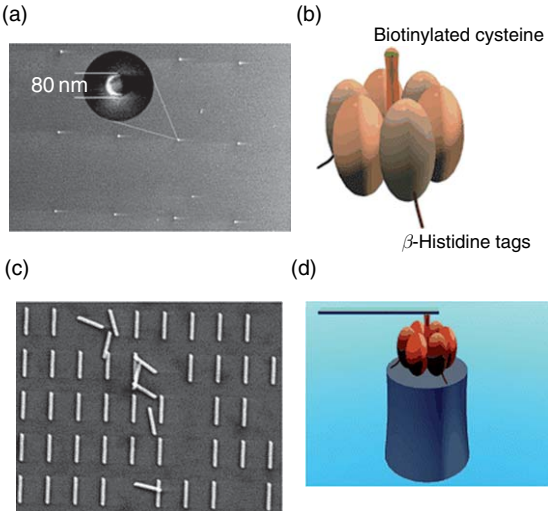

Figure 9 F_1-ATPase-powered nanomechanical device. The device consists of (a) nickel post (height 200 nm, diameter 80 nm), (b) F_1-ATPase motor, (c) nanopropellers (length 750–1400 nm, diameter 150 nm), and (d) assembled device. (Source: Soong R K, Bachand G D, Neves H P, Olkhovets A G, Craighead H G, Montemagno C D 2000 Powering an inorganic nanodevice with a biomolecular motor. *Science* **290**, 1555–8.)

catalytic sites contained in the $\alpha_3\beta_3$ hexamer, together with subunits a, b_2, and δ. The rotor consists of 9–12 c-subunits arranged in a ring and connected to the γ- and ε-subunits that form the central shaft.

Recently, the rotation of F_1-ATPase was directly observed during ATP hydrolysis by attaching a fluorescent actin filament to the γ-subunit and immobilizing the $\alpha_3\beta_3$ subunit on a coverslip (Noji *et al.* 1997). In another experiment (Soong *et al.* 2000), F_1-ATPase was integrated with inorganic nanoengineered systems to form hybrid organic–inorganic nanomechanical devices powered by biological molecular motors (**Figure 9**). The device consisted of three parts: (1) nanofabricated nickel posts; (2) recombinant F_1-ATPase motors that were engineered to adhere with the nanofabricated structures; and (3) engineered nanopropellers. To integrate these components into one functional unit, the F_1-ATPase biomolecular motors were biotinylated and then attached to the nickel posts using histidine tags engineered into the β-subunit. In addition, the nickel nanopropellers were linked to the γ-subunit using streptavidin/biotin. The rotation of the propellers was tested with and without ATP to prove the dependency on the F_1-ATPase motor. With the ATP, only five of the 400 propellers rotated continuously. Approximately 80% of the propellers did not move at all. It is thought that the propellers may have been attached to move than one motor or attached to the substrate in addition to the motor. Rotational velocity of the propellers varied depending on the point of attachment and the length of the propeller. Even though the device needs further improvement, it laid the foundation for the future development of NEMS using F_1-ATPase as the active nanostructure.

3.20.3 Artificial Molecular Machines

Biological molecular motors are intrinsically designed for the physiological conditions (37°C, pH 7.0) within the human body. These restrictions, in addition to the difficulties in modifying their structure and functionality, hinder integration with man-made devices. In this regard, the future of molecule-driven actuators lies in the development of artificial molecular motors as opposed to biomolecular motors. The ability to synthesize analogical molecular versions of macroscopic machinery is considered to be an essential step toward the construction of molecular devices capable of performing mechanical work and storing/transmitting information (Balzani *et al.* 2003). Like their macroscopic counterparts, artificial molecular machines are characterized by the (1) form of energy input enabling activation, (2) kind of movement executed by their components, (3) way in which their operation can be controlled and monitored, (4) possibility to repeat the

operation at will, (5) timescale needed to complete a cycle of operation, and (6) function performed. Recent advances in synthetic chemistry have yielded analogs of rotors, gears, switches, shuttles, turnstiles, and ratchets (Balzani *et al.* 2003). This section focuses on some of the most successful artificial molecular machines: rotaxanes, catenanes, and pseudorotaxanes.

Catenanes and rotaxanes along with their mechanically threaded supramolecular progenitors, pseudorotaxanes, are composed of mutually recognizable and intercommunicating ring and dumbbell-shaped components (Anelli *et al.* 1991, 1997, Ashton *et al.* 1991, Bissell *et al.* 1994, Brouwer *et al.* 2001, Martínez-Díaz *et al.* 1997, Raehm *et al.* 1999, Stoddart and Tseng 2002). When stimulated by light, electricity, or chemical reagents, mechanically interlocked molecules experience relative internal motions (rotary and linear), with their components behaving like the moving parts of macroscopic machines (**Figure 10**). These mechanically interlocked components recognize each other by means of donor/acceptor ([$\pi\cdots\pi$]) and additional ([C–H$\cdots$O] and [C–H$\cdots\pi$]) interactions that can be switched off by either oxidizing the donors or reducing the acceptors. The redox chemistry is usually reversible, and consequently, the interactions can be turned on again at will. Through proper selection of the redox-controllable recognition sites within the components, these interlocked molecules can be induced to switch chemically, electrochemically, or photochemically between two or more mechanically different states.

A rotaxane is a molecule composed of a macrocyclic and a dumbbell-shaped component (**Figure 10a**). The macrocycle encircles the linear rod-like portion of the dumbbell-shaped component and is trapped mechanically around it by two sizable stoppers. Thus, the two components cannot dissociate from one another, even though they are not covalently bonded to each other. The structural formula and graphical representation of a bistable rotaxane **R1** is shown in **Figure 11**. **R1** consists of a tetracationic $CBPQT^{4+}$ ring component and a linear rod section that contains two different stations: a tetrathiafulvaline (TTF) unit and a dioxynaphthalene (DNP) unit. The **R1**'s starting state has its TTF unit encircled by the positively charged ring. Upon oxidation, the TTF unit becomes dicationic (TTF^{2+} and experiences electrostatic repulsion with the ring, causing the ring to shuttle toward the DNP unit in the oxidized state. Conversely, the reduction of the TTF^{2+} back to a neutral TTF unit causes **R1** to return to its starting state. This reversible bistable rotaxane via ring translation can therefore be equated as a linear molecular motor.

By contrast, a catenane is a molecule composed of two interlocked macrocyclic components. The two macrocycles are not covalently bonded to each other, but rather mechanically linked, preventing their dissociation. The incorporation of two different recognition sites within the asymmetric macrocycle (**Figure 10b**) allows the symmetric macrocyle component to preferentially reside around one of these two positions. By switching on or off the properties at one of the two recognition sites of the asymmetric macrocycle, the relative position of the two species can be reversibly controlled. The complexation/decomplexation of metal ions or neutral organic molecules, protonation/deprotonation, and oxidation/reduction processes can all be exploited to reversibly alter the stereoelectronic properties of one

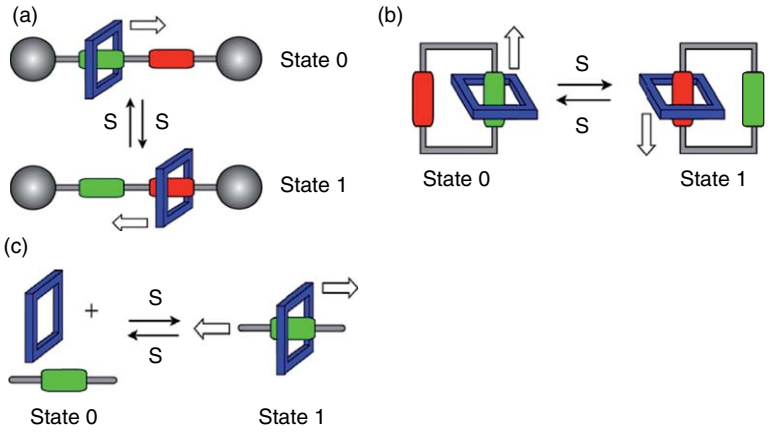

Figure 10 Schematic of a bistable (a) rotaxane, (b) catenane, and (c) pseudorotaxane.

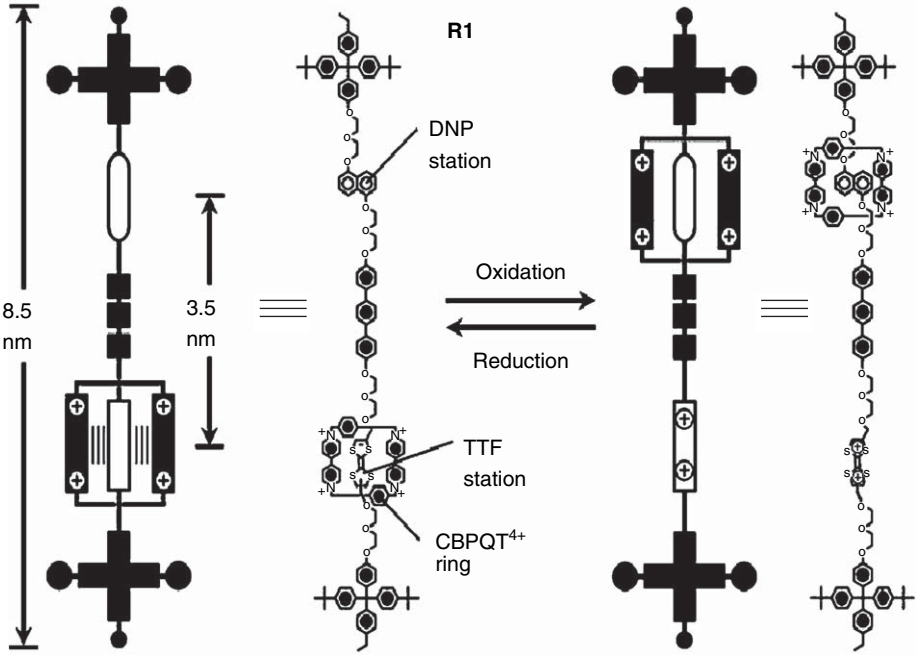

Figure 11 Molecular structure and schematic representations of a redox-controllable rotaxane molecular motor **R1**.

of the two recognition sites, thus affecting the ability to sustain noncovalent bonds. A pseudorotaxane is rotaxane's mechanically threaded supramolecular progenitor and can be reversibly dissociated into a free ring-type host and a free thread-type guest, thus giving rise to a dethreading/rethreading motion (**Figure 10c**).

Artificial molecular machines such as rotaxanes, catenanes, and pseudorotaxanes are integral components in developing functional nanosystems for nanotechnology. For example, as actuation materials, bistable rotaxanes have at least six advantages: (1) They can generate large strains up to 42%, while the strains generated by the gold-standard actuation materials, such as piezoelectric materials, are typically 0.1–0.2% (**Figure 12**) (Gad-El-Hak 2001, Kovacs 1998, Liu 2006, Madou 2002). (2) They have high force density, e.g., a bistable rotaxane generates a 100-pN force (Brough *et al.* 2006, Liu *et al.* 2005), while a kinesin biomotor, which is much larger than a bistable rotaxane, can only generate 6 pN (Howard 1997, Kull *et al.* 1996). (3) They can undergo controlled mechanical motion for various external stimuli (chemical (Bissell *et al.* 1994, Martínez-Díaz *et al.* 1997), electricity (Brouwer *et al.* 2001, Raehm *et al.* 1999), and light (Ashton *et al.* 1991)), while traditional actuation materials and biomotors must both rely on a single stimulus. (4) They can be

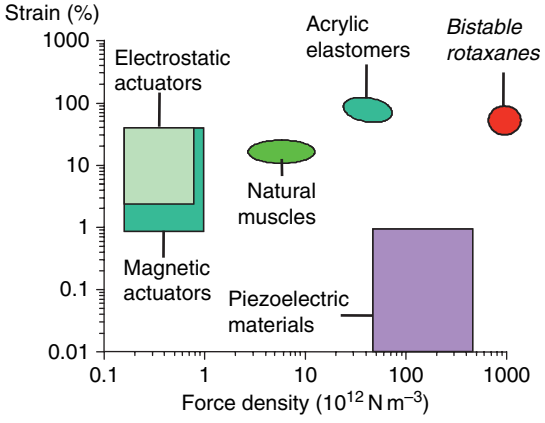

Figure 12 Comparison of different actuation materials.

made metastable, with the molecules persisting in their actuated state long after the stimulus has been removed, and thus saving energy. (5) They can be customized and optimized, therefore conferring the flexibility necessary for a multitude of engineering applications. For example, they can be derivatized with disulfide tethers to facilitate the formation of self-assembled monolayers (SAMs) (Tseng *et al.* 2004) or prepared with amphiphilic properties to facilitate the formation of Langmuir–Blodgett (LB) films (Lee *et al.* 2004, Petty 1996), both of which are key bottom-up nanomanufacturing technologies for

Table 1 Comparison between biomotors and bistable rotaxanes

	Biological molecular motors	*Bistable rotaxanes*
Surviving condition	Physiological conditions only (37°C, pH 7.0)	T −30 to +100°C, pH 5.0–9.0
Flexibility	Difficult to modify structures/functions	Easy to modify
Stimuli	Chemical only	Chemical, electricity, or light
Frequency	~1 Hz	Up to 1 MHz
Size (nm^3)	30–100	8
Force (pN)	~6 (kinesin)	40–100

the simultaneous self-organization of a multitude of molecules. (6) Bistable rotaxanes can survive in a wide range of temperatures (−30°C to 100°C) and pH values (5.0–9.0), while biomotors are restricted to physiological conditions ($T \sim 37°C$, $pH \sim 7.0$). These advantages indicate that although biomotors are perfect actuators in human bodies, artificial molecular motors such as bistable rotaxanes are more suitable for the development of molecular motor-based engineering applications (**Table 1**).

3.20.4 Moving Artificial Molecular Machines from Solution to Solid Supports

Thus far, it has been demonstrated in solution by numerous researchers that artificial molecular machines can exhibit substantial relative movements of their rings with respect to their dumbbell-shaped components (Balzani *et al.* 2000, 2003, Goodsell 1996). A solution, however, contains a large number of randomly distributed molecules that cannot be addressed individually or expressed coherently as they would be required to do in a device setting. In order to explore the full potential of these molecular-level machines and to develop functioning mechanical devices, molecules must be interfaced with the macroscopic world by imposing upon them a high degree of orientational control. In the ideal interface between artificial molecular machines and a solid support, the molecules would behave coherently, either in parallel or in series, and be addressable on the nanometer scale. More importantly, molecular machines' switching behavior demonstrated in solution still exists when molecules are in condensed phases on solid supports. This section will focus upon the author's and his colleagues' work on moving artificial molecular machines from solution state to solid state (Huang *et al.* 2004b, 2006).

3.20.4.1 Switching Artificial Molecular Machines in Solution

Since rotaxanes and catenanes were invented, UV/Vis spectroscopy has been established as an efficient tool to characterize the rotaxanes' chemical states in solution (Goodsell 1996). The UV/Vis spectrum (**Figure 13**, *curve a*) of a starting-state bistable rotaxane (**Figure 11**) revealed a charge transfer (CT) absorption band centered at 846 nm, characteristic of the translational isomer in which the TTF recognition site was encircled by the ring component. Furthermore, no absorption band was observed in the 500–560 nm region for the CT interaction that would result from another suspected translation isomer in which the DNP recognition site is encircled by the ring.

Chemical switching of the rotaxane molecular motor (8.0×10^{-4} M in acetonitrile) can also be monitored by UV/Vis spectroscopy (Tseng *et al.* 2003). $Fe(ClO_4)_3$ was used as the oxidant in MeCN. As shown in **Figure 13** (*curve b*), addition of the equivalent of one oxidant leads to a decrease in the intensity of the

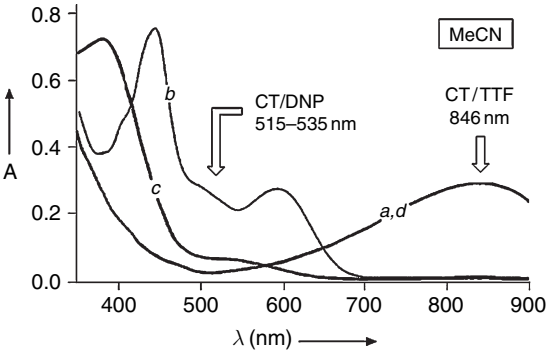

Figure 13 Absorption spectra (MeCN, 298 K) of a solution of bistable rotaxane **R1** (*curve a*) and of the same solution after the addition of 1 and 2 equivalents of $Fe(ClO_4)_3$ (*curves b* and *c*). Addition of ascorbic acid (2 equivalents) regenerates the original spectrum (*curve d*). (Source: Tseng H-R, Vignon S A, Stoddart J F 2003 Toward chemically controlled nanoscale molecular machinery. *Angew. Chem. Int. Ed.* **42**, 1491–5.)

CT band at 846 nm. Accompanying this decrease, an increase in the intensity of absorption bands centered at 450 and 600 nm, characteristic of the mono-oxidized form of the TTF unit, was observed. As a consequence of these spectral changes, a new CT interaction was observed at 515 nm as a shoulder-like absorption band. Further addition of the oxidant (up to 2 equivalents) caused the disappearance of the absorption band of mono-oxidized TTF and formation of a new band at 375 nm, which is attributed to the bis-oxidized TTF unit. A clear CT band (at 530 nm) corresponding to the encirclement of DNP ring system by the cyclophane ring can now be seen (**Figure 13**, *curve c*). Furthermore, addition of 2 equivalents of ascorbic acid as the reductant leads to restoration of the original spectrum (**Figure 12**, *curve d*).

3.20.4.2 Depositing Artificial Molecular Machines on Solid Substrates

We have used the LB technique (Petty 1996) to deposit artificial molecular machines onto solid substrates. In a typical LB experiment, amphiphilic molecules, with hydrophobic and hydrophilic ends, are dissolved in an organic solvent and the organic material is spread onto the air–water interface. After the organic solvent evaporates, a monolayer is left on the water surface. Next, moving barriers compress the films to a more organized and closely packed state. Films on the subphase, usually water, are called Langmuir monolayers, or Langmuir films. Monolayers transferred from the liquid–air interface to a solid substrate are called LB films. Atomic force microscopy (AFM) has been used to investigate the rotaxane LB film on solid supports. All monolayers were transferred to mica. As shown in **Figure 14**, domains formed at the air–water interface can be transferred to solid substrates, and at higher transfer pressure, domains are more compact. At surface pressures higher than 35 mN m^{-1} (Kovacs 1998), monolayers start to form folds in some regions and partial collapse can happen. AFM studies have confirmed that the optimal deposition pressure is around 30 mN m^{-1}.

(Source: Huang T J, Flood A H, Brough B, Liu Y, Bonvallet P A, Kang S, Chu C, Guo T F, Lu W X, Yang Y, Stoddart J F, Ho C M 2006 Understanding and harnessing biomimetic molecular machines for NEMS actuation materials. *IEEE Trans. Autom. Sci. Eng.* **3**, 254–9.)

3.20.4.3 Operating Artificial Molecular Machines in Condensed Phases on Solid Substrates

We have demonstrated, for the first time, from analyses of X-ray photoelectron spectra that redox-controllable molecular machines in the shape of amphiphilic, bistable rotaxanes are mechanically switchable in closely packed Langmuir films with chemical reagents. Most importantly, mechanical switching has been proven to occur in LB bilayers while mounted on solid substrates. The results not only constitute a proof-of-principle but also provide the impetus to continue forward and develop solid-state, artificial molecular machine-based NEMS.

3.20.4.3.1 Molecules' structural formulas

The structural formula and graphical representation of the amphiphilic, bistable rotaxane **R2** are shown in Figure 15. The molecule consists of a tetracationic ring component (dark blue) and a linear rod section that contains two different stations, a TTF unit (green) and a DNP unit (red), separated by a rigid

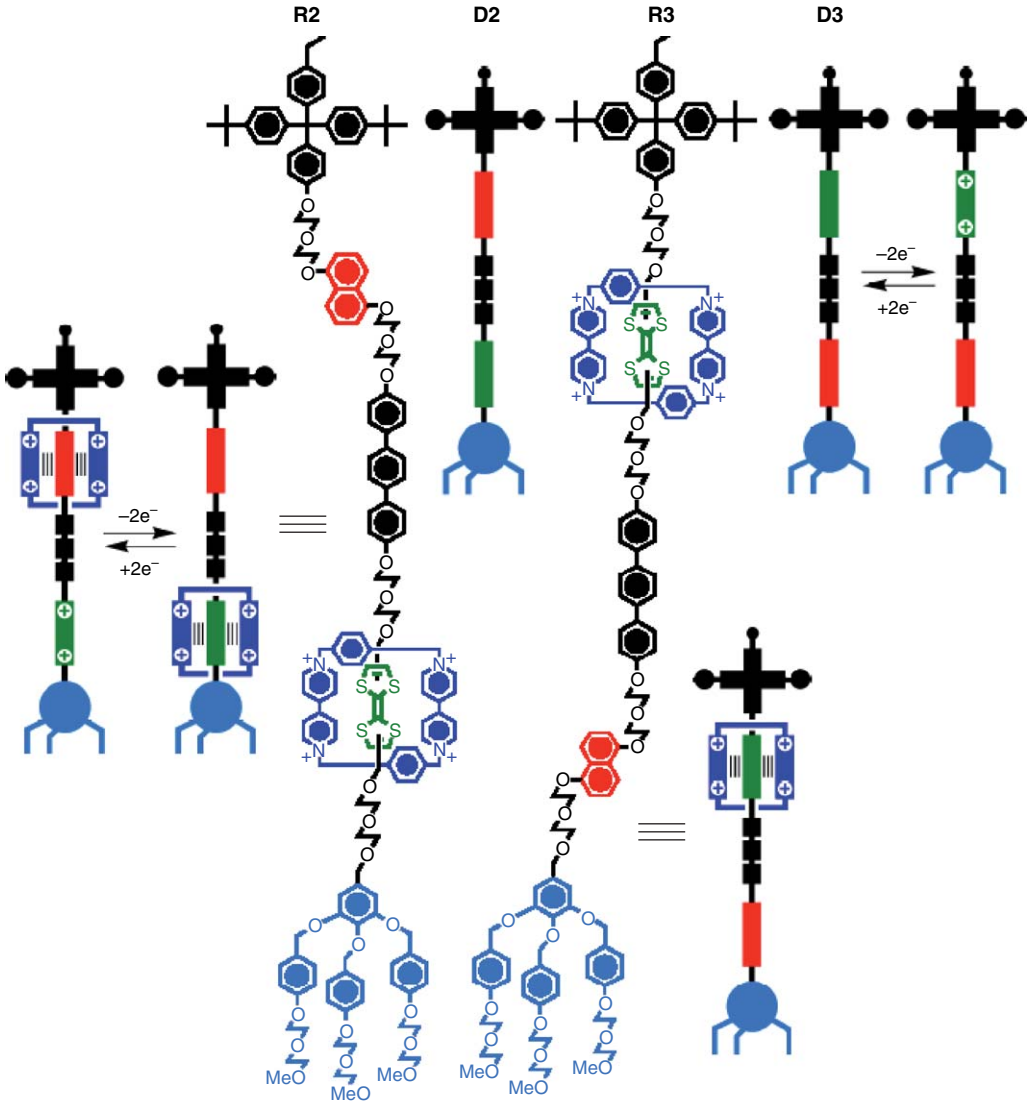

Figure 15 Structural formulas and idealized graphical representations of the rotaxane **R2** and control compounds – the dumbbell **D2** of **R2** and the constitutionally isomeric rotaxane **R3** and its dumbbell **D3**. (Source: Huang T J, Tseng H-R, Sha L, Lu W, Brough B, Flood A H, Yu B-D, Celestre P C, Chang J P, Stoddart J F, Ho C-M 2004b Mechanical shuttling of linear motor-molecules in condensed phases on solid substrates. *Nano Lett.* **4**, 2065–71.)

terphenylene spacer (black). A hydrophilic (light blue) and hydrophobic (black) stopper is incorporated at each end of the rod, enabling the molecules to form LB films. The starting-state **R2** of this bistable rotaxane has its TTF unit encircled by the tetracationic ring. Upon oxidation, the TTF unit becomes dicationic (TTF^{2+}) and experiences coulombic repulsion with the tetracationic ring, causing the ring to shuttle toward the DNP unit in the oxidized state. Conversely, the reduction of the TTF^{2+} dication back to a neutral TTF unit causes the rotaxane to return to its starting state. Thus, this rotaxane, with these two reversibly switchable redox states involving ring translation, can be likened to a linear molecular motor.

Figure 15 also shows the structural formulas and graphical representations of other compounds, the dumbbell **D2** of **R2** and the constitutionally isomeric rotaxane **R3** and its dumbbell **R3**, used in the control experiments. The difference between **R2** and **R3** relates only to the relative positioning of the TTF and DNP recognition sites with respect to the two different stoppers. The dumbbells **D2** and **D3** are both neutral compounds in which the rings have been removed from the rotaxanes **R2** and **R3**, respectively.

3.20.4.3.2 X-ray photoelectron spectroscopy (XPS) analysis

The LB technique of generating monolayer films allows the transfer of organized monolayers from an air–water interface to a solid substrate. It takes advantage of the amphiphilic nature of rotaxanes, allowing the construction of highly ordered molecular assemblies. In addition, artificial molecular machines in LB films are considered to be in a liquid-crystal-like environment, which maintains the mechanical switching properties seen in solution. The combination of the ordered structure in solid state and switching behavior in solution state makes the LB technique an ideal method for establishing the interface between rotaxane and solid supports.

XPS measurements (Compton 2001, Woodruff and Delchar 1994) have been carried out on Langmuir films of both amphiphilic, bistable rotaxanes (**R2** and **R3**) and their respective dumbbells (**D2** and **D3**). The XPS data were obtained on a VG ESCALAB electron spectrometer using A1 Kα X-ray radiation (1486.6 eV) with a pass-energy of 20 eV at a take-off angle of 90° (normal to the film surface). The photoemission of surface carbon (C 1s) at 284.6 eV was used as the reference binding energy. Langmuir monolayers and LB films were fabricated using a KSV 2000 Alternate Trough System. All monolayers were transferred to hydrophilic silicon dioxide substrates at a surface pressure of 25 mN m^{-1} as LB films. Before monolayer depositions, the silicon dioxide substrates were prepared as follows: (1) Piranha ($H_2SO_4/H_2O_2 = 5{:}1$) cleaning for 5 min, (2) deionized water cleaning for 5 min, and (3) air drying. Film thickness measurements were performed using a Gaertner L116B Ellipsometer with a refractive index of 1.46.

The photoemission intensity of each element depends on the depth at which the photoelectron is emitted and it attenuates exponentially with increased depth. Therefore, the XPS technique can be used to differentiate atoms at different depths within a film. The XPS signal intensity ($I_{A,Z}$) for a layer of atoms (A) buried at a distance Z underneath the film surface can be expressed as (Huang *et al.* 2004a):

$$I_{A,Z} = I_A^0 \cdot \exp\left(\frac{-Z}{\lambda(E_A)\cos\theta}\right)$$

where I_A^0 represents the signal intensity obtained from a layer of atoms located at the film surface, $\lambda(E_A)$ is the photoelectron attenuation length of A, which is a function of the kinetic energy of the emitted photoelectrons, and θ is the electron emission angle, which equals 0° in the present investigation. Thus, the photoemission intensity from a layer of atoms A embedded closer to the surface (smaller Z) will be stronger than that arising from a layer of the same atoms buried deeper (larger Z) in the film.

Molecular shuttling can be monitored by using XPS to track nitrogen (N), which is solely present on bistable rotaxane's only moving unit: the ring component. Langmuir monolayers were prepared for both the starting-state and oxidized rotaxanes (**R2** and **R3**), along with their dumbbell counterparts **D2** and **D3**, respectively. Next, monolayers were transferred to substrates as LB films for XPS analysis. **Figure 16a** shows the N 1s photoemission spectra of the starting-state and oxidized **R2**, along with its dumbbell counterparts **D2**. There is no nitrogen signal observed in the ringless dumbbell experiments, confirming that the peaks revealed in the **R2** scans are from the nitrogen atoms in the ring. Furthermore, a higher intensity of N 1s peak is observed for the oxidized rotaxane **R2** film than for the starting state,

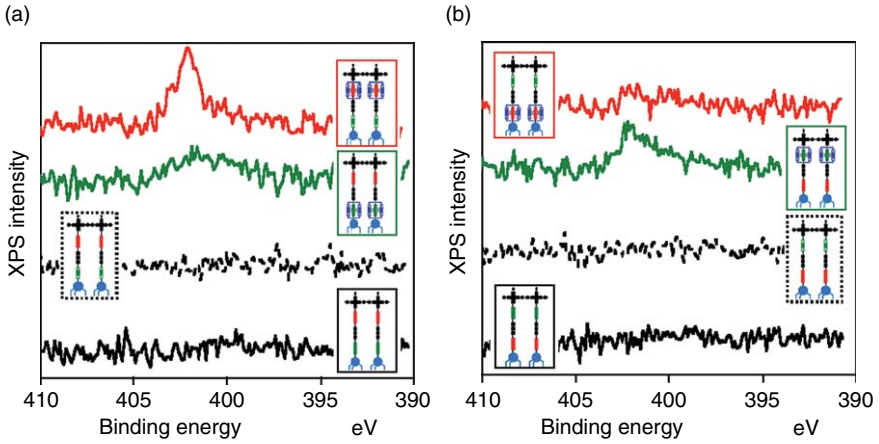

Figure 16 Nitrogen 1s X-ray photoemission spectra for (a) the starting-state rotaxane **R2** (solid green line) and its oxidized form (solid red line) and their respective dumbbell **D2** (black solid line) and its oxidized form (black dashed line) and (b) the starting-state rotaxane **R3** (solid green line) and its oxidized form (solid red line) and their respective dumbbells **D3** (black solid line) and its oxidized form (black dashed line). (Source: Huang T J, Tseng H-R, Sha L, Lu W, Brough B, Flood A H, Yu B-D, Celestre P C, Chang J P, Stoddart J F, Ho C-M 2004b Mechanical shuttling of linear motor-molecules in condensed phases on solid substrates. *Nano Lett.* **4**, 2065–71.)

an observation which supports the hypothesis that, in the oxidized molecule, the ring encircles the DNP recognition site, as opposed to the TTF^{2+} site, placing it closer to the film surface. Control experiments were conducted using the rotaxane **R3** in which the positions of the TTF and DNP units are the reverse of those in **R2**. **Figure 16b** shows clearly that the N 1s photoemission intensity was the highest from the starting-state rotaxane **R3** in which the ring encircles the TTF site, i.e., the one closer to the film surface. These control experiments ruled out the possibility of an oxidation-induced change in the N density and demonstrated the capability of XPS measurements to track the movement of the rings in LB films of redox-controllable rotaxanes.

Molecules of **R2** were *in situ* switched in highly packed Langmuir monolayers and transferred to substrates for XPS analysis. Once again, a much higher intensity of the N 1s peak is observed (**Figure 17a**) for the molecules *in situ* switched in highly packed Langmuir monolayers than that observed for the starting state of the bistable rotaxane, and the line

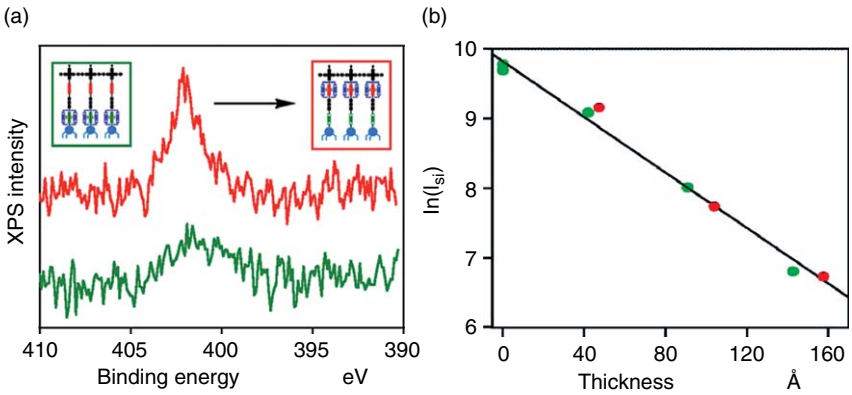

Figure 17 (a) The rotaxane **R2** (solid red line) having been switched (oxidized) in a highly packed monolayer compared with its starting-state form (solid green line). (b) The logarithms of Si 2p photoemission intensities versus film thickness measured by ellipsometry. The solid red dots represent samples composed of oxidized rotaxane molecules and the green solid dots represent samples composed of the starting-state molecules **R2**. (Source: Huang T J, Tseng H-R, Sha L, Lu W, Brough B, Flood A H, Yu B-D, Celestre P C, Chang J P, Stoddart J F, Ho C-M 2004b Mechanical shuttling of linear motor-molecules in condensed phases on solid substrates. *Nano Lett.* **4**, 2065–71.)

shape and intensity of N 1s remain similar to those recorded (**Figure 16a**) for the oxidized molecule. This datum proves that the molecules of the bistable rotaxanes are mechanically switchable in closely packed Langmuir films.

Next, the distance traveled by the ring component in the switchable rotaxane was quantified, thereby establishing that the ring moves completely from one station to the other while molecules are in closely packed Langmuir films. Quantitative XPS analysis indicated that the distance traveled by the ring in the *Z*-direction was 1.9 nm based on the data shown in **Figure 17b**. Molecular modeling indicates that the distance of the ring shuttling along the fully stretched 8.0 nm length of the rotaxane **R2** molecule is 3.7 nm, 46% of the total molecular length. Molecular modeling was performed in Chem3D by extending the molecule fully and then optimizing with the MM2 force field to obtain correct bond lengths and angles. The distance was measured from the center of the TTF unit to the center of the DNP unit. Since the film thickness was found to be only 4.4 nm by ellipsometry measurement, the translational value of 1.9 nm, or 42% of the total film thickness, is in good agreement with the modeling result.

To turn a rotaxane-based mechanical device into an engineering reality, it must be proven that these mechanically interlocked molecules maintain their shuttling properties while mounted on a solid substrate. Therefore, we extended our investigations into the realm of LB films. LB double layers of the starting-state rotaxane $\mathbf{3}^{4+}$ molecules were deposited on a silicon dioxide substrate at a surface pressure of 25 mN m^{-1} and the N 1s photoemission intensity was measured by XPS. The substrate coated with the LB double layers was then immersed in a solution containing oxidant and probed again by XPS. The oxidant solution was prepared by mixing $Fe(ClO_4)_3$ into deionized water to a concentration of 10^{-3} M. Typically, the sample was immersed in the oxidant solution for 30–40 min. Ellipsometry data show that the thickness of the films did not change while the samples were immersed in the oxidant solution. A double layer, instead of a single layer, was chosen because the surfaces of double-layer samples are hydrophilic, as opposed to the hydrophobic single layer, allowing the oxidant in an aqueous solution to penetrate the surface and oxidize the TTF unit. It is expected that only molecules in the top layer will be oxidized and switched. The observed difference (**Figure 18**) in the two N 1s spectra supports the hypothesis that mechanical switching, as characterized by ring movements in one of the two molecular layers, occurs within the film, even while the molecules are attached to the solid substrate.

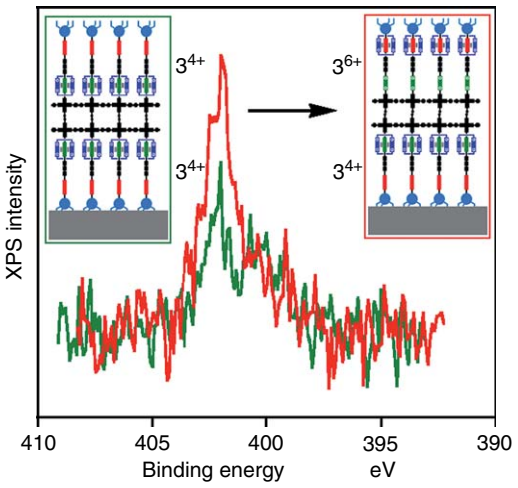

Figure 18 Nitrogen 1s photoemission spectra for the rotaxane **R3** in double Langmuir–Blodgett (LB) films prior to (solid green line) and after (solid red line) immersing samples into an aqueous solution of $Fe(ClO_4)_3$. 3.20.4.4 Remarks

Quantitative XPS analysis has proven that the ring component of a bistable amphiphilic rotaxane can be switched completely from one station to the other along the dumbbell component in self-organized, closely packed Langmuir monolayers. Moreover, XPS analysis also indicates that the mechanical operation of these linear motor molecules is maintained, even when they are closely packed within LB films mounted on solid supports. Isotherm analysis and other techniques employed also support this conclusion. This work marks a substantial step toward the development of motor molecule-based nanomechanical systems.

3.20.5 A Nanomechanical Device Based on Artificial Molecular Machines

Nanoscale actuators, capable of converting chemical or electrical energy into mechanical motion, are

needed for a wide range of applications. The bottom-up approach, which employs atoms and molecules both as the fundamental building blocks and as the working units, is potentially capable of delivering efficient operations at dramatically reduced scales in comparison with traditional microscale actuators. Artificial molecular machinery is an attractive means for performing controllable mechanical work at the nanoscale. Bistable rotaxanes hold particular promise in this regard. They have been likened to linear molecular motors on account of their ring component's ability to undergo controllable mechanical switching between two or more recognition sites via chemical, electrochemical, or photochemical stimulus. This section will describe the nanomechanical response of microcantilever beams coated with a SAM of artificial molecular motors following the cycled addition of chemical redox reagents (Huang *et al.* 2004a). A simple model that considers the mechanical movements of each molecule within the SAM verifies chemomechanical transduction as a likely mechanism for cantilever bending. In addition, this section will discuss the results of a structure–function study conducted through a series of control experiments and provide rational assessments to account for a wide range of alternative interaction mechanisms. The data provide compelling evidence for chemomechanical transduction as a general mode of operation for the generation of force from surface-bound linear molecular motors.

Expanding upon a series of bistable [2]rotaxanes, a bistable [3]rotaxane **R4** (**Figure 19**) was created as a molecular muscle to mimic the contraction and extension movements of skeletal muscle. This design takes advantage of well-established recognition chemistry that selectively positions the cyclobis(paraquat-*p*-phenylene) ($CBPQT^{4+}$) rings around the two TTF units of **R4**, as opposed to the two DNP units. Chemical oxidation of the TTF units to their dicationic forms (TTF^{2+}) drives the $CBPQT^{4+}$ rings to the DNP units. This power stroke arises primarily from electrostatic charge–charge repulsion between the $CBPQT^{4+}$ rings and the TTF^{2+} units. Upon reduction of the two TTF^{2+} stations back to their neutral form, the interring distance increases as the $CBPQT^{4+}$ rings return to the TTF stations by means of a thermally activated diffusive stroke. Thus, the cycle of contraction and extension within **R4** mimics the motion that takes place inside natural muscle fibers. The incorporation of a disulfide tether onto each $CBPQT^{4+}$ ring component provides an anchoring point by which the [3]rotaxane can be attached to a gold surface as a SAM. Oxidation of **R4** will generate a tensile stress upon a gold surface through the contractive action of its two disulfide-tethered $CBPQT^{4+}$ rings. If the substrate is sufficiently thin and flexible, such as a long cantilever beam, the cumulative effect of each individual molecular muscle will produce an upward mechanical bending of the beam. Correspondingly, reduction of the oxidized and contracted **R4** will return the $CBPQT^{4+}$ rings to the TTF stations and consequently relieve the stress upon the beam, resulting in a downward motion and a return to the beam's equilibrium position.

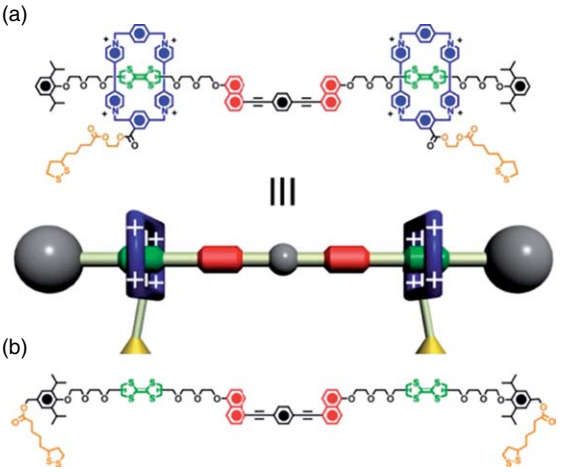

Figure 19 Molecular structure and schematic of (a) a bistable [3]rotaxane molecular muscle **R4** and (b) its dumbbell **D4**. (Source: Huang T J, Brough B, Ho C-M, Liu Y, Flood A H, Bonvallet P A, Tseng H-R, Stoddart J F, Baller M, Magonov S 2004a A nanomechanical device based on linear molecular motors. *Appl. Phys. Lett.* **85**, 5391–3.)

A single beam's deflection upon contraction of the molecular muscle was analyzed using a simple model for the [3]rotaxane **R4** bound to a section of the beam (**Figure 20a**). Oxidation produces a contraction of the interring distance and correspondingly exerts a force F plus a bending moment M upon the beam. Only the sections of the beam between the two moving rings will be subjected to the action of the bending moment M, whereas the other sections have a zero bending moment. The out-of-plane displacement w of a cantilever beam (**Figure 20b**) is governed by the Euler–Bernoulli beam equation

$$w = \frac{M_{\text{beam}} L^2}{2EI}$$

in which M_{beam} is the moment on the beam, L the total length of the cantilever beam, E the Young's modulus of the cantilever, and I the area moment of

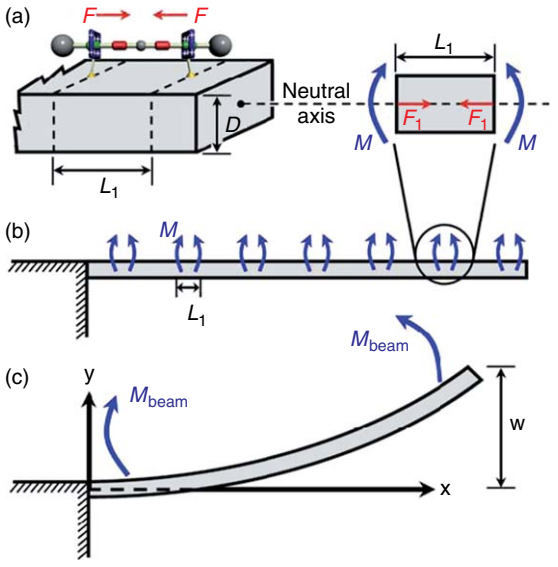

Figure 20 Free-body beam analysis. (a) Free-body diagram showing the contractive force *F* exerted within a single functional unit of the beam (*left*), its geometric translation **F1** to the neutral axis, and its associated upward bending moment *M* (*right*). (b) Overall diagram demonstrating the collective upward bending moments exerted by each of the functional units of the cantilever beam. (c) The bending moment M_{beam} for the entire cantilever beam produces an out-of-plane displacement *w*. (Source: Huang T J, Brough B, Ho C-M, Liu Y, Flood A H, Bonvallet P A, Tseng H-R, Stoddart J F, Baller M, Magonov S 2004a A nanomechanical device based on linear molecular motors. *Appl. Phys. Lett.* **85**, 5391–3.)

inertia of the beam's cross section. The parameter M_{beam} can be obtained by assuming that the force generated (40 pN) by a single molecule is solely due to electrostatic effects ($\varepsilon_{water} = 80$), the SAM covers 100% of the gold surface, and the molecules are idealized as randomly oriented noninteracting rigid rods. Based on this simplified model, the force generated by the molecular muscle can act against the spring-like restoring force of a cantilever beam (500 μm × 100 μm × 1 μm) to produce a theoretical beam displacement *w* of 48 nm.

This chemomechanical design was tested with a gold-coated silicon cantilever array that was coated with a SAM of **R4** (Figure 21a) and placed in a transparent fluid cell. The silicon cantilever arrays employed in this experiment incorporate cantilever beams with a length of 500 μm, a width of 100 μm, a thickness of 1 μm, and a spring constant of 0.02 N m^{-1}. They were fabricated using silicon-on-insulator (SOI) wafers. The gold coatings were prepared by thermally evaporating 1.5 nm of Ti, followed by 20 nm of Au onto the topside of the cantilever devices. Immediately afterward, the cantilever arrays were immersed in a 0.1 mM MeCN solution of the disulfide-tethered palindromic [3]rotaxane for 48 h in order to form a SAM of the compound. Following SAM formation, the cantilevers were rinsed with MeCN to remove any unbound material.

The experimental setup (Figure 22) is based on a Digital Instruments Scentris™ Research Tool. The cantilever array is housed in a 50-μl sample chamber covered by a transparent window in order to record the cantilevers' deflections by the beam-deflection method. Light from multiple superluminescent diodes emitting at 850 nm is coupled to an array of multimode fibers and projected onto the end of a single cantilever. Upon reflection, the light is collected by a linear position-sensitive detector (PSD), and the photocurrents are converted into voltages. The position of the beam is determined within ±0.5 nm or better. After amplification, the signals are digitized and stored. A time-multiplexing scheme is applied by switching individual light sources on and off to illuminate only one cantilever at a time. Continuous flow driven by gravitational force propels solutions of chemical reagents from different reservoirs through the sample chamber into a waste container at rates of 250–300 μL min^{-1}. The sample reservoirs were connected to a computer-controlled six-way valve in order to minimize the disturbance of the flow when switching between the different solutions. Addition of the oxidant solution was observed to cause the cantilever beams to bend to an upward limit of ~35 nm (Figure 21b, top series of traces). The entry of the reductant solution caused the beams to bend back downward to their starting positions. This behavior was observed for all four cantilever beams for 25 cycles (the first three complete cycles are shown here). The slight attenuation in beam deflection following each cycle is attributed to a gradual chemical and/or physical passivation of the SAM. Nevertheless, the movement of the cantilever beams is directly correlated with the cycling of the oxidant and reductant solutions and the experimental data (35 nm displacement) matches closely with the theoretical quantitative analysis (48 nm displacement).

In order to assert that the beams' bending is not a consequence of mundane conformational and/or electrostatic changes within the semirigid **R4** backbone, the disulfide-tethered dumbbell compound **D4** (Figure 19b) was synthesized. This control

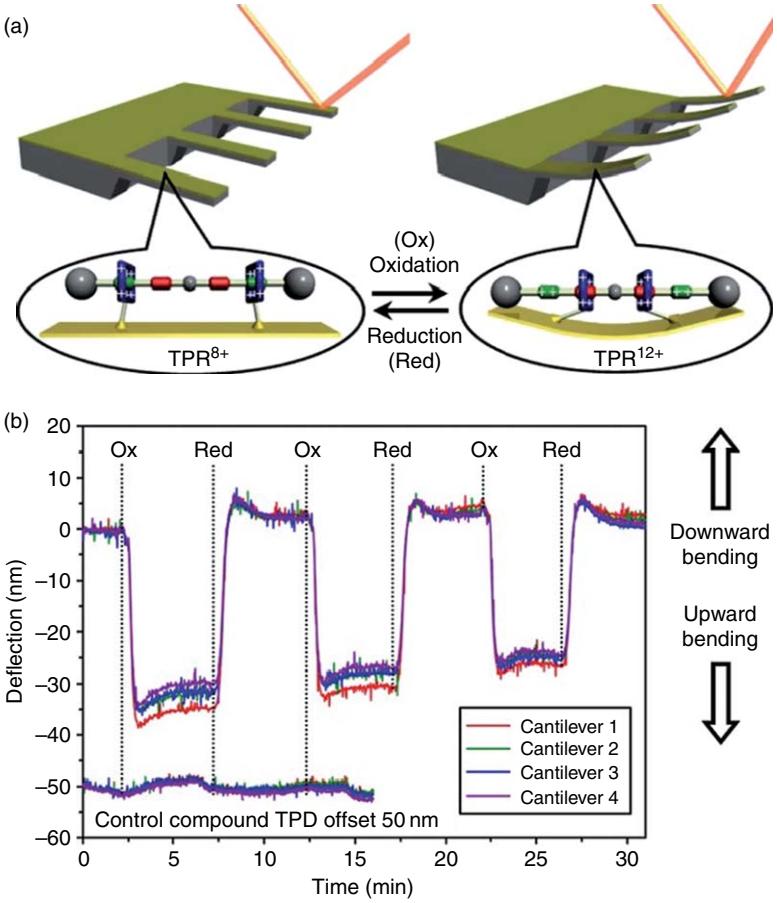

Figure 21 (a) Schematic of the proposed mechanism of the device operation. (b) The experimental data show bending of the four cantilever beams, as the aqueous oxidant (Ox) and reductant (Red) solutions are delivered to the sample cell. The top series of traces shows the deflection of the cantilever array coated with **R4**, whereas the bottom series of traces (offset by 50 nm) shows the limited movement of the cantilever array coated with the dumbbell control compound **D4**. (Source: Huang T J, Brough B, Ho C-M, Liu Y, Flood A H, Bonvallet P A, Tseng H-R, Stoddart J F, Baller M, Magonov S 2004a A nanomechanical device based on linear molecular motors. *Appl. Phys. Lett.* **85**, 5391–3.)

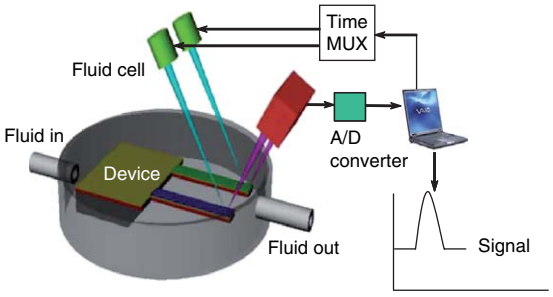

Figure 22 Schematic of the experimental setup. (Source: Huang T J, Brough B, Ho C-M, Liu Y, Flood A H, Bonvallet P A, Tseng H-R, Stoddart J F, Baller M, Magonov S 2005 A nano-chemo-mechanical actuator based on artificial molecular machines. *MEMS 2005*, Miami, FL, USA, January 30–February 3, 2005, pp. 871–4.)

compound contains pairs of TTF and DNP recognition sites with the same relative geometries that are present in **R4**. However, **D4** lacks the mechanically mobile $CBPQT^{4+}$ rings and the disulfide tethers are attached at different locations on the dumbbell's two stoppers. An array of cantilever beams coated with a SAM of **D4** bends only slightly (**Figure 21b**, bottom series of traces) following sequential injections of the same oxidant and reductant solutions used to study **R4**. This observation suggests that the presence of the mechanically active, disulfide-tethered $CBPQT^{4+}$ rings in $\mathbf{R1}^{8+}$ is essential for the redox-controlled bending of the cantilever beams.

Furthermore, control experiments and quantitative analysis (supporting online text) have established that pH variations (**Figure 23**), electrostatic charge

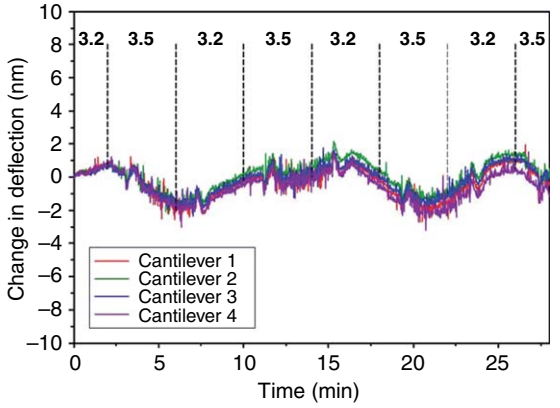

Figure 23 Control experiment demonstrating that the cantilever beam coated with the [3]rotaxane molecular muscle **R4** does not display any significant deflection when exposed to the same variation in pH (3.2 and 3.5) that accompanies the addition of oxidant and reductant, respectively. (Source: Huang T J, Brough B, Ho C-M, Liu Y, Flood A H, Bonvallet P A, Tseng H-R, Stoddart J F, Baller M, Magonov S 2004a A nanomechanical device based on linear molecular motors. *Appl. Phys. Lett.* **85**, 5391–3.)

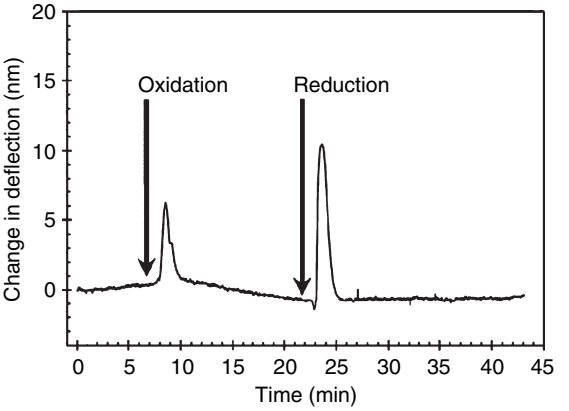

Figure 24 Control experiment demonstrating that refractive index has very limited effects on the cantilever beams' deflection. (Source: Huang T J, Brough B, Ho C-M, Liu Y, Flood A H, Bonvallet P A, Tseng H-R, Stoddart J F, Baller M, Magonov S 2004a A nanomechanical device based on linear molecular motors. *Appl. Phys. Lett.* **85**, 5391–3.)

repulsion, thermal contributions, and photothermal differences have an inconsequential effect on the bending of cantilever beams coated with SAMs of the [3]rotaxane molecular muscle. Changes in solution pH, for example, have been demonstrated to cause silicon cantilevers to bend (Fritz *et al.* 2000). A control experiment (**Figure 23**) with citrate buffer solutions, which have the same pH as the oxidant and reductant solutions (3.2 and 3.5, respectively), establishes that pH variations have an insignificant effect on the bending of the cantilever beams that are coated with the SAM of the [3]rotaxane molecular muscle. Furthermore, the direction of beam bending does not correlate in any repeatable way with the pH of the surrounding solution. Control experiments conducted in solution also suggest that the [3]rotaxane molecular muscle is stable in acidic solutions for extended periods of time, indicating that pH-controlled chemical decomposition does not affect significantly the molecular SAM that coats the cantilever beams. Specifically, the prototypical [3]rotaxane molecular muscle displays no apparent UV/Vis and ^{1}H NMR spectroscopic changes following exposure to trifluoroacetic acid over a 2-week period.

Another control experiment was conducted to rule out the effect of any change in the reflective index (**Figure 24**). Instead of focusing the laser beam on the tip of the cantilever, it was focused on the unbendable substrate. As different solutions were introduced into the sample chamber, only a change in the reflective index of the different solutions will cause a variation in the signal output. As shown in **Figure 24**, this variation has a minimal effect when changing between two solutions. After the flow has stabilized, there is very little difference in the signals between the addition of water, oxidant, or reductant.

Other factors such as charge repulsion and thermal effects may also contribute to beam bending (Varesi *et al.* 1997). Upon oxidation, the electronic charge of the disulfide-tethered palindromic [3]rotaxane molecular muscle changes from +8 to +12, giving rise to a change in the electrostatic interactions between neighboring surface-bound [3]rotaxane molecules. The proximity of two like-charged molecules directly on the cantilever surface could create a repulsive force, thus leading to the beam bending downward. Yet this is contrary to what is observed. Similarly, when considering thermal effects, the release of energy upon oxidation of the [3]rotaxane would cause the bimorph-like beams to bend downward on account of the higher thermal expansion coefficient of the upper gold surface in comparison with the lower silicon surface (Moulin *et al.* 1997). However, subtle thermal effects are negligible in aqueous solutions because of the high heat capacity of water. Finally, the photothermal bending effect (Barnes *et al.* 1994) initiated by the 850-nm detection laser beam is discounted, both on account of the water's high heat capacity and by the fact that the incident laser light with a spot size of 3 μm irradiates an insignificant amount (0.02%) of the cantilever's total surface area.

Given that all these factors do not contribute to a concerted motion of the cantilever, the deflections of the beams coated with SAMs of [3]rotaxane molecular muscle are consistent with our assignment of the movement to the redox-driven changes in the molecular monolayer. This result correlates directly with the collective effect of molecular-scale contractions and extensions of the interring distances in the disulfide-tethered palindromic [3]rotaxane molecules and supports the hypothesis that the cumulative nanoscale movements within surface-bound molecular muscles can be harnessed to perform larger-scale mechanical work.

It appears that **Figure 21** also indicates that as the oxidation–reduction cycle is repeated, the magnitude of the beam bending decreases. A 25-cycle experiment confirms this observation. As seen in **Figure 25**, the magnitude of the beam deflection decreases from 35 nm in cycle 1 to 3 nm in cycle 25. Interestingly, this exponential decrease in the cantilever's deflection matches qualitatively with a separately observed trend in which rotaxane degrades in solution following multiple oxidation–reduction cycles (**Figure 26**). The solution-phase decay was estimated from the percent recovery of the original UV/Vis absorption intensity of rotaxanes after one oxidation–reduction cycle. This correlation suggests that chemical degradation is probably responsible for the gradual decrease in the magnitude of the beams' bending. In order to develop more efficient and practical molecular machine-based nanomechanical actuators, electricity or light could be used instead of chemicals as a switching stimulus. This modification would allow molecules to remain in an environment without air, water, or solvents, thereby increasing the system's lifetime.

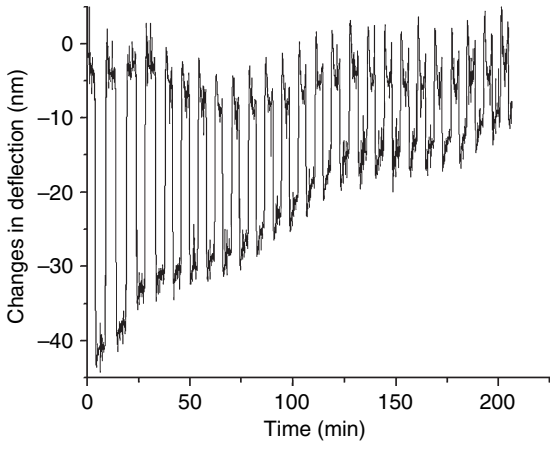

Figure 25 A 25-cycle experimental data showing that as the oxidation–reduction cycle is repeated, the magnitude of the beam bending decreases. 3.20.6 Conclusions

Inspired by biological molecular machines, we are developing a new class of mechanical nanodevices that employ a group of artificial molecular machines called rotaxanes. As a substantial step toward this long-term objective, we have proven for the first time that rotaxanes are mechanically switchable in condensed phases on solid substrates. We have further developed a rotaxane-powered microcantilever actuator utilizing an integrated approach that combines bottom-up assembly of molecular functionality with top-down micro/nanofabrication. By harnessing the nanoscale mechanical motion from artificial molecular machines and eliciting a nanomechanical response in a microscale device, this system mimics natural skeletal muscle. We have every reason to believe that the chemically driven redox process we demonstrated thus far can be replaced with direct electrical or optical stimulation, a logical development that would establish a technological basis for the production of a new class of multiscale NEMS devices based on molecular mechanical motion.

Acknowledgments

This work was supported in part by the NSF NIRT grant (ECCS-0609128) and the start-up fund provided by the ESM Department, College of Engineering, Materials Research Institute, and Huck Institutes for the Life Sciences at The Pennsylvania State University. The author wishes to thank Xiaole Mao, Dana Mallen, John Waldeisen, and Jinjie Shi for their help with the manuscript.

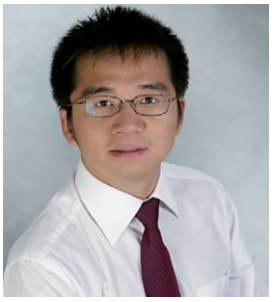
Biography



Tony Jun Huang received his Ph.D. degree in Mechanical and Aerospace Engineering from the University of California, Los Angeles (UCLA) in 2005, and his B.S. and M.S. degrees in Energy and Power Engineering from Xi'an Jiaotong University, Xi'an, China, in 1996 and 1999, respectively. He is the James Henderson Assistant Professor in the Department of Engineering Science and Mechanics at The Pennsylvania State University. His research interests include Biomedical NanoElectroMechanicalSystems (BioNEMS), Molecular Mechanics, Nanomaterials/Nanodevices, and Microfluidics. During his young career, he has already received many awards and honors including the 2006 Rustum and Della Roy Innovation in Materials Research Award, by *The Pennsylvania State University*; 'One of the five most intriguing articles in the third quarter of 2005', by *CAS Science Spotlight*; the James Henderson Endowed Professorship, by *The Pennsylvania State University*; Outstanding Ph.D. Award, by *UCLA School of Engineering.*
